Though leaks and splits of quite a large size may be fixed in this way, it is occasionally necessary to tear the radiator down and to put in new tubes. The hardest part of the job is tearing the radiator down to the core and building it up again. New cores can be purchased with the top of the bottom tank soldered on.

There are many other methods of cleaning and soldering leaks. The leaky parts are often scraped bright with small **scrapers** made from three-cornered files with the teeth ground off, and then acid is applied and the parts are soldered with **a soldering iron made especially for this work** by taking a 1½ lb. soldering iron, heating it red hot, and drawing out long and slim. Then tin the iron carefully.

Soldering by dipping: In large shops the tubular radiator is dipped into a solder bath (Fig. 93). The parts to be soldered are thoroughly cleaned and treated with muriatic acid solution, then dipped. The solder naturally will adhere only to the parts that are clean. **The solder** is made of 50 per cent lead and 50 per cent bar tin melted together.

Radiator Fin Repair

Where the lateral fins of a tubular radiator (Ford type) have been removed for a repair, a false fin (**D**) may be made as shown in Fig. 94, by folding a ¾″ strip of light brass, copper, or even sheet iron longitudinally upon itself to make a double strip ⅜″ wide. Bridge it across the gap in the fin or fins, and then paint the patched place the same color as the rest of the core.

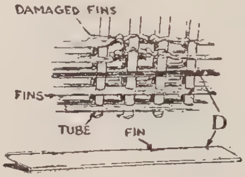

Fig. 94

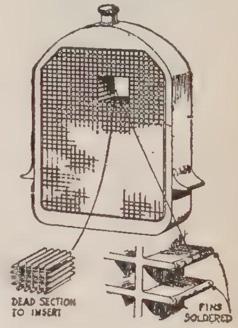

Fig. 95

Another fin repair (Fig. 95) is shown of a cellular-type radiator.

Repairing Cellular Cores

The cellular core is removed from the tank by melting the solder with a blow-pipe torch. As inch by inch is melted away, insert a piece of sheet iron between the core and the tank, so that when the flame is removed the solder hardens and the core and tank are not reunited.

Inside leaks in cellular cores[1] can be soldered with a torch throwing a fine needle flame. Be very careful, however, to not burn the light metal up. Squirt acid or soldering flux on the spot with an ordinary oil squirt can. Deposit solder on the spot, using wire solder and the blow-torch. Smooth the solder over afterward with a small thin iron. A suitable iron for this work may be made from ordinary ¼″ iron.

To remove a leaky cellular section from a core, the leaky section is cut out (Fig. 95) and all water passages into all sides are soldered up. After testing, a dummy section is inserted and soldered. The cooling capacity will be reduced slightly.

It is advisable to secure an old radiator core and to practice soldering it before attempting a repair.

Remember, when soldering parts of the radiator, that the metal must be scrupulously clean before the flux is applied, or else the solder will not hold.

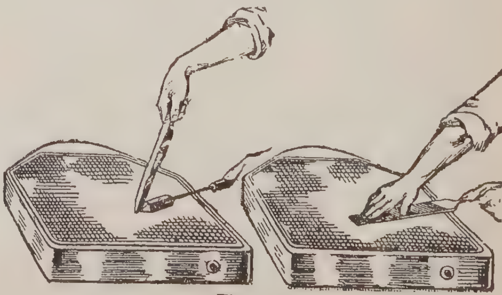

Fig. 96

---

[1] It is not necessary to remove the core from the radiator shell unless there are several leaks or the core is damaged.

After completing the soldering, file smoothly and then place the radiator in the water and again test it with air pressure, in order to see if the leak is properly repaired.

Small leaks are dealt with on pages 151, 152.

Painting a Radiator

It is very difficult to paint a radiator quickly and thoroughly with a paint brush, and the usual plan, where a great deal of the work is done, is to dip the radiator in a paint solution. A very satisfactory job can, however, be quickly done with a spraying outfit. A very simple home-made device is here illustrated.

It consists simply of a construction such as is shown in Fig. 97, in two sizes and designs, which comprises a can (**D**) for the paint, consisting of a mixture of lampblack and turpentine, a hollow cylindrical tin handle (**B**) attached to the can, an air pipe (**A**) passing through the handle and through the can, as indicated by the dotted lines; and another similar pipe or tube extending downward at right angles from the one end of the horizontal tube into and near to the bottom of the can, as is also indicated by dotted lines. This is merely an adaptation of the principle employed in most atomizers.

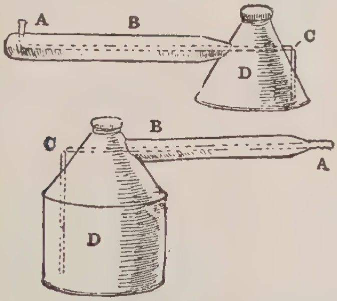

Fig. 97. A home-made sprayer for painting radiators.

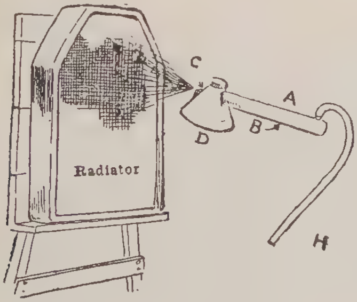

Fig. 98. Showing how the paint is sprayed on the radiator.

When a stream of air is forced through the air tube (**H**) and (**A**), passing through the handle, and directed across the opening (**C**), at the top of the vertical tube the fluid from the inside of the can is drawn up and sprayed on to the radiator. It is best to tilt the radiator when spraying, so that the solution will drain off. (*Motor Age.*)

A home-made spraying outfit similar to the one shown above is shown in Fig. 99.

The outfit consists of a ½-gal. oil can, made into an atomizer by attaching a tire pump to the end of the air pipe (**B**). A piece of small brass pipe (**A**) is mounted in one side of the can, the upper end of it extending a short distance outside of the top. A second piece of pipe is mounted in a horizontal position in the top of the can, as shown at (**B**). If a handle is attached to the can, as at (**C**), the piece of pipe (**B**) may pass through it lengthwise and extend a short distance beyond the end of the handle. Both pipes are soldered to the top of the can, and the screw top is provided with a gasket to make it tight.

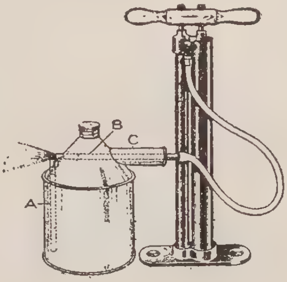

Fig. 99. Spraying device made of an oil can and a foot pump.

When the air is forced through the horizontal tube (**B**) and caused to pass across the opening in the upper end of the vertical tube (**A**), the liquid in the can is drawn up and forced out in a fine spray. A mixture for spraying the radiator may be made of lampblack and turpentine. A sheet of paper should be placed back of the radiator to protect the engine, and around the outer edge, to prevent the liquid from bespattering the finish. Wipe off any of the mixture which may splash on the painted part of the radiator before it dries. At first the color will appear gray, but will soon darken. (*Popular Mechanics.*)

Paint for a radiator: Mix 3 oz. boiled linseed oil, 4 oz. lampblack, 1 oz. turpentine, and thin down with turpentine to the proper consistency. In applying, the radiator must be either dipped into the solution (in this case a great deal more must be mixed), or sprayed, or the radiator can be placed on boxes, face up, and painted with a thin mixture as described above, applied plentifully so that it will run through the cellular parts of the radiator. A camel's hair brush can be used to reach places not covered.

Paint for fins can also be made from drop-black ground in japan and gold size, thinned with turpentine.

Radiator Leak Preventives

There are many so-called leak preventives. For instance, the manufacturers claim for a cement called "cold solder" that if it is pasted externally on a leak (Fig. 100), it will harden and stop a leak temporarily until the radiator can be repaired. (Made by Stone Solder Co., Cleveland, Ohio.)

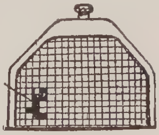

Fig. 100

Another leak preventive is a chemical mixture of cement which is placed internally into the radiator when the water is hot. The solution is supposed to pass out of the leak in the radiator, and as it is exposed to the air it hardens and closes the leak. It is claimed that this preparation will also close cracks in water manifolds, etc. It is stated that slight leaks in radiators, and even a crack in the water manifold, can be stopped by the use of some of the radiator cements circulated in the water system. Some of the manufacturers of radiator cements are, Woodworth Mfg. Corpn., Niagara Falls, N.Y.; X-Laboratories, 630 Washington St., Boston, Mass.; N. W. Chemical Co., Marietta, Ohio.

Cleaning a Radiator

The circulating system should be carefully washed out, early in the spring, because the anti-freezing solutions, used in the winter, are prone to leave the tube clogged up. In summer, it is advisable to flush out the circulating system about once a month (see page 151).

To do this properly, the radiator inlet and outlet hose should be disconnected, and the radiator flushed out by allowing the water to enter the filler neck at ordinary pressure, whence it will flow down through the tubes and out at the drain cock and hose. The water jackets can be flushed out in the same manner.

To remove scale from the inner surface of the radiator: One method is to use hot water, in which a small amount of ordinary washing soda has been dissolved, afterward rinsing this out with clean water.

For very hard deposits a solution of one quart of commercially pure muriatic acid to five gallons of water should be circulated through the cooling system slowly for five minutes.

Another good method is, to one pint of glycerine add enough boiling water to fill the system, then run the motor slowly and drain out after running, and flush with fresh water. Reversing the flow of water in flushing also helps.

When it is necessary to clean the radiator spaces of accumulated mud, the radiator should be flushed from the rear, not from the front. In that way you avoid getting water into the magneto or ignition system, which is often short-circuited when the moisture enters it.

Radiator Repair Pointers

The following paragraphs will give an idea as to where to obtain some of the parts, such as cores, fins, etc.

Radiator Cores

The Ford radiator has a tubular core with fins (see Fig. 83).

The core of a radiator is the principal part, and can be purchased separately from the upper and lower tanks.

The core can often be purchased cheaper than it can be repaired. For instance, if any great number of tubes, say more than ten, need repairing, then a new core is advisable.

The core is usually measured by its thickness. The Ford radiator is 2⅝" thick.

A firm that makes a specialty of supplying cores to repairmen is the Ideal Auto Radiator Co., 213-23 N. Morgan St., Chicago, Ill. **Cores are sold by the square inch.** The height of the core is multiplied by the width, to find the number of square inches in a core. The manufacturers just named make five standard thicknesses, 2", 2¾", 3½", 4", 4½", to fit Ford, Chevrolet, Dodge, Studebaker 6, Cadillac, and Maxwell.

Radiator Parts

The material listed below can be secured of F. L. Curfman, Maryville, Mo. Mr. Curfman also issues a very interesting **booklet on radiator repairing** of a practical nature, covering repairs of both "tubular" and "cellular" radiator cores.

False fins made of tin or brass.

Paint for radiator fins.

Side walls, bottom and lower tanks, cores, filler necks, brass rivets, etc.

Copper tubing tinned, ¼" outside diameter, in lengths of 15", 17¼", 20", and 22".

Brass pipes 5/16" tinned, for overflow pipes, 29" long.

Soft sheet brass, hose clamps, drain cocks, etc.

Radiator Repair Tools

In addition to the tools listed on page 736, the following are further suggestions:

Electric flash light for examining close places, and also a special magnifying mirror.

Brushes for cleaning, acids swabs, etc.

Soldering irons made specially for small places.

Scrapers for close places.

Rubber stoppers: a gasoline torch of special design with a needle-point flame.

Torch with larger flame.

Flux and a flux squirter.

Air compressor of special design which can be operated from a 1/6 h.p. motor and from a lamp socket, to be used for air pressure for testing and for a gasoline torch. No tank required.

Gasoline gas generator for use with a gasoline torch.

Coil spring for placing in copper overflow tubing, so that it can be bent, etc.

Radiator Solder and Flux

Cleaning parts to be soldered is most important. This can be done by **scraping** and also, if in a close place, by using **muriatic acid** applied to a cloth attached to a wire.

Soldering flux, which is applied after cleaning in order that the solder may stick, is made of cut muriatic acid, as described on pages 736, 720, 721.

Wire solder with acid or flux in the core of the solder is best for radiator work. Write Chicago Solder Co., 218 No. Union Ave., Chicago, Ill.

Thawing Radiators

This would seem to be a simple matter, but, as in everything else, there is a right and a wrong way of doing it. The common practice is to block off the air and run the engine with a retarded spark, depending upon the heat generated to do the work. This method is permissible if the freezing is slight. However, if the unit is frozen solid, damage to the engine may result long before the solid mass liquifies, for the reason that the water in the jackets very quickly boils away, leaving the engine dry. By far the better plan is to remove the radiator and immerse it in hot water in the testing tank, as shown in Fig. 101. See also pages 153, 150, 154.

INSTRUCTION No. 66

OXY-ACETYLENE WELDING AND CUTTING

OXY-ACETYLENE WELDING[1]

Blow-pipe welding is a very ancient art, and was first practiced by the Egyptians. The early process consisted of heating metals of a low melting point by means of a torch, using a crude fuel gas and drawing the necessary oxygen from the air.

The modern process of blow-pipe welding is somewhat similar, but it is applied successfully to the welding of high melting-point metals,[2] as well. This was not possible until oxygen was obtainable on a commercial scale, and a fuel gas giving the necessary high-flame temperature could be provided in safe, convenient, and purified form.

Blow-pipe welding is generally known as "autogenous" welding, although the same term could apply to electric welding. Autogenous welding must not be confused with brazing or soldering. Brazing or soldering is where a joint is made in which a different metal, having certain adhesive qualities, is used as a binder—it adheres, but does not "fuse." Oxy-acetylene welding is where pieces of metal are **united,** or new metal is added, as in the case of **building up worn parts**—welding iron, steel, cast iron, malleable cast iron, aluminum, brass, copper, etc.

Before this process of welding was invented, when a crank case or an exhaust manifold, gear case, cylinder, or other metal part was cracked or broken, it was necessary to get a new part, fully machined, from the factory. This was quite an expensive proposition. With the oxy-acetylene outfit it is possible to repair these at a very slight cost and to save those parts which would otherwise be worthless. Steel, iron, aluminum, brass, copper, platinum, and other metals can be perfectly united by this process.

Method of welding: To those who are not familiar with the method by which welding operations are performed with this process, it may be said that welds are made by directing the oxy-acetylene flame on the pieces to be welded at the place where they are to be joined, until the metal is molten, and then adding additional metal of the same character, which is provided in the form of wire or sticks of suitable dimension for the purpose.

There are two types of oxy-acetylene outfits: the **stationary** type and the **portable** type. The parts of the stationary outfit consist of a generator which generates the acetylene gas from carbide, a tank of oxygen, a torch of special design, and a special iron table with a brick top.

The portable outfit consists of the same parts, but instead of there being a gas generator, the acetylene gas is compressed into tanks by concerns who make a specialty of this work in all large cities. This type is the one mostly in use in small shops. The portable outfit can be put into a car and carried right to a garage for the work to be done, and will often save dismantling the engine or broken part.

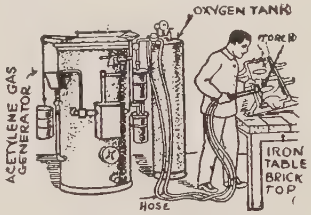

Fig. 1. The stationary oxy-acetylene outfit. Note the iron table with brick top.

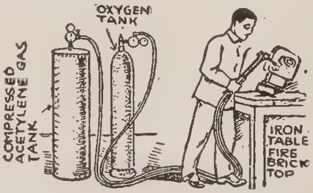

Fig. 2. The portable oxy-acetylene outfit.

The oxy-acetylene welding and cutting outfit can be used for various purposes as follows:

1. Welding broken frames, gears, shafts, crank cases, engine supports, axle parts, castings, cylinder water jackets, gear-sets, etc.
2. Cleaning tire vulcanizer molds.
3. Removing solid tires.
4. Burning carbon from cylinder (see Index under "Carbon removal").
5. Removal and replacement of terminal straps, plates of storage batteries, and other lead parts (see Index under "Lead burning").

Qualifications of a Welding Operator

A few weeks' practice will develop the skill necessary to handle ordinary work likely to be met with in the average shop. Very thin plate work and neat work will, of course, require skill and longer practice.

Welding of plates over ¼″ thick should not be attempted on particular work, until the operator has demonstrated his ability by first welding some sample pieces.

The operator must have a fair knowledge of the nature and properties of the metals being welded, the effects of expansion and contraction, the reason for the use of fluxes and filling rods (see page 746), the proper kind of filling material, how to apply heat without burning the metal, etc., all of which can be learned from books treating on the subject.

With this knowledge and practice the business can be made very remunerative.

---

[1] An instruction book on oxy-acetylene welding can be obtained of A. L. Dyke, Pub., Granite Bldg., St. Louis, Mo. (price $1.10 prepaid). It treats on carbon burning or decarbonizing, cutting and welding. A larger book, which is the most complete book published on the subject, can now be obtained also from A. L. Dyke, at the address given above (price $3.00 plus 25c. postage).

[2] See Index under "Melting points of metal."

Gases Used for Welding

The oxygen needed is furnished to customers in portable steel cylinders into which the oxygen is compressed to 1,800 lbs. to the square inch.

To estimate the pressure readings, a gauge is supplied. Take, for instance, an oxygen cylinder that holds 100 cu. ft. at 120 atmospheres, or 1,800 lbs. pressure approximately; each atmosphere represents 5/6 cu. ft. With a 250 cu. ft. oxygen cylinder, each atmosphere, or 15 lbs. pressure, represents 2.08 cu. ft. of oxygen.

Acetylene is supplied to users in specially constructed steel cylinders of various capacities. The maximum charging pressure is 250 lbs. to the square inch at 70° F. The cylinder contains about ten times its own volume of acetylene for each atmosphere of pressure that is on the gas. The porous substance, such as pumice stone or charcoal which is in the tank, is saturated with a liquid solvent which has the peculiar property of absorbing or dissolving many times its own volume of acetylene at atmospheric pressure. When pressure is applied, the solvent continues to dissolve acetylene.

Cylinders are, as a rule, charged to 15 atmospheres pressure at 60° F., so they contain 150 times their own volume when charged. Thus a cylinder that would hold 2 cu. ft. of water when empty will hold 300 cu. ft. of acetylene at 225 lbs. pressure at 60° F.

Prest-O-Lite acetylene cylinders for welding are furnished in large-sized cylinders, style "WC," having approximately 100 cu. ft. capacity, and style "WK," with approximately 300 cu. ft. capacity. They are made as small as 30 or 40 cu. ft. capacity.

No cylinder should be exhausted at a rate greater than one-seventh of its total capacity per hour. Where the needed amount of acetylene per hour exceeds one-seventh of the capacity of one cylinder, connect two, three, or even more cylinders so that the total capacity is at least seven times their hourly discharge.

It should be borne in mind that the contents are not accurately determined by pressure or gauge readings, which are affected by variations in temperature. The only accurate method of determination is by weight, one pound of gas equalling 14½ cu. ft. Gauge pressures, however, are of great convenience in **estimating roughly** how much gas remains in the cylinder. In the case of a 100 cu. ft. cylinder, each 15 lbs. of pressure represents 6 2/3 cu. ft. of gas (approximately), and in a 300 cu. ft. cylinder each 15 lbs. of pressure represents 20 cu. ft. (approximately), according to temperature.

Sources of Gas for Welding and Cutting

For welding, oxygen and acetylene gases are needed.

For cutting, oxygen and acetylene are also most generally used. However, other gases are frequently substituted for the acetylene.

Hydrogen, carbo-hydrogen, and butane are gases which can be substituted. These gases do not give enough **heat for welding** purposes, and so are not adaptable to it.

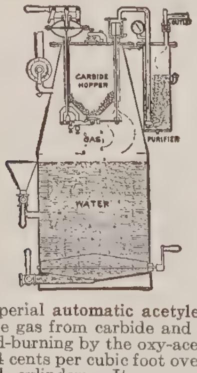

Fig. 3. The Imperial **automatic acetylene generator** produces pure acetylene gas from carbide and water, for welding and cutting and lead-burning by the oxy-acetylene process at a saving of from 2 to 4 cents per cubic foot over the cost of acetylene in compressed cylinders. It possesses many marked advantages, the most important of these being the absence of weights, clock-work, and complicated mechanism. In the Imperial generator, the carbide feed is simple, sure, and dependable, and is automaticaly controlled by the gas consumed by the torch. The generating of gas automatically stops when the torch is extinguished, and automatically starts generating when the torch is relighted, thus automatically maintaining a constant, even gas pressure. (15 lb. generator, $155.00; 25 lb. generator, $180.00; 50 lb. generator, $275.00; 100 lb. generator, $425.00.)

Note. This method saves from two to four cents per cubic foot over the cost of gas compressed in cylinders. Carbide in 100 lb. cans is easily obtainable anywhere in the United States, and usually costs from $5.00 to $6.00 per 100 lbs. in small lots, and less in ton lots. 100 lbs. of carbide will produce 500 cubic feet of acetylene gas in an Imperial generator.

The acetylene gas can be generated from carbide and water in a generator (see Fig. 3), or can be secured in portable steel tanks (Fig. 4) from one of the several companies mentioned farther on, who compress gas into a special tank and ship it to you. When the gas is used out of this tank, it is returned and exchanged for a refilled one.

The usual pressure in a full acetylene tank is 250 lbs. per square inch at 70° F., and the **capacity** is either 100 cubic feet, 225 cubic feet, or 300 cubic feet, depending upon the size of the tank.

Smaller tanks of 40-ft. capacity are also obtainable, but are intended for lighting purposes only. It is not advisable or practical to use these 40-ft. cylinders for welding or cutting.

Oxygen gas is obtained in steel tanks. The usual **pressure** is very high, ranging from 1,800 to 2,000 lbs. per square inch, with a **capacity** of either 100 or 250 cu. ft. of gas.

On the welding torch (Fig. 5, page 743) there are two connections, one for acetylene and one for oxygen. Each gas is carried through a separate tube in the handle of the torch under pressure. Each is controlled by the valves located just ahead of the handle, and the gases are led into the mixing chamber located just ahead of the valves. In the mixing chamber they are thoroughly mixed and are then led to the tip through a tube and burned.

Parts of the Prest-O-Lite Welding Outfit[1]

The welding blow-pipe is shown in Fig. 5. Various sizes of tips are used for different kinds of work.

The acetylene regulator (Fig. 6) is connected to the valve of the acetylene cylinder by means of the union nut (**M**), which must be drawn up tightly.

The oxygen regulator (Fig. 7) is connected to the valve on oxygen cylinder by means of union nut (**AA**).

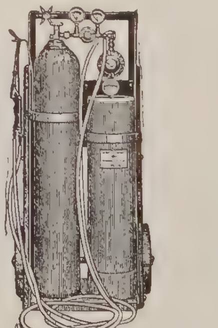

Fig. 4. The Standard Prest-O-Lite, type H, **welding outfit:** 1 cylinder of Prest-O-Lite, dissolved acetylene; 1 cylinder of compressed oxygen; 1 welding blow-pipe with seven interchangeable welding tips, Nos. 1, 2, 3, 4, 5, 6 and 7 (Fig. 5); 1 automatic constant pressure acetylene regulator, fitted with inlet and outlet pressure gauges (Fig. 6); 1 automatic constant pressure oxygen regulator fitted with inlet and outlet pressure gauges (Fig. 7); 2 suitable lengths of rubber hose; 1 set of four hose clamps; 1 box-end wrench for needle on Prest-O-Lite dissolved acetylene cylinder valve (T-socket); 1 wrench for attaching oxygen regulator; 1 stuffing nut wrench for Prest-O-Lite dissolved acetylene cylinder and for attaching acetylene regulator; 1 box end wrench for welding blow-pipe; 1 box wrench for welding tips; 1 pair special-colored lens goggles.

The Welding Flame

The welding flame should be obtained gradually, by increasing the regulating screws alternately, until the correct flame is obtained. The correct oxygen and acetylene working pressures vary slightly for the various sizes of blow-pipe tips which are used for different work. All adjustments are made at the regulators while the blow-pipe is alight.

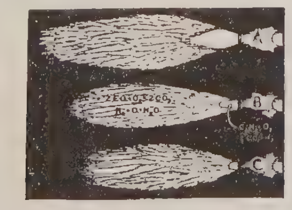

Fig. 8. The **oxy-acetylene flame.** (A) shows a welding flame with an excess of acetylene; (B) shows a correct natural welding flame; (C) shows a welding flame with an excess of oxygen.

Flame adjustment: It is absolutely necessary at all times that the welding flame be neutral, that is, that there be no excess of oxygen or acetylene. A correctly adjusted (neutral) flame is shown at (B) (Fig. 8). It will be noted that the **inner cone is clear, and well defined.** (A) (Fig. 8) shows a flame having an excess of acetylene. The inner cone is ragged in appearance. To make such a flame "neutral," the acetylene should be cut down by reducing the pressure either at the regulator or at the blow-pipe, or by increasing the oxygen supply. (C) (Fig. 8) shows an excess of oxygen. The inner cone has a very pale violet color, and is shorter than the cone in the neutral flame at (B). Proper adjustment, in this case, is accomplished by reducing the oxygen pressure or increasing the acetylene pressure at the regulators or at the blow-pipe.

The temperature of the oxy-acetylene flame is 6,300° F.

The regulation of the welding flame really means the regulation of the white inner cone. This cone should always be as large as possible, provided its outline is sharp and distinct. A long, clear inner cone should always be sought. The gases should be readjusted several times, if necessary, until the desired result is obtained.

When the blow-pipe is first lighted, it is cold. Radiated heat from the molten metal will gradually warm it. This is likely to affect the welding flame slightly. It usually will be found necessary to make readjustment of the gas pressures by means of the oxygen and acetylene needle-valve on the blow-pipe after the blow-pipe has been at work for a few minutes.

Method and Material for Welding

Preheating and reheating is sometimes necessary, in order to bring the metal to a uniform heat to insure uniform contraction while cooling. Figs. 9 and 10 show devices for this purpose.

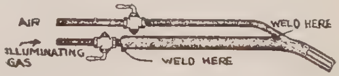

Fig. 9. Construction of air-illuminating gas **preheating torch.** Over-all length, approximately 2 feet.

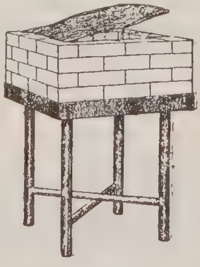

Fig. 10. Fire-brick **furnace** mounted on small welding **table.**

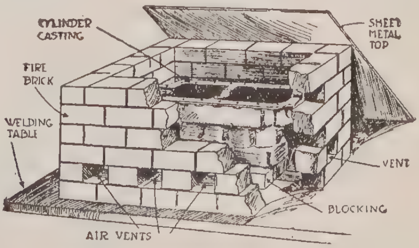

Fig. 11. Brick **oven for preheating work.** The work should remain in the oven while the welding is done. When the welding is finished the cylinder should be covered with a fresh layer of charcoal, heated; then allow it to grow cold slowly. Many shops will not take in water-jacketed cylinder work, because of the difficulty in making the job hold. Difficulties of this sort are generally due to improper preheating. Small jobs may be preheated with a welding torch, a blow torch, or a forge (*Motor World*).

Fig. 11 shows a small **furnace for preheating automobile cylinders.** After a layer of firebrick has been placed on the table, the cylinder is supported on several bricks, and the walls of the furnace built up around it. Half-bricks are used for the second layer from the bottom, so that openings are left for the air supply.

The fuel used should be of the best grade of hardwood charcoal obtainable. This burns freely, without smoke or odor, requires no forced draft, and does not injure finished surfaces. It is necessary only to pack it around the piece to be heated, to light it, and let it burn at will. When in use, the top of the furnace should be covered with a sheet-metal plate. Vent holes should be closed when cooling (cool slowly).

Filling rods are used to fill in gaps or cracks. Rods or wires are used of various lengths.

Fluxes: Some metals do not flow together rapidly when heated (owing to oxidation); therefore a suitable flux, in the form of powder, is used. It is sprinkled in the weld by dipping the heated filling rod from time to time into the flux.

The size of the blow-pipe tip is decided upon before welding. For instance, cast iron requires a larger flame than steel.

Preparation before Welding

In all welding operations, the parts to be welded should be set in proper alignment before the flame is applied. In the absence of precautions of this nature, the work is sometimes found to be out of alignment, and the part is rendered useless otherwise.

It is always advisable to **have on hand a good supply of different size clamps, "V"-blocks, and mandrels.** These are always useful in setting up various jobs. See Figs. 12, 13, 14, and 15.

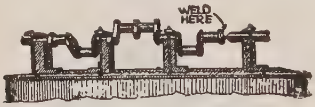

Fig. 12. Example of six-throw crank shaft lined up on V-blocks and clamped on the face plate for welding. The broken sections are shown beveled to a chisel edge.

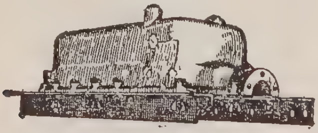

Fig. 13. Lower half of aluminum crank case clamped to angle irons to insure true alignment. A patch is shown "tacked" in position ready for welding.

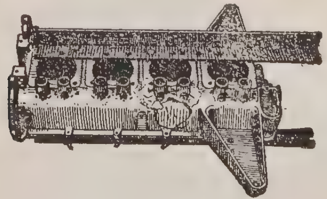

Fig. 14. Upper half of aluminum crank case bolted to angle irons to insure true alignment while patching.

Expansion and contraction: In every case of welding, internal strains are inevitably set up, as a result of expansion when heating and contraction when cooling. When parts being welded form part of a structure and are not free to move during the welding process, the strains produced may cause the metal to crack. This is especially true of cast iron.

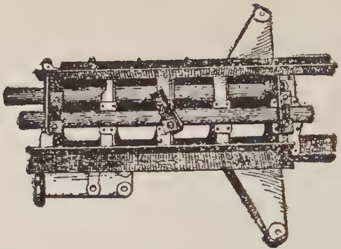

Fig. 15. Under side of upper half of aluminum crank case shown in Fig. 14. Note mandrels clamped in crank and cam-shaft bearings.

If cooling after welding is too rapid, or is irregular, a crack is liable to occur. Therefore it is advisable to heat the parts before welding (termed "pre-heating") and then to heat after welding (termed "reheating").

Fig. 25. **Two correct movements** to give the **welding flame.** (A) "figure eight" movement best suited to ordinary work. (B) zigzag movement which some operators prefer.

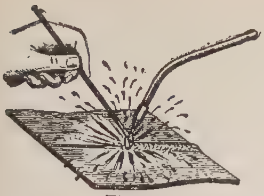

Fig. 26

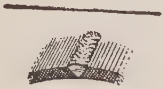

Fig. 27

Fig. 26. Incorrect method of applying filling material. The blow-pipe is also held at the wrong angle with relation to line of weld.

Fig. 27. Metal is slightly built up over beveled joint.

Examples of Welding

Fig. 28 shows a **section of one side of a steel cylinder and a convex head** which is to be welded on. The weld should be made in the straight portion of the cylinder as shown, and not directly at the bend.

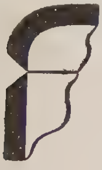

Fig. 28

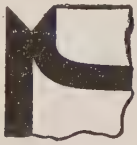

Fig. 29

Fig. 28. Location of joint when welding convex to steel cylinder.

Fig. 29. Example of welding concave head in steel cylinder. Note: Both head and shell are beveled. This shows the method of accomplishing the same result in the case of a **concave end.** If the parts are beveled as shown the joint will be a strong one.

Fig. 30 shows the **correct method of welding pipe.** The pipe, where possible, should be rolled away from the operator in such a way that the portion being welded will be on top. "Tacking" at several points is necessary before the actual welding is started. However, if rolling is impossible, the pipe may remain stationary, and the operator can weld entirely around it without difficulty after some practice, although this method is bound to be somewhat slower.

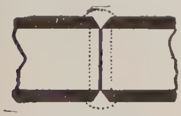

Fig. 30

Fig. 31

Fig. 30. Pipes beveled before butt welding.

Fig. 31. Correct method of preparing shaft (beveled to chisel edge) for welding.

Fig. 31 shows the **proper method of preparing a shaft for welding.** Note that this is beveled to a chisel edge, and not pointed.

If the shaft is pointed (Fig. 32), the molten metal will fall upon the cold part of the shaft and adhesion will result, which means that the new metal is merely "plastered" on at certain points, and is not "fused."

Fig. 32

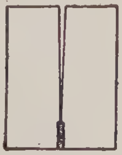

Fig. 33

Fig. 32. Incorrect method of preparing shaft (pointed) for welding.

Fig. 33. Sheets spreading apart away from point of weld.

When butt-welding two lengths of plate, or when welding the longitudinal seam of a cylinder (Fig. 33), it is advisable to "tack" along the line of weld before commencing on the finished weld. This will prevent the overlapping of the sheets at the end farthest away from the point of welding. When starting to weld two lengths of sheet at one end, which have previously been placed in proper alignment, it will be found that they tend to spread apart, as shown in the illustration. As the welding progresses, this spreading movement of the sheets ceases, and later they come together again with a tendency to overlap.

"Tacking" (Fig. 34) holds the sheets in true alignment and prevents this overlapping.

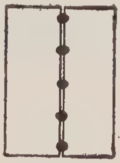

Fig. 34

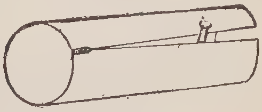

Fig. 35

Fig. 34. Sheets "tacked" before welding, to prevent spreading. The black spots are small welds.

Fig. 35. Wedge inserted to split tube ahead of weld, to prevent overlapping.

Another method of preventing over-lapping of the plates (Fig. 35), in the case of cylinders, is to insert a wedge a short distance ahead of the weld, moving the wedge as the weld progresses.

In some cases when welding a longitudinal seam, it will be found advantageous to start to weld in the middle of the seam, and to work first toward one end and then toward the other.

When welding angle-iron rings to cylinders where the thicknesses are the same (Fig. 36), both edges should be set up as shown.

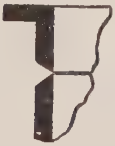

Fig. 36

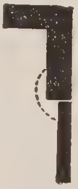

Fig. 37

Fig. 36. Preparation of angle iron and tube of same thickness before welding.

Fig. 37. Dotted line shows how filling material must be built up when welding angle to thinner section plate.

When the angle to be welded to the plate is thicker than the plate (Fig. 37), apply the flame more on the angle than on the plate. This will tend to bring the parts to the fusion point at the same time. Metal must be added, as shown by the dotted line.

When welding a flat end into a tube (Fig. 38), prepare the end as shown, making a driving fit.

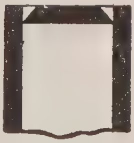

Fig. 38

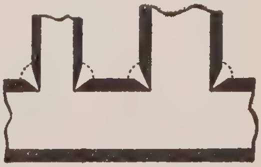

Fig. 39

Fig. 38. Preparation of flat end to be welded into tube.

Fig. 39. Shows preparation of pipes before welding to form branches.

To weld a branch into a pipe (Fig. 39), prepare the work as shown, adding metal as indicated by the dotted lines.

The welding of flat flanges to tubes (Fig. 40) is an operation that requires care, as the flange is usually considerably thicker than the tube and has to stand a good deal of strain. The flange and tube are best prepared as shown. The welding flame should play more on the flange than on the tube.

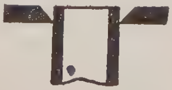

Fig. 40

Fig. 41

Fig. 40. Preparation of flange to be welded to a thinner section plate.

Fig. 41. Patch plate bellied and with edges beveled before welding.

When repairing cracks in plates (Fig. 41), always see that the crack is beveled through its entire thickness. The plate being welded should be free to move. If it is impossible to provide for this, instead of attempting to repair the crack, use a patch. A patch piece should always be slightly bellied and have edges beveled, as indicated in the illustration.

Fig. 42

Fig. 43

Fig. 42. Beveling cast iron. Note that the bevel does not penetrate the entire thickness to be welded.

Fig. 43. Beveling from both sides in thick section of cast iron. Note that the points of the bevels do not meet.

Fig. 44

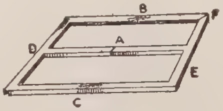

Fig. 45

Fig. 44. Fracture in the middle of a long bar to be welded. No precautions to overcome expansion and contraction strains are necessary, as the parts are free to move.

Fig. 45. Fracture in cross-member (A) of frame. The broken bar will contract on cooling, causing a strain on the end members (D) and (E). Risk of fracture may be avoided by heating the side members (B) and (C), or by cutting at the corner (F). The cut (F) may be welded up without risk of fracture after the break (A) is welded and cooled.

Selection of blow-pipe tip: The size of tip to use for welding iron and steel depends upon the thickness of the metal. Do not forget that the flame should be neutral at all times.

Welding Iron and Steels

Under this heading are included commercial wrought iron and mild or "low-carbon" steel.

Practically all of the so-called **"wrought" iron** on the market today is in reality a **mild steel.** For this reason, wrought-iron and mild-steel metals are discussed as one.

"Low-carbon" or mild steel is quite ductile and malleable, but has a lower tensile strength and lower elastic limit than the "high-carbon" or hard steels. No close distinction can be made between high and low-carbon steels, but, in general, anything below 25-point carbon (0.25 per cent) may be designated as mild steel, while those containing more than this amount are either half-hard or hard.

Most of the steels that the operator will be called upon to weld are mild. There are various special or alloy steels, such as vanadium, nickel, chrome, manganese, etc., which will be taken up separately.

Preparation of parts: Mild-steel parts are prepared in the manner described in the general instructions. Several methods of preparing the various parts to be welded are shown in the illustrations on page 745.

High carbon or hard steel: Weld as directed for mild steel or wrought iron, and use a larger blow-pipe tip. For filling, use a drill rod of hard steel. This can be tempered; ordinary mild steel cannot. Use cast-iron flux. Execute weld rapidly. A slight excess of acetylene may be advantageous.

Cast steel: Weld in accordance with instructions on cast iron. Cast bars of the same material or of vanadium steel or of Norway iron will answer for fillers.

For special steels, such as manganese steel (low carbon), use as a filler the same material or Norway iron.

Nickel steel (low carbon) is to be welded in the same manner as mild steel, but use a nickel steel filling rod.

Vanadium steel (low carbon) probably uses most of the various steel alloys. Weld as mild steel; use vanadium steel filler.

Chrome steel: Weld as mild steel; use a chrome steel filler. Many chrome steels are in the high-carbon class, and the general remarks on "special steels" apply.

Welding Cast Iron

This is **more difficult to weld.** Carbon exists in cast iron in different states. In what is called white iron, which is very hard, the carbon is combined with or dissolved in the iron. In the grey iron, which is soft and easy to work, most of the carbon is in a free state in the form of graphite. Since it is generally necessary to machine or file a weld in cast iron, it is indispensable that the line of the weld be constituted of soft grey iron. Thus, in welding cast iron, always remember that too rapid cooling brings about a combination of the carbon and iron, forming hard, brittle white iron; while slow cooling or reheating after the weld is completed keeps the carbon in a free state, resulting in a softer, more workable material.

Preparation of parts: Castings, before welding, should be very carefully freed from grease and rust. Cracks in metal over 3/16″ thick must always be beveled before welding. When beveling cast iron it is not necessary that the groove penetrate through the entire thickness of the metal. It will be found best to leave about ⅛″ of the thickness unbeveled, as shown in Fig. 42, above. When the metal is over 1″ in thickness, and it is possible to weld from both sides, it will be well to bevel as shown in Fig. 43. A diamond point or cape chisel may be used for beveling cast iron. Remember that careful lining up and clamping is very necessary when broken flanges or lugs are to be welded.

A larger blow-pipe tip is used. To overcome expansion and contraction, preheat. While welding is in progress and after its completion, it is advisable to apply a blow-torch or light a fire under some part of the casting away from the weld.

Filling material: Use a cast-iron filling rod containing a percentage of silicon. The percentage must not be too great or the weld will be soft. For **flux,** a cast-iron flux is necessary.

Malleable cast iron is probably more difficult to weld and treat than any other metal. Castings to be made malleable are made of white iron. Use the same process as for cast iron with a white iron filler.

Welding Cast Aluminum

This metal has a **low melting point** (1,200° F.). See Index under "Melting point of metals" for other melting points. A large welding flame is used. Aluminum is not generally used in pure form. Alloys of aluminum and copper or zinc are generally used. Alloys of aluminum and copper are easier to weld; there is less tendency to crack. Parts over ¼″ thick must be beveled as in the case of cast iron.

In order to prevent collapse during the welding and preheating operations, it is good practice to place a sheet of paper on the inside of the casting next to the crack to be welded. Back this paper with damp fire clay and pack up with asbestos fiber until a firm support is obtained. The paper prevents the fire clay from getting into the weld. With this light backing, or mold, the castings can be welded easily. The mold should be large enough to cover a sufficient area around the crack so that the heated aluminum in the vicinity of the weld will not break down. Whenever a weld is to be made close to a bearing, it is necessary to remove the babbitt (which would melt), and then to clamp mandrels (Fig. 15, page 744) in the bearings to keep them in alignment.

Preheating should not be done except in cases where there is a projecting lug or flange. Preheating must be done carefully and slowly. A blow-torch is generally used, but must not be left on one part too long. When preheating, test with a stick of half-and-half solder—if it melts on touching the casting it shows sufficient heating.

Filling: Alloy rods or pure aluminum rods can be employed of the same thickness as the metal to be welded.

Flux: Opinions differ. Use aluminum flux, if any.

Welding Copper, Bronze, and Lead

Copper radiates heat very rapidly and is also a good conductor of heat. Preheating and continued heating are therefore necessary. The metal is prepared in a manner similar to steel and iron. Cover as much as possible with asbestos. It should be left free to allow for contraction when cooling. **Filling:** phosphor copper. **Flux** must be used the same as when welding brass.

Brass: Preheating is not necessary. Use a special flux for brass and bronze, with a filler of brass spelter. Tobin bronze with brass flux may be used where great strength is desired. The weld should be made rapidly, but the white cone of the flame must not touch the metal.

Lead: Can be readily welded, but the operation is known as "lead burning." (See Index.)

Welding Thin Castings

The inexperienced operator will find it a big help to build a form of fire clay as a support for the broken sections while repairing thin castings. This holds the parts true, and also assists in the control of the molten metal.

Whenever it is necessary to weld in a patch, a new piece of the same metal should be cut to the proper size and shape, the edges of both parts should be beveled, and the patch held in place temporarily by **"tacking,"** that is, welding at several spots some distance apart along the line to be welded. To hold a large patch in position while being "tacked," it may sometimes be necessary to drill a small hole in the center of the patch into which a length of rod can be inserted, and by which the patch may be handled. This hole may afterwards be plugged and welded up. Small patches, that must be placed in difficult positions, may be conveniently handled by simply welding a filling rod to the center of the patch. This may later be melted off.

Sundry Uses of Welding Outfit

Tool hardening: The welding flame will be found useful as a source of heat for the heat treatment of small tools.

Gear-tooth hardening: Gear teeth may be hardened by playing the welding flame along the face of a tooth and then allowing the heat to be conducted away by the body of the gear. The intense heat of the flame permits a single tooth being heated very rapidly, before much heat is conducted to the rest of the gear. As soon as the flame is removed the heat in the treated tooth is conducted away to the body of the gear. This causes hardening of the tooth. This operation is repeated until the desired depth of hardening is reached.

Teeth may be hardened by this method to a depth of about 3/32″. The rapidity with which the treated tooth may be chilled will be increased if the gear is partly immersed in water while the treatment is performed.

Burning battery terminals or connections: For this operation, see Index under "Lead burning."

The metals and parts mentioned above, and many other parts from an automobile too numerous to mention, can be welded successfully.

All up-to-date welding and cutting shops have the latest modern equipment installed to take care of all classes of work, such as preheating cylinders, cases, etc.

The cutting process of this art consists of the cutting and wrecking of all kinds of "I-beams," "channel iron," "girders," cutting of boilers, tanks, cutting and opening of safes, "steel pilings," etc.

Pure **oxygen** used in the process of **removing carbon from cylinders** is one of the most advantageous agents at the service of the automobile owner. See also page 751.

Channel Iron, Angle Iron, etc.

These terms are often used in connection with automobiles. For instance, the front axle is often spoken of as an **"I-Beam"** (see Fig. 46); **"channel iron"** or steel is used for chassis frames of a car, and an end section is shown in the illustration; other sections are also shown.

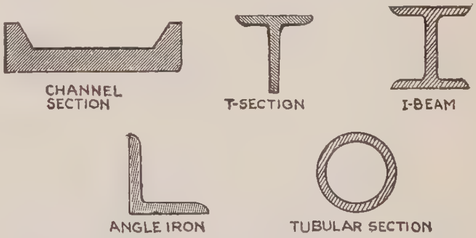

Fig. 46. Sections of iron and steel members which explain why certain shapes are termed **"I-Beam," "Channel," "Angle,"** etc.

Molybdenum steel is a steel that is lighter than any other steel of equal strength, and stronger than any other steel of equal weight.

Oxy-Acetylene Cutting

The cutting blow-pipe is commonly usd for cutting through various thicknesses of wrought iron and steel up to 14 inches. (Wrought iron and steel are the only metals that can be cut by this process.) As an adjunct to a welding equipment, it is used for beveling and for cutting out patches and holes.

The process is based on the fact that a jet of oxygen directed upon a previously heated spot of iron or steel causes it to ignite, with the result that the metal, acting as its own fuel, burns away rapidly in the form of iron oxide. A special blow-pipe is provided for this work (Fig. 47).

The oxygen cutting blow-pipe cannot be used for welding, any more than can the welding blow-pipe be used for cutting.

The difference between the cutting and the welding torch lies principally in the fact that three jets are used, but two gases are used in cutting the same as for welding.

The same source of gas supply is used as for welding. The same acetylene regulator is used, but if work over 3″ thick is to be cut, a special oxygen regulator must be employed. This is exactly the same in appearance as the oxygen regulator for welding, but it is fitted with a stronger spring and a higher reading outlet or "working" pressure gauge.

The special oxygen regulator, as used for cutting thick work, should not be used for welding, as the regulation is not delicate enough to maintain a strictly neutral flame, especially when the smaller tips are in use. The oxygen regulator for welding however, can be used for cutting on work up to 1½″ in thickness.

The oxygen cutting regulator is connected to the oxygen bottle in the same manner as the welding regulator. The cutting blow-pipe is connected to the gas supply through the regulators in exactly the same way as the welding blow-pipe.

There are two kinds of oxy-acetylene cutting blow-pipes, known as the "central" and "following" jet types. The "central" jet type has a number of oxy-acetylene heating flames surrounding a central hole through which oxygen only passes. The "following" jet type consists of one oxy-acetylene heating jet and one oxygen jet. The holes for these jets are usually drilled in the same tip, but sometimes have separate tips which are set close together.

The principles of construction and operation of an oxy-acetylene cutting blow-pipe of the central jet type are shown in Fig. 47. The oxygen and acetylene supplies are connected up through the regulators and rubber hose to the hose nipples on the blow-pipe.

The outlet valves on both regulators and also all valves in the blow-pipe are closed. The gas is then turned on at the cylinders, as in welding, and the regulators are adjusted until the outlet or working pressure gauges show the working pressures specified on the instructions issued with the cutting blow-pipe by its manufacturer. The acetylene valve in the blow-pipe is then slightly opened and the blow-pipe lighted; the oxygen for the heating flame is then turned in at valve (**D**) (Fig. 47). This permits oxygen to mix with the acetylene at (**J**). The flow of the mixture of the gases is indicated by arrows. Valves (**D**) and (**I**) are adjusted until a neutral heating flame is produced. The cutting oxygen is then turned on at (**E**).

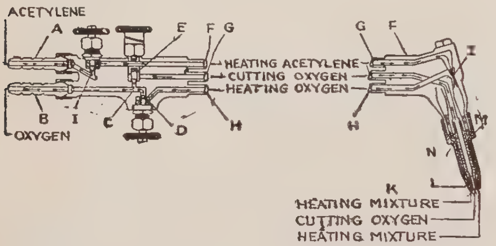

Fig. 47. Diagram illustrating the principle of the oxy-**acetylene cutting** blow-pipe torch.

The line of flow of the cutting oxygen is shown by arrows. The nipple or inner tip through which it discharges is interchangeable, and manufacturers indicate in their instructions the number or size of tip to be used on different thicknesses of metal.

Watch the working pressure gauge on the oxygen regulator, and see if it reads the right pressure for the metal to be cut as originally set; if not, adjust the regulator, and when this is done readjust the heating flame if necessary. Do this as quickly as possible, to avoid waste of oxygen. Now shut off the cutting oxygen at (E), and the blow-pipe is ready for work.

When the metal to be cut is sufficiently heated at the point where the cutting is to start, the cutting oxygen is turned on. When the cutting operation is once under way, the heating and cutting proceed together. The cutting operation is very simple, and can be mastered in a few hours.

The point to observe is that (I) is the acetylene valve and (D) is the oxygen valve, which are turned on first. With them the part to be cut is heated. Then valve (E) is opened, which permits a stream of oxygen to be directed upon the heated spot. See the two preceding paragraphs.

Cutting may be made to follow any desired line. When special forms and shapes have to be cut, it is advisable to make a special mechanical contrivance with which to steady and guide the blow-pipe and thus to insure a clean cut. Hold the blow-pipe tip about ¼" away from the surface of the metal to be cut.

A cut should start from the edge of the metal, whenever possible. When it is desired to cut a piece out of the center of a plate, start inside the circumference of the piece to be cut (Fig. 48). On thick plates, where the cut cannot be started from the edge, it may be necessary to drill a hole to get a quick start.

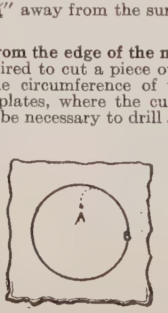

Fig. 48. Shows point of start (A) when cutting circular hole in plate (From Prest-O-Lite instruction book).

Certain precautions are necessary before the operator starts to work on a piece of metal. A bucket of water should be near at hand for cooling the cutting tip when necessary. Both oxygen and acetylene should be shut off at the blow-pipe to extinguish the flame before dipping the tip of the blow-pipe into the water. To expel any steam formed inside the tip, turn on the oxygen valves at the blow-pipe and allow oxygen to flow for a moment before turning on acetylene and lighting it.

Approximate Prices to Charge for Welding Broken Parts by the Oxy-Acetylene Process

The following list gives approximate prices usually charged for welding, and the cost. The prices are not standardized.

Cylinders, Water-Jacket Fractures

Double	$8 .00	to	$15.00
Single	4.00	to	8.00
Block of four or six	10.00	to	15.00
Lug or ears each	$3.50	two or more	3.00

Aluminum Crank Case and Lower Cases

It is very difficult to determine an exact price on this line of work without a thorough examination of the fractures, but as a general rule the average cost of welding is as follows:

Top cases	$ 6.00	to	$25.00
Lower cases	6.00	to	12.00

Manifolds—Aluminum

1 lug or ear	$1.50	Two or more $1.00 each.

Manifolds—Cast Iron

1 lug or ear	$1.25	Two or more $0.75 each.

Crank Shafts

1 throw crank	$ 6.00	to	$ 8.00
2 throw crank	8.00	to	10.00
4 throw crank	10.00	to	14.00
6 throw crank	12.00	to	16.00

Body Frames

Two inches	$ 7.00
Three inches	8.00
Four inches	10.00
Five inches	12.00
Six inches	15.00
Eight inches	17.00

Rear-Axle Housings

Prices vary according to size and fractures, but they average from $3.00 to $18.00.

Lamp brackets	$0.50	to	$1.50
Levers	.75	to	2.00

The Cost of Welding[1]

Thickness Metal	Size tip to be used	Acetylene		Oxygen	
		Consumption per hour	Cost of gas per hour	Consumption per hour	Cost of gas per hour
3/16" to ¼	No. 3	15 cu. feet	$0.30	17 cu. feet	$0.34
⅜" to ½	No 5	43 cu. feet	.86	47 cu feet	.94

The total cost of gas per hour would be 30c. + 34c. = 64 cents, and 86 cents + 94 cents = $1.80.

The approximate capacity per hour of welded seams (3/16" to ¼") would be 15 to 20 lineal feet, and 7 to 12 lineal feet on ⅜" to ½".

Note. In welding metals of from 3/16" to ¼" in thickness, the average approximate capacity, expressed in terms of lineal feet of welded seam, would be from 15 to 20 feet per hour, being a cost for gas of from 3 to 4 cents per lineal foot. For metals ⅜" to ½" in thickness, the approximate capacity would be from 7 to 12 lineal feet per hour, being a cost for gas of from 15 to 25 cents per lineal foot.

Under continuous use with the No. 3 tip, a cylinder containing 100 cubic feet of acetylene will run about 6½ hours, while the same quantity of oxygen would run about 6 hours.

With the No. 5 tip, a cylinder containing 100 cubic feet of acetylene would run about 2 1/3 hours, while the same quantity of oxygen would run about 2 hours.

---

[1] The acetylene prices quoted above are based on a price of 2 cents per cubic foot, whereas the price is now 3 cents. Oxygen prices given are based on a price of 2 cents per cubic foot, whereas the price is now 2⅓ cents.

The Cost of Cutting[1]

Thickness of Metal	Acetylene		Oxygen	
	Consumption per lineal foot	Cost per lineal foot	Consumption per lineal foot	Cost per lineal foot
¼	.13 cu. feet	$0.003	.50 cu. feet	$0.01
⅜	.18 cu. feet	0.0036	.90 cu. feet	0.018

The time required per foot of cutting length of the ¼″ thickness of metal named above is 1 minute and 1¼ minutes for the ⅜″ thickness.

The total cost of gas per cutting foot on the ¼″ thickness would be 1¼c. to 1½ cents, and 2¼ cents to 2½ cents on the ⅜″ thickness.

Note. In continuous cutting through metal ¼″ thick, the cost for gas would be about 2 cents per running foot and the time about one minute.

For metal ⅜″ thick, the cost of gas per running foot would be about 3 cents per foot and the time about 1¼ minutes.

When cutting ¼″ metal, a cylinder containing 100 cubic feet of acetylene would run about 12 hours, while the same quantity of oxygen would run about 3 1/3 hours.

For ⅜″ metal, a tank containing 100 cubic feet of acetylene would run about 11½ hours, while the same quantity of oxygen would run about 2 1/3 hours.

It will be noted that in the process of cutting the extra quantity of oxygen required is due to the cutting jet of pure oxygen which is used in addition to that mixed with the acetylene.

Tanks containing 200 cubic feet of gas would run twice as long as the 100-foot tanks.

The foregoing estimates are based on acetylene and oxygen gas costing $2.00 per 100 cubic feet. The cost of labor should be added to the total cost of gas.

Where to Obtain Gas Tanks for Welding

Gas tanks can readily be obtained at branches of the various firms mentioned below.

Oxygen and Acetylene Gas for Use with Imperial Welding and Cutting Outfits

Oxygen for welding and cutting can be obtained from the Linde Air Products Co., of Chicago, and New York, which has twelve plants and twenty-five warehouses in various parts of the country. It furnishes oxygen in tanks containing 100 and 200 cubic feet respectively, with free use of tanks.

Acetylene Gas for Welding and Cutting

Some manufacturers of acetylene gas are mentioned below:

The Prest-O-Lite Company of Indianapolis, Ind., which has branches in nearly all the large cities of the United States.

The Commercial Acetylene Ry. Light & Signal Company of New York has numerous branches. We are advised it supplies acetylene for welding and cutting. The tanks contain 120 and 225 cubic feet.

Approximate shipping weights are as follows:

Linde	100 cu. ft.	122 lbs.
Linde	200 cu. ft.	150 lbs.
Prest-O-Lite	100 cu. ft.	85 lbs.
Prest-O-Lite	300 cu. ft.	220 lbs.
Searchlight	100 cu. ft.	75 lbs.
Searchlight	225 cu. ft.	180 lbs.
Commercial	120 cu. ft.	120 lbs.
Commercial	225 cu. ft.	180 lbs.

The weight of acetylene is approximately 14½ cu. ft. to a pound.

The price of oxygen and acetylene varies somewhat, depending on location, prices in the extreme West and South being somewhat more than in the East. The prices in the East for both oxygen and acetylene are approximately $2.00 per hundred cubic feet at the filling station or warehouse.

You can obtain full information regarding oxygen and acetylene by corresponding with the companies named above, at the branch nearest to you.

To provide a constant supply of gas for your shop, you can no doubt arrange to get the use of from three to six cylinders or more, according to requirements which would eliminate possibility of running out of gas by having extra cylinders on hand for use while getting empties recharged.

Your automobile supply house with whom you are trading may be able to give you additional information on this subject.

Oxy-Hydrogen

An important feature to the Imperial welding and cutting equipment is its adaptability for use with oxy-hydrogen as well as oxy-acetylene. When it is desired to equip for both oxy-hydrogen and oxy-acetylene, the only change necessary is the addition of one hydrogen regulator and a set of hydrogen tips.

Tips for welding as well as cutting with hydrogen can be furnished. The tip is marked with the pressure of gases required.

Where a supply of hydrogen is available at reasonable prices, **it is recommended in connection with oxygen for cutting of wrought iron and steel of any thickness. The cut will be found smoother and the operation more economical** than by the use of acetylene for the preheating flame.

For **welding in general repair work, such as gears and castings, aluminum crank cases and other alloyed metals, the use of the oxy-hydrogen flame is recommended.** For welding thin sheet steel, from 16 gauge up, the oxy-hydrogen flame is found very effective. Its temperature being about 4,000 degrees F., the metal is not burned so easily and as hydrogen contains no carbon, the weld is softer and very uniform. Cast iron may be welded with oxy-hydrogen very successfully up to ¾″ in thickness.

For welding steel of more than ¼ inch in thickness, the oxy-acetylene flame should be used under all circumstances.

Internal Construction of Regulators for Acetylene and Oxygen

Two regulators are necessary, one for **oxygen** and one for **acetylene,** except when a stationary type of generator is used, such as the Imperial (Fig. 3, page 742), as in that case the acetylene regulator is not necessary.

The regulator is a very important part of the equipment and in order further to simplify its operation, a sectional view of the Imperial regulator (Fig. 49) will be used.

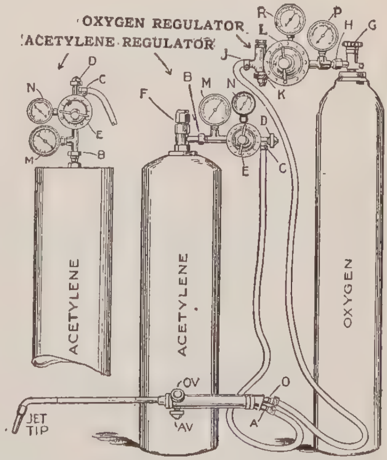

Fig. 48. Showing **Imperial welding outfit** connected to tanks: (**A**) acetylene inlet to torch; (**AV**) acetylene valve on torch; (**B**) tank coupling; (**C**) hose coupling; (**D**) outlet valve to hose; (**E**) acetylene regulating screw; (**F**) acetylene tank valve; (**G**) oxygen tank valve; (**H**) tank coupling; (**J**) hose coupling; (**K**) outlet valve to hose; (**L**) oxygen regulating screw; (**M**) acetylene tank pressure gauge; (**N**) acetylene working pressure gauge; (**O**) oxygen inlet to torch; (**OV**) oxygen valve on torch; (**P**) oxygen tank pressure gauge; (**R**) oxygen working pressure gauge.

Note. When either the Air Reduction or Commercial Companies' acetylene tanks are used, the acetylene regulator stands out at right angle to the tank, as shown in center tank.

When Prest-O-Lite tanks are used, the regulator stands up on end, as shown in partial view of tank at left.

---

[1] Used most.

In order to weld successfully, it is necessary that two gases be used by delivering the gases in equal proportions to the torch, in order to make a flame of the proper intensity.

The purpose of the regulator is to reduce the pressure in the cylinders or tanks to a working pressure.

The pressure of the acetylene tank, when full, shows 250 lbs. The regulator reduces the pressure to from 1 to 10 lbs. for **welding** and from 10 to 15 lbs. for **cutting.**

The acetylene regulator and the oxygen regulator, one of which must be used on each tank, are similar in construction.

The acetylene regulator has a German silver diaphragm.

The oxygen regulator has a bronze diaphragm, the thickness of which is approximately one one-hundredth of an inch.

Fig. 49. Sectional view of the Imperial pressure regulator.

Regulator action (Fig. 49): The gas enters the regulator through the gas inlets (B) and (H) and travels through the passage indicated by arrows to the nozzle (X). It is stopped here because the seat (S) is held against the end of the nozzle by the spring (A) which pushes against it.

To make the regulator operate, the regulating screws (E) and (L) are screwed in (to the right), thus placing tension on the spring (Z) which forces the diaphragm (B) downward.

Inasmuch as the seat (X) is carried in the yolk (O) which is fastened to the diaphragm, this spring tension pushes the seat (S) away from the seat (X) and allows the gas to flow into the bowl of the regulator.

This gas forms a pressure against the inside of the diaphragm, as indicated by small arrows, and has a tendency to push the seat back against the nozzle. The pressure on the spring (Z) and the gas pressure against the diaphragm balance, and the regulator is held open just enough to allow as much gas to escape through the nozzle as is being drawn out at the outlets (C) and (J).

To obtain more pressure, screw in on the regulating screws (E) and (L). **To reduce the pressure,** unscrew the regulating screw.

The oxygen and acetylene regulators are the same except that in the oxygen regulator there are two springs, and in the acetylene, only one, and the gauges are different.

The pressure of the oxygen tank, when full, is 2,000 lbs. The regulator reduces the pressure to anything from 1 to 15 lbs. for welding, and from 20 to 150 lbs. for cutting.

The cutting torch (Fig. 47, page 748), has two connections, one for acetylene and one for oxygen, but the difference here is that after the two gases are used to heat the article to be cut, more oxygen is admitted through a third tube, with the result explained on pages 747, 748.

Acetylene Gauges

Refer to the illustration (Fig. 48) and note the location of the gauges.

In Fig. 48 **(M) is calibrated in pounds from 0 lbs. to 500 lbs.,** and is the gauge connected with the acetylene tank (Fig. 48).

(N) is calibrated in pounds from 0 lbs. to 50 lbs., and is the gauge from the regulator to the torch, and shows the reduced pressures (Fig. 48).

Oxygen Gauges

High-pressure oxygen gauges (P) (Fig. 48) are graduated to show both the tank pressure and the percentage of gas in the tank. The outside reading from 0 to 3,000 lbs. gives the pressure of the gas in the tank.

The smaller readings are to be read as follows: If the regulator is being used on a tank of 100 ft. capacity, the readings from 0 to 100 are used. If the regulator is being used on a tank of 250 cu. ft. capacity, the scale from 0 to 250 is used. Therefore, if, after completing a job, the pointer on the gauge should show on the 200 point and the regulator was being used on a 250 ft. cylinder, it would mean that there were 200 cu. ft. of gas left in the tank.

(R) is calibrated in pounds from 0 lbs. to 150 lbs. (Fig. 48), and shows the reduced pressure from the regulator to the torch.

Sometimes gauges are calibrated in atmospheres. An "atmosphere" is equal to about 15 lbs. Therefore, if a tank is full, and the gas is compressed to 1,800 lbs. to the square inch, the gauge would show 120 atmospheres (see page 442 explaining atmospheres). If tanks are placed where there is considerable heat, the gas will expand and increase the pressure.

Sometimes both an atmosphere and pound calibration is used on the same gauge.

Capacity of tanks generally used is 50, 100, 150, and 200 cu. ft. The size of the tank gives its capacity.

The Cost of Welding, Cutting, and Decarbonizing Outfits[1]

No. 1 Imperial welding outfit (Fig. 50): For all general welding work, from thin sheet metal to heaviest castings. Consists of type B welding torch, with ten welding tips, extension, decarbonizing torch, regulators, gauges, hose, connections, goggles, complete supply of welding materials, ready for service. Weight, approximately 75 lbs. net, each $75.00

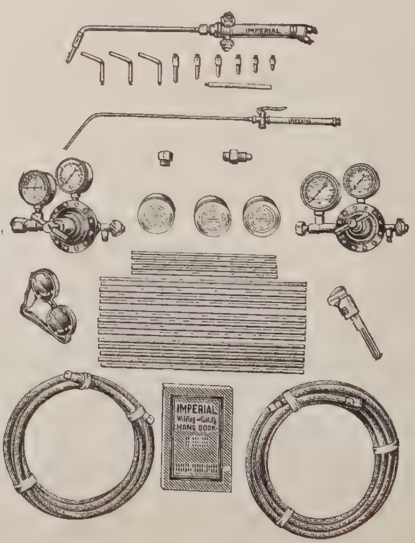

Fig. 50. No. 1 Imperial welding outfit.

---

[1] A book of instructions on welding and cutting, as supplied with the Imperial outfits, can be secured of A. L. Dyke, Granite Bldg., St. Louis, Mo., price $1.10 prepaid.

No. 2 Imperial all-purpose garage welding outfit (Fig. 51). This fills the requirements of the small shop or garage, as with this outfit it is possible to do welding, carbon burning, lead burning, radiator soldering, brazing, preheating and cutting. The No. 2 cutting attachment (Fig. 52) which will cut steel and wrought iron up to 2½″ thick, is $10 extra.

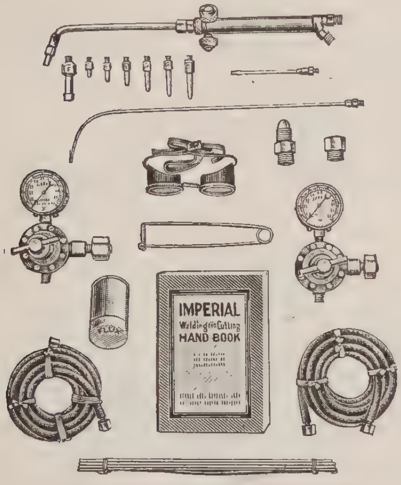

Fig. 51. No. 2 Imperial welding outfit.

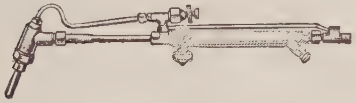

Fig. 52. No. 2 cutting attachment.

The No. 2 Imperial Welding outfit (Fig. 51) consists of:

1 type BB welding torch, with 6 welding tips, Nos. 1, 2, 3, 4, 5, and 6.
1 type H carbon-removing tip.
1 type OO lead-burning tip.
1 type G radiator-soldering tip.
1 type F brazing tip.
1 type D oxygen regulator, with 50-lb. working pressure gauge.
1 type DD acetylene regulator, with 50-lb. working pressure gauge.
1 No. 60-H adaptor for Prest-O-Lite tank.
1 No. 61-H adaptor for commercial and air-reduction tanks.
1 10-ft. oxygen hose, with couplings.
1 10-ft. acetylene hose, with couplings.
1 pair welding goggles, supply of cast iron, and Norway iron welding rod, flux.
1 spark lighter and welding handbook, weight 16 lbs., packed in carton.

The price of the No. 2 welding outfit complete, without cutting attachment, is $44.50; with cutting attachment, $10 extra.

No. 4 Imperial combination welding and cutting outfit: A splendid equipment for all general work, garages, repair shops, etc. The combination welding and cutting torch performs both operations with one torch. Consists of type B welding torch, with type DB cutting attachment, ten welding and three cutting tips, decarbonizing torch, regulators, gauges, hose, connections, goggles, complete supply of welding materials, ready for service. Weight, approximately 80 lbs., net, each $90.00.

No. 5 Imperial duplex welding and cutting outfit: This is a combination of the Nos. 1 and 3 outfits for both welding and cutting, and is the best all-purpose apparatus obtainable at any price, being fully adequate to handle all kinds of welding and cutting within the limits of the process. Consists of a complete No. 1 welding outfit as described, and also includes a type E cutting torch with two housings and four tips, and an extra pair of goggles and 25-ft. lengths of hose. Weight, approximately 90 lbs., net, each, $120.00.

(**Manufacturer**, The Imperial Brass Mfg. Co., 1200 W. Harrison St., Chicago, Ill.)

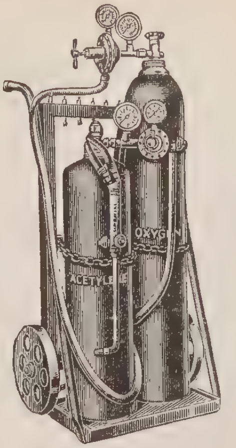

Fig. 53. Imperial portable truck.

Oxygen Decarbonizing or Carbon Burning (Also Called Decarbonizing)

All traces of carbon can easily be removed from the cylinders and the head of pistons of an automobile engine with the No. 6 Imperial carbon burning outfit (Fig. 54) in less than thirty minutes, at the small cost of from 10 to 15 cents per cylinder.

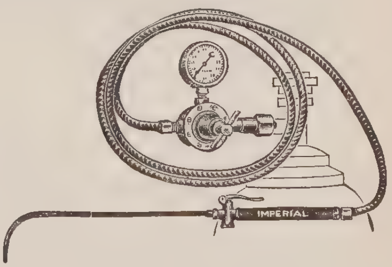

Fig. 54. Decarbonizing outfit.

This is a wonderful improvement over the old, expensive, and slow process of removing carbon by scraping the cylinder.

Oxygen can be purchased from service stations located in most prominent cities. The outfit consists of type G carbon burning torch, type D regulator, gauge, hose, connections, etc. ($15.00).

Brazing and Soldering Outfit

An outfit ideal for radiator repair work and which can also be used to advantage for all kinds of soldering, brazing, and light preheating work in garages and repair shops, is the Imperial No. 30 brazing and soldering outfit shown in illustration (Fig. 55).

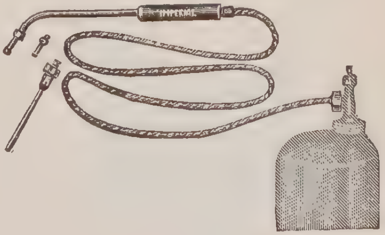

Fig. 55. Brazing and soldering outfit; also used for radiator repairing.

The torch burns acetylene and the tip draws in the necessary oxygen from the atmosphere, making it economical to use.

The tank connection fits the small automobile acetylene lighting (Presto) tank, but the outfit can be used on large-size cylinders by means of an adapter fitting. The outfit consists of type AD torch, 3 tips (one with a long spout for radiator soldering), 6 ft. of hose and connections ($4.50).

Lead Burning

Lead burning of connectors on storage batteries, etc., with acetylene, oxygen, or illuminating gases, etc., including the equipment and torches used, is explained elsewhere; see Index under "Lead burning."

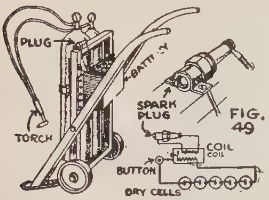

Fig. 56

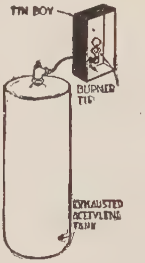

Fig. 57

Fig. 56. A means of **electrically lighting the welding torch** is shown above. A box, holding several dry cells, and a spark coil are mounted at the rear of the welding truck, and are connected to a spark plug attached to the top of the frame. The plug is thrown into operation by a push button connected into the battery circuit. This system of lighting is adapted to short welding jobs.

Fig. 57. A **welding pilot light.** When the gas in the welding tank becomes too low for welding purposes, there is still sufficient gas for supplying a pilot light as in Fig. 57. The light comprises a small gas tip arranged in a tin box as shown.

Welding Precautions

1. Always shut off the gas at the cylinder valves when the work is finished.
2. Never leave pressure in the regulators when not in use. The pressure gauges will indicate.
3. Never clean out a blow-pipe tip with a sharp, hard tool.
4. Before attaching rubber hose to a blow-pipe or regulator, make sure that the inside of the hose is free from dust or powder (used as a preservative), which is apt to choke the blow-pipe.
5. Do not under any circumstances use oil or grease on oxygen cylinder valves or regulators.
6. Always see that the hose is clamped securely to the blow-pipe and regulators before using.
7. Always turn on the cylinder valves slowly.
8. Never open the acetylene cylinder valve more than one full turn of the spindle.
9. In case the flame goes out at the tip or burns back of the tip, shut off first the oxygen, then the acetylene, at the blow-pipe.
10. Always have a bucket of water handy while welding or cutting, for cooling the blow-pipe tips when necessary.
11. If the flame is not blue and the part being welded is smoked black, then the oxygen line is likely to be stopped up or the tank is empty.
12. In disconnecting an empty acetylene cylinder from the welding outfit, remember to **close the cylinder valve** tightly. Remember that the acetone in an empty cylinder is inflammable, and that, should the temperature in the room increase, an open valve would permit vapor to escape, as well as any slight quantity of gas which might yet remain in the cylinder. For these same reasons, the railroads require that valves be closed before shipping.
13. Remove "inflammable" red labels from acetylene cylinders before shipping back, and ship as "empty returned gas cylinder," in order to get the lowest freight rate.

INSTRUCTION No. 67

TOP REPAIRING[1]

Any repair shop, by the investment of a small amount of money in equipment, and the exertion of reasonable care, can develop a profitable top repair department. It is as essential a part of the trade as is the machine shop or the vulcanizing shop.

Only a small amount of equipment is necessary in a top repair shop, and this, with the exception of the sewing machines, may be made by the repairman himself.

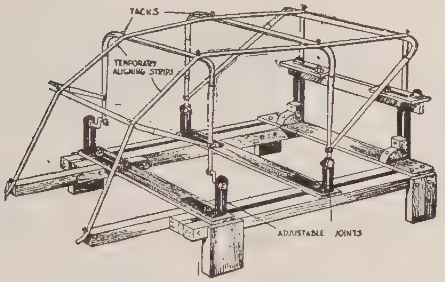

Fig. 1. When the car cannot be left in the shop, this adjustable frame enables the mechanic to duplicate the method of holding used on the car.

The top building frame is shown in Fig. 1, and it is used only when the car for which the top is being repaired cannot be left during the work. It is simply an adjustable framework upon which the top may be placed in exactly the position it occupies when up, and on the car. For each car the frame is set to duplicate the measurements of the top-supporting irons and the car body. Then the workman can repair or rebuild the top with assurance that it will fit when returned to the car. When possible, the top should be left on the car during the repair.

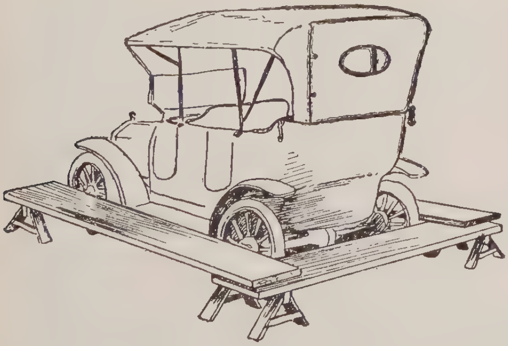

Fig. 2. Most tops are repaired right on the car, and a framework on three sides of the car renders all parts accessible.

In order to render all parts of the top accessible, when left on the car, a framework shown in Fig. 2 is set up around three sides of the car. This framework is about 18″ high, and comprises three planks resting on four small wooden horses.

Another method of accomplishing the same result, yet one which the author has never seen, would be to construct a pit below the floor level. This would permit the workman to work directly from the floor and save the time lost in stepping to and from the platform.

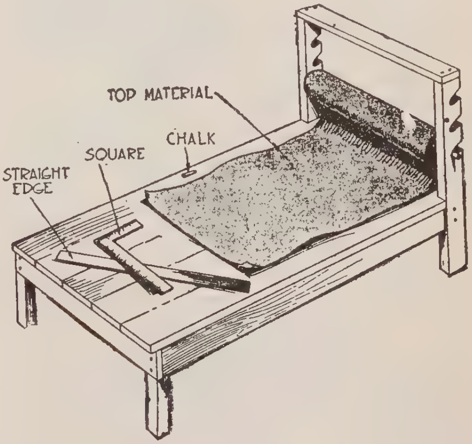

Fig. 3. The rolls of top material are carried on rods hung in a notched upright, and the material is marked out and cut to form on the laying-out table.

All work is laid out and cut on the laying-out table shown in Fig. 3. This table is about 6 ft. wide, 12 ft. long, and 28 in. high. A notched rack at one end supports the rolls of top material and enables the workman to obtain or replace the top material readily when desired. Rolls may be easily removed from the frame, or as many as three rolls of material may be carried at one time.

The tools of the workman are few, comprising a light cross-peen **hammer,** with a tack puller fitted to the end of the handle; a heavy pair of **shears,** a small **cold chisel,** and a **nail set** or **punch.** These are carried in a special apron, made of top material, as shown in Fig. 4. In addition, **a carpenter's square,** a 10-ft. **straight edge, a yardstick,** and a **plumb bob** are required. The plumb bob is used to plumb up the edges of the back curtain, when fitting, to make certain that they are hung straight.

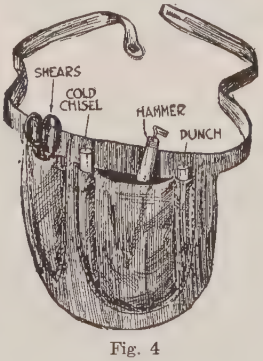

Fig. 4

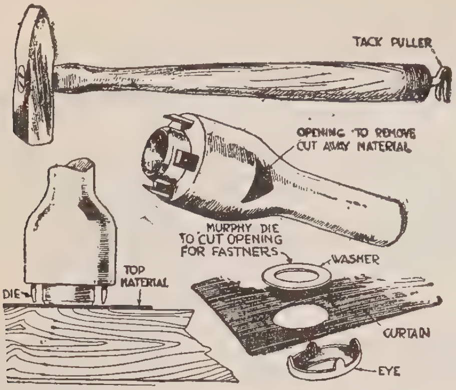
---

[1] From *Motor World*, by S. Thorton Williams. Note. The shop layout and special tools, together with the procedure, were obtained from the Barton Auto Top Co., Detroit, Mich.



TACK PULLER

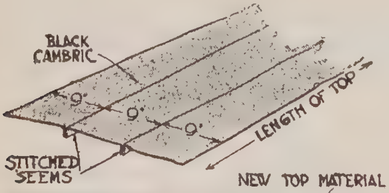
MURPHY DIE TO CUT OPENING FOR FASTNERS
WASHER
TOP MATERIAL
DIE
CURTAIN
EYE

Fig. 5. The other end of the hammer (at top of illustration) is fitted with a tack puller, thus combining the two tools. Special dies are required to cut the openings for the fasteners. The most common type is shown in the lower part of the illustration.

In addition, several special punches and dies will be necessary for cutting the openings for the curtain fasteners. One of these—styled the **Murphy die**—is shown in Fig. 5, and corresponding dies are used for each type of fastener.

The sewing machine used in this work is of extra heavy construction, and is similar to those used by harness makers. These machines should be motor-driven, and may be purchased from almost any reliable sewing-machine manufacturer. See page 755.

So much for the equipment. Now for **the method of doing the work.** Briefly this consists of removing the top material, part by part, using the parts as patterns to cut the new parts by; fitting the parts to the top frame; removing the parts; sewing them together, and then placing them again on the frame. Careful work is essential, and after carefulness has become a habit, speed may be developed. Carefulness, then speed, are the only two requirements for a successful top repairman.



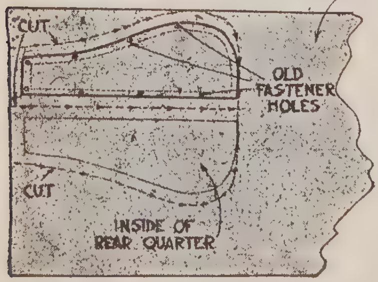


Fig. 6. The side pads are a single strip of cambric 9" wide and sewed as shown.

The following is a typical example of the method used in re-covering an automobile top. Though it specifically applies to a Ford top, it may, in general, be applied to any car.

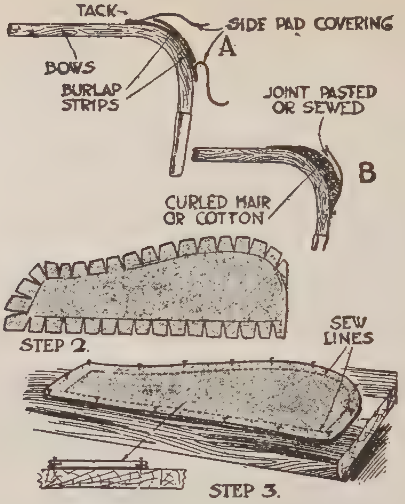

Fig. 7. In the upper half of the illustration is shown the method of building up the side pads.

The lower half of the illustration shows the various steps in laying out and cutting a rear quarter. It is then taken to the machine and sewed.

1. **Remove the top covering from the frame,** part by part, using the hammer and cold chisel as tools. Note how each part is fastened, as the rebuilding must be exactly the reverse of the tearing down.

2. **Using each part as a pattern, one by one, mark out the new parts on the top material.** Care must be taken to allow extra material at the edges for fastening the material to the frame. The method of constructing the rear quarter is shown in Fig. 7 (lower half), and this method applies in general to each of the top parts.

All metal fastener holes should be punched, using the holes in the old parts as guides, and all square corners should be checked up by means of the square. The parts are then sent to the machine, and the necessary sewing is done. The celluloid windows are also placed in the rear curtain at this time.

In the meantime, the top frame should be placed in good condition. If any bows are broken, new bows should be fitted. Ordinarily, new wrapping should be tacked around the bows, but if this wrapping is only faded, it may be dyed to conform to the inside of the top material.

3. **The side-pad covers should now be made,** according to the pattern shown in Fig. 6. On the Ford, black cambric is used, but in every case the material should conform in color and quality to that used in the top material.

4. **Line up the top bows.** The method of doing this is shown in Fig. 1. Heavy canvas straps are passed over each side of the bows, drawn tight, and tacked in place. The front bow should fit down over the windshield; the two middle bows should be vertical, and the position of the rear bow can be gauged by the length of the straps holding it down to the body back.

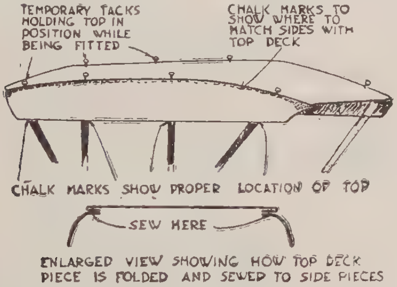
5. **The side-pad liners are next tacked in place,** and the burlap strips are tacked tightly in place.

After this the curled hair, or cotton packing, is replaced, and the side-pad flaps are pasted into place. If desired, the edges of the pad may be sewed together. These operations are shown in detail in Fig. 7 (upper part).

6. **The rear quarters and back curtain are now fitted and tacked in place,** after the metal fasteners have been applied, as shown in Fig. 5. All vertical edges are plumbed up with a plumb bob, as any edge out of the vertical here is particularly noticeable.

7. **The two side quarters are now temporarily tacked in place,** beginning at the front and working to the back. These quarters should be drawn tight, without wrinkling. The edges of the deck are then turned under, and the deck is temporarily tacked in place.

8. **By carefully fitting and changing, the top may be fitted to the bows in exactly the position it is to occupy.** When everything appears to fit correctly, the side curtains should be placed in position, and if necessary, the tacks should be removed and the top pieces shifted until the side curtains fit. (In most cases new side curtains do not have to be made; but if so, the new curtains should be fitted at this point.)



TEMPORARY TACKS HOLDING TOP IN POSITION WHILE BEING FITTED
CHALK MARKS TO SHOW WHERE TO MATCH SIDES WITH TOP DECK
CHALK MARKS SHOW PROPER LOCATION OF TOP
SEW HERE
ENLARGED VIEW SHOWING HOW TOP DECK PIECE IS FOLDED AND SEWED TO SIDE PIECES

Fig. 8. After all parts of the top are made, they are temporarily tacked to the bows and fitted. When a perfect fit is secured, the edges are marked, and the parts removed and sewed. They may then be replaced on the frame, and permanently fastened in place.

9. **When everything is right, the mating edges of the top pieces should be marked with chalk,** and these marks should be crossmarked, as shown in Fig. 8. Then, by joining the corresponding marks together, the sewing-machine operator can sew the parts together correctly. Chalk marks should also be placed at the points where the edge of the top crosses the bows. This permits the top to be correctly replaced after a sewing.

10. **The parts of the top are then removed, and the flaps on the edges that are to be sewed are trimmed down to a width of about 2 in.** The parts are then sent to the machine and sewed together.

11. **To complete the work it is only necessary to replace the top covering and tack it securely in place.** All extending edges are removed and the joints covered by a narrow strip of cloth material fastened by black upholstering tacks.

The foregoing covers the method of completely replacing the top covering, with the exception of the side curtains. As stated, this is rarely necessary, as the side curtains are little used. If desired, any one part of the top may be replaced with new material, providing the other parts are in good condition. However, if either the deck or side-quarters must be replaced, it is necessary to tear the top completely down in order to sew it together again.

In cases where it is necessary to replace some parts of the top covering, it will usually be found advisable to renovate the interior and exterior of the rest of the covering to make it conform to the appearance of the new part. Or this renovating may be done at any time to improve the appearance of the top.

After applying any patches that are necessary, replacing broken windows, and tacking on new binding at the edges where required, the top should be thoroughly brushed and cleaned. Gasoline should never be used for this purpose if rubber is used in the top material construction, as its action tends to destroy the rubber. Soap, warm water, and a brush are all that are usually required.

When the top is thoroughly cleaned and dried, **top dressing may be applied** to the outer surfaces, and the faded inner surfaces may be dyed black. There are many brands of top dressing on the market for this purpose, and any well-known brand should prove entirely satisfactory. By exercising a little care, the appearance of a shabby top may be greatly improved by this simple cleaning, patching up of loose ends, and application of top dressing.

Top roof patching strips adapted for mending tops can be cut to fit any repair needed in roof, side or back curtains and are permanent and waterproof; they are convenient for all repair shops, and are made of different material to meet different requirements. They can be secured of supply houses.

Fig. 9

An assortment of window and all styles of top roof patching materials, known as the "Stik-Tite" brand, can also be secured of supply houses.

Celluloid windows, bound with suitable material to match different curtains, can be attached in ten minutes by anyone, without removing and without stitching the back curtain.

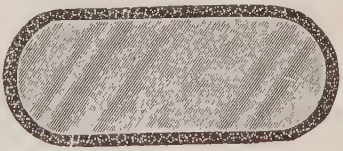


Fig. 10. **Celluloid windows.**

They are made to fit almost all popular cars, and can be secured of supply houses. A well-known brand is the "Stik-Tite," already mentioned.

Where to Obtain Top Material

Tools, such as eyelet punches and dies for sockets and eyelets, special hand screwdrivers, curtain fasteners, etc, are obtainable from Carr Fastener Co., Cambridge, Mass.; G. W. Murphy Co., Amesbury, Mass.

Top material is sold by Cray Bros., Cleveland, Ohio; Thomas Auto Top Co., Muncie, Ind.; Cincinnati Auto Specialty Co., 312 Main St., Cincinnati, Ohio; Du Pont Fabrikoid Co., Wilmington, Del.; F. S. Carr, Boston, Mass.; L. C. Chase Co., Boston and Chicago; Pantasote Co., 11 Broadway, New York, N.Y.

Top and upholstering dressing and celluloid for curtain, lights, etc. is to be had of Cray Bros., Cleveland, Ohio; F. S. Carr, Boston, Mass.; Ero Mfg. Co., 753 W. Jackson Blvd., Chicago, Ill.; Boyer Chemical Co., 940 N. Clark St., Chicago, Ill.; Cincinnati Auto Specialty Co., 312 Main St., Cincinnati Ohio.

Sewing machine: The Singer Sewing Machine Co., Singer Bldg., New York, manufactures a sewing machine especially designed for top and curtain work, seat covers, etc. It is known as "class 1688."

Rain shields, similar to that shown in Fig. 14, for placing over the windshield to prevent snow and rain accumulating, is another profitable accessory to handle (manufactured by Jos. N. Smith Co., Detroit, Mich.; Gemco Mfg. Co., Milwaukee, Wis.).

Seat covers are also profitable to handle (obtainable from Cray Bros., Cleveland, Ohio; Glover Eq. Co., Indianapolis, Ind.).

Top and upholstering dyes and dressing are to be had of Cray Bros., Cleveland, Ohio; Northwestern Chemical Co., Marietta, Ohio.

Complete tops are also to be had of Cray Bros., Cleveland, Ohio.

Glass curtain lights (Fig. 11) are very popular. They are rather expensive, however, but add considerably to the appearance of a car. The glass is beveled and comes with a frame ready to place in the curtain. Can be secured of supply houses or of Frankel Specialty Corpn., 356 W. 56th St., New York, N.Y.; Wm. R. Johnston Mfg. Co., 451 E. Ohio St., Chicago, Ill.; Nurre Mirror Plate Co., Bloomington, Ind.

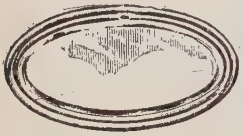

Fig. 11

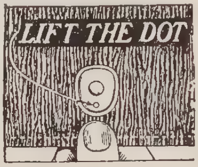

Fig. 12

Fig. 11. Glass curtain light.

Fig. 12. "Lift-the-dot" curtain fasteners.

The "Lift-the-dot fastener" is a very popular curtain fastener (Fig. 12). To unlock and remove, lift the dotted end of the socket which is placed nearest the edge of the curtain. It is natural to lift the edge of the curtain, so there should be no difficulty in remembering always to "lift-the-dot" and avoid tearing the curtains. Manufactured by Carr Fastener Co., 31 Ames St., Cambridge, Mass.

Miscellaneous

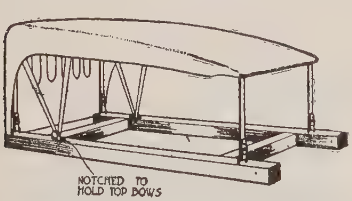

Fig. 13. It is often desired **to paint or repair a top** without leaving the car in the repair shop. A simple support that permits this is a rectangular wooden framework notched to hold the top irons. The top is placed on this framework.

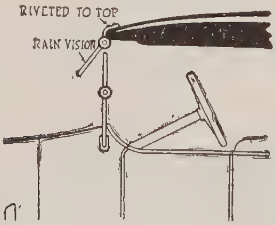

Fig. 14. **Rain vision windshields** are common on closed cars, but unusual on open ones. It is a simple matter, however, to add this feature. The upper section of a windshield is mounted on the front of the top, two specially made brackets being used to hold it in place. It catches the rain and the regular windshield protects the driver from the wind.

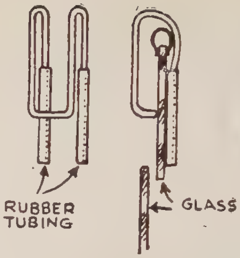

Fig. 15

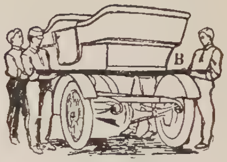

Fig. 16

Fig. 15. One of the essentials of bad-weather driving is some provision for keeping the **top glass of the windshield free from snow or rain.** Chemical preparations are sometimes used to give the surface of the glass a greasy surface, so that the rain will run off rapidly, but this method is not effective against snow.

Scraping off the surface of the glass is perhaps the most effective method yet devised.

A simple cleaner may be made of a piece of rather heavy steel or brass wire, about a quarter of an inch in diameter, and a piece of rubber tubing. The wire is bent in the form of a double loop, and a piece of rubber tubing is slipped over each free end of the wire. If the wire is coated with rubber cement, before the rubber tubing is pulled on, there will be no chance for the tubing to come loose.

The middle of the wire loop should rub on the inside of the glass at a point about opposite the middle of the rubber tubes, so that an even pressure will be exerted by the rubber tubes over their whole length on the surface of the glass. (*Ford-owner.*)

Fig. 16. **Removing a body.** Showing how the body of a car can be lifted easily from or on to the chassis, and conveniently transported about the garage or shop.

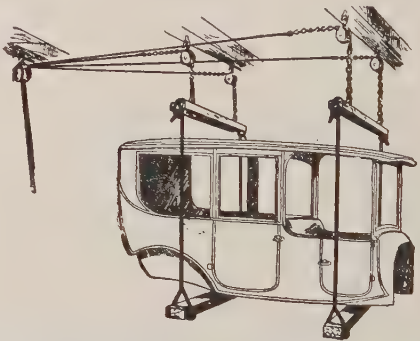

Fig. 17. **Closed bodies** may be **removed** without strain by the aid of the hoisting cradle illustrated. Two cross-pieces are attached to separate chain hoists and are so spaced that they hang 2 ft. from the ends of the body to be removed. First one end of the body is pried up, and a lower cross-member slipped beneath it. Then the other end is raised, and the other lower member put in place. The steel stirrups are then used to attach the lower and upper cross-pieces, after which the body may be raised and the chassis rolled from under.

Vulcanizing Small Holes in Tops

Dr. S. A. Peake's method of **vulcanizing small holes** as large as ½" in tops is as follows: First clean both sides of the surface with gasoline; then use "Mastic" or "Tire-Doh" and work it to a point, and insert in the hole, so as to fill it completely. Cut off on each side. Then place a hot sad-iron underneath and on top. This will vulcanize the Mastic in the hole.

Cleaning Tops, Upholstering, Etc.

On this subject see Index under "Care of a car."

INSTRUCTION No. 68

REPAIRING AND ADJUSTING A CAR: Overhauling a Car; Cleaning and Lubricating; Removing Carbon; Causes of Loss of Power; Compression Tests; Grinding Valves; Testing for Engine Knocks; Refacing and Reseating Valves

WHAT CONSTITUTES A CAR OVERHAUL

Automobile overhauling is essentially a process of general cleaning, inspection, tightening-up and re-adjusting, involving, perhaps, some minor replacements, all of which will be taken up in their respective order.

Engine[1]

Test compression: Test for knocks; clean carbon; grind valves; adjust valve clearance; fit new rings if necessary; re-bore cylinders if necessary; take up on bearings; check the valve timing; examine valve springs; examine gaskets.

Ignition and wiring: Test the ignition timing; test battery and electrical apparatus; clean spark plugs and adjust gaps, also clean, oil, adjust and tighten the generator and starter, nuts, etc., and see that all ground connections are tight.

Clean engine: Flush out old oil as explained on page 167. Refill oil pan with a good grade of oil.

Miscellaneous engine parts: Examine water pump; see if water hose requires replacement; examine intake and exhaust manifolds and see that gaskets and joints are tight; tighten all cylinder and cylinder head bolts and nuts.

Radiator

The radiator should be disconnected and a **stream of water forced through it** for several hours. **If scale exists,** cleaning can be done with a solution of 1 lb. ordinary washing soda and 5 gallons of water, allowing it to stand for an hour (see Index under "Cleaning radiator").

Carburetion

The carburetor should be removed and thoroughly **cleaned and tested for float leak.** Examine the gasoline line and see that all joints are tight.

Clutch and Transmissions

The clutch is one part that should receive attention, and here the repairman should resort to a large extent to the maker's instruction book, if it is still at hand. The cone clutches are usually faced with leather or fabric. The leather can be cleaned with a dry cloth and can then be painted very lightly and evenly with neatsfoot oil. The fabric facing can be given a squirt-gunful of kerosene. Be free with oil on all the clutch connections, and take especial care that the clutch thrust bearing is properly fed. Oil all connections from the clutch pedal lever to the clutch proper. Do not take up on the clutch spring unless you are certain that it is needed.

With wet-plate clutches the housing should be flushed with kerosene and the engine turned over a number of times. At the same time that the engine is turned over someone should push the clutch pedal in and out. This works the kerosene around the plates and tends to remove any gummy deposits. Then drain the housing, and repeat the operation. That finished, fill to the required level with oil. Usually 1 pint is used with ½ pint of kerosene.

With a dry-plate clutch the only thing that may be needed is a cleaning with kerosene, to remove gum. However, use a squirt gun in this case. No matter what the type of clutch, be free with oil at all the various connections.

Look for small oil holes which are clogged with dirt. Oil the clutch cross-shaft, the clutch collar, and all the parts which move.

Universal joint: Back of the clutch or transmission there may be a universal. Clean it thoroughly with kerosene, whether it is exposed or housed. Allow this to dry, and then pack with graphite. If you have no graphite, get some, or use a good grade of grease.

Next, proceed to the transmission. Drain the old lubricant, replace the drain plug, and remove the cover if there is one. Fill the case half-full of kerosene, and with a clean cloth mop it. This is a dirty job, but it will be worth your while, because the gear-set usually is neglected throughout the year and is required to give efficient service with oil that is perhaps a year old. With the case clean, add a grade of oil as recommended by the manufacturers, or see page 171. Do not put too much oil in the case. There usually is a level-plug, but if there is none, allow the level to be about up to the shaft of the highest or upper gears.

Running-Gear Parts

Wheels: First in order come the wheels. The car has been jacked up, and the next step is to see that the wheels run true on their bearings. There are many ways of doing this. A good way is to sight with one eye closed, while the wheel is revolving. Any irregularity in wheel movement is easily detected. However, sometimes the rim is bent a little and one will imagine the wheel is running untrue. Grip the wheel firmly with both hands and test for side play and up-and-down play by pushing and pulling on the wheel in all directions. A loose bearing usually causes this trouble, and in many cases the looseness can be overcome by tightening the nut slightly. Sometimes new bearings are needed, because they are worn excessively. This subject is more fully treated farther on, under discussion of the cause of "wobbly wheels," etc.

Align the wheels, as explained farther on.

The steering assembly, brakes, and other parts require the same sort of attention and will be taken up in their separate order farther on.

---

[1] See Index under "Testing a car before overhauling."

The rear axle should be cleaned and lubricated, and the drive pinion tested as to its relation with the drive gear on the differential. If noisy, it is probably loose and requires adjustment, as will be explained under "Adjustment of rear-axle gears."

Inspection after Repairing

See that the following are in proper condition:

1. Cylinder head tight.
2. All spark plugs firing, and tight.
3. Fan belt tight.
4. Fan bracket bolt and cotter pins tight.
5. Adjust carburetor properly.
6. Water connections tight and no leaks.
7. Hood fits properly.
8. Head lamps burn, properly focused; connections tight.
9. Front wheels adjusted, lubricated, and lined up.
10. Fenders and running board bolts and nuts tight.
11. Doors work properly.
12. Brakes adjusted.
13. Transmission bands adjusted (on Ford car).
14. Floor boards fit properly.
15. Grease in rear axle.
16. Grease in all cups.
17. Oil in engine.
18. Water in radiator.
19. Tires properly inflated.
20. Examine tool kit.
21. Curtains fit.
22. Horn in working condition.
23. Starting motor and generator is in working condition.
24. Battery fully charged.

A SUGGESTED METHOD OF OPERATING A REPAIR SHOP; ALSO A GUIDE FOR OVERHAULING A CAR

The following lay-out is one recommended by Mr. K. R. Wilson, Buffalo, N.Y. Note the flat rate system of charging for the work, as shown in column A, and the flat rate to pay the mechanic, as listed in column B. This method of "selling service," as it is termed, is meeting with success. The list below refers to the Ford, but can be worked out for other popular cars.

The idea involves dividing the shop into divisions for doing a certain class of work; to charge for the work done, as enumerated, and to pay the mechanics accordingly. Note that each job of work is numbered.

The following data give information covering the overhauling of the entire Ford car, so far as labor cost is concerned, and the average schedule of prices charged for doing the work as shown under column A. This is worked out on the piece-work basis, as shown in column B. Therefore, as you will note, the repair shops get practically 60 cents out of every dollar taken in, and the mechanic gets approximately 40 cents.

Engine Division

		A	B
1A.	Remove motor from car	$3.00	$1.10
1B.	Overhaul motor and transmission out of car	20.00	8.00
1C.	Replace motor in car	7.00	3.00
2.	Overhaul motor only—out of car	15.00	6.00
3.	Overhaul transmission only, or repair, replace magneto out of car	5.00	2.00
4.	Braze crank-case arms; support or repair leak in case by taking out the motor	12.00	5.00
5.	Install or refit one piston or one connecting rod	3.00	1.20
6.	Install or refit two or more pistons or connecting rods	5.00	2.00
8.	Tighten two or more connecting-rod bearings	4.00	1.50
9.	Replace transmission bands without starter	2.50	1.00
9A.	Replace transmission bands on cars equipped with starter	3.50	1.40
15.	Grind valves and clean carbon	3.00	1.10
20.	Replace cylinder-head gasket	1.00	.40
21.	Replace radiator or all three hose connections	.75	30
22.	Replace one hose connection only	.40	15
23.	Replace crank-shaft starting pin, or pulley	1.50	.50
24.	Tighten motor to frame	1.25	.45
25.	Clean crank case or install gasket under lower cover	.50	.15
26.	Replace carburetor or manifold; repair leak in manifold	.75	.25
27.	Install new butterfly spring	.75	.25
28.	Overhaul carburetor	1.50	.50
32.	Replace commutator pull-rod joint	.60	.20
33.	Replace or rebush fan-pulley assembly	.60	.20
34.	Adjust clutch fingers and transmission bands	.60	.20
35.	Adjust transmission bands only	$ .40	$ .15
40.	Tune and adjust motor, regular, only	1.25	.40
41.	Tune and adjust motor, special, only	1.75	.60
42.	Tune and adjust motor, regular, with operation No. 15	1.00	.40

Parts Brought in or Shipped in for Repairs

		A	B
57B.	Overhaul transmission, only	4.00	1.60
58B.	Rebore cylinder only	2.75	.50
59B.	Rebore cylinder only, including fitting of pistons	3.00	.60
60B.	Rebore and re-babbitt cylinder, including fitting pistons	5.00	1.00
61B.	Re-babbitt cylinder only	2.75	.40
62B.	Re-babbitt cylinder, fit crank shaft, and run in	6.00	2.00
63B.	Rebore and re-babbitt cylinder fitting of pistons, crank shaft, connecting rods, and running in	8.00	3.00
64B.	Rebore and re-babbitt cylinder, fit pistons, valves, push-rods, cam shaft, crank shaft, connecting rods, and run in	11.00	4.00
66B.	Rebore and fit pistons, valves, and push rods, and straighten and fit cam shaft	4.00	1.50
68.	Rebush three transmission drums	1.50	.50
69B.	Rebush transmission drums, each	.60	.20
70B.	Rebush and re-rivet three triple gear assemblies	.75	.25
77B.	Straighten cam shaft and fit bearings	1.25	.50

Rear System Division

Model "T" Chassis

		A	B
96.	Overhaul rear axle and re-bush springs and perches when necessary	7.00	2.75
96A.	Overhaul rear axle when car has shock absorbers, truss rods, or special hub brakes	8.00	3.25
98.	Repair or replace one rear radius rod	1.50	.60
99.	Replace rear spring; tie bolt or new leaf, including polishing and graphiting or leaves and lining up of body	3.00	1.20
102.	Pad rear spring to line up body or replace rear spring tie bolt only	2.00	.80
107A.	Install felt and steel washers—both sides	1.25	.50
108.	Install brake shoes and equalize emergency brakes—one shoe	.75	.30
108A.	Install brake shoes and equalize emergency brake—both shoes	1.00	.40
116.	Adjust pull rods or replace one	.75	.30

Model "TT" Chassis

		A	B
96T.	Overhaul rear axle and re-bush springs and perches where necessary	15.00	6.00
97T.	Repair or replace drive-shaft tube	7.00	2.80
98T.	Repair or replace one rear radius rod	3.00	1.20
99T.	Replace rear spring (one)	3.00	1.20
99TA.	Replace rear spring (both)	5.00	2.00
100T.	Remove front and rear springs, polish and graphite only	7.00	2.80
101T.	Replace spring perches—one	1.50	.60
101TA.	Replace spring perches—both	2.50	1.00
104T.	Install universal joint	5.50	2.20
106T.	Tighten rear radius rod	1.75	.70
107T.	Install felt and steel washers (one side)	1.25	.50
107TA.	Install felt and steel washers (both sides)	2.25	.90
108T.	Install brake shoes and equalize emergency brakes—one	1.25	.50

		A	B
108TA.	Install brake shoes and equalize emergency brakes—both	$2.25	$ .90
109T.	Tighten universal ball-cap bolts	.75	.30
110T.	Install or tighten rear-spring clips	1.50	.60
111T.	Tighten rear hub lock nut—one side	.50	.20
111TA.	Tighten rear hub lock nut—both sides	1.00	.40
112T.	Fit new hub keys—one side	1.00	.40
112TA.	Fit new hub keys—both sides	1.75	.70
113T.	Replace pull-rod supports—one	.50	.20
113TA.	Replace pull-rod supports—both	.75	.30
114T.	Replace or re-bush hub-brake cam—each side	2.50	1.00
115T.	Replace rear axle assembly	5.00	2.00
117T.	Straighten radius rod in car	1.50	.60
118T.	Install outer roller bearing—each	2.00	.80

Front System Division

167.	Overhaul front axle, including re-bushing of springs and perches when necessary, straightening and lining up and readjusting of wheels	5.00	2.00
167A.	Overhaul front axle when car has shock absorbers, special front radius rod, etc.	6.00	2.40
168.	Rebush spindle bodies and arms—each side	1.50	.60
169.	Replace or straighten front axle (no other repair)	2.50	1.00
171.	Rebush spindle arm—each	.75	.30
173.	Replace front spring tie bolt or new leaf, including polishing and graphiting of leaves	2.50	1.00
174.	Replace front spring or tie bolt only	1.50	.60
177.	Replace radius rod	.75	.30
179.	Replace spindle arm or body, and line up assembly	.75	.30
181.	Tighten all sockets and joints of front end	1.25	.50
182.	Replace or straighten spindle or steering-gear connecting rod	.60	.25

Chassis Division

Front End and Frame

228.	Replace front cross-member	6.50	2.50
230.	Straighten front cross-member without removing from car	2.50	1.00
232.	Replace side member of frame	20.00	8.00
242.	Repair hand-brake lever assembly, including replacing of pawl	1.00	.40
243.	Replace hand-brake lever quadrant without removing running-board shield	1.25	.50

Fenders and Running Boards

258.	Replace one fender or running board	1.00	.40
259.	Replace one fender or running board and straighten iron or bracket	1.25	.50
260.	Remove fender or running board and straighten	1.00	.40
261.	Replace running board shield—one	1.25	.50
264.	Replace rear fender iron	.75	.30
265.	Replace truss rod—one rod	.40	.15

Dash

276.	Replace dash	4.50	1.80
279.	Replace coil box, install new switch, or repair the box	.60	.25

Steering Gear

291.	Overhaul steering gear, including replacing of quadrant or gear case, and re-bushing of bracket	3.50	1.40
292.	Overhaul steering gear when motor is out	2.50	1.00
298.	Re-bush steering-gear bracket only	2.00	.80

Muffler

310.	Change long exhaust pipe	.75	.30
311.	Replace muffler	.60	.25
312.	Repair muffler	1.00	.40
313.	Repack exhaust pipe pack nut	.40	.15

Gas Tank and Line

324.	Clean sediment bulb and gasoline feed line, and clean carburetor	.75	.30

Radiator

350.	Repair radiator, solder one or two tubes, and replace one or both sides	3.00	.90
352.	Solder casting to lower or top tank when necessary to remove radiator	1.50	.50

Wheels

		A	B
365.	Change hub, rear or front	$1.00	$ .40
366.	Replace wheel and tire—each	.75	.30
367.	Adjust and dope front wheels	.60	.25
368.	Remove front wheels and replace bearing parts—one wheel	.75	.30
369.	Line up front wheels	.40	.15
370.	Oil and dope car (including material)	.75	.25

Body Division

412.	Install new lock—Touring or Runabout—each	1.00	.40
413.	Replace Town Car or Sedan door lock	1.50	.60
415.	Install new leather on door panel—one	.60	.25
418.	Re-upholster Touring body—using new materials	10.00	4.00
419.	Re-upholster Runabout body—using new materials	6.00	2.40
420	Change closed body	10.00	4.00
421.	Change Touring or Runabout body	6.00	2.40

For removing dents and other general repairs to bodies make contract price, according to amount of work necessary, using operation No. 2000.

Paint Division

Make contract price according to quality of job desired and condition of car when brought in. Consult paint foreman. Use operation No. "P."

Top and Windshield Division

455.	Overhaul Touring car on Torpedo Top, including re-covering, lining up, and fitting of curtains	7.50	3.00
456.	Replace top deck or side quarters—each or both	3.00	1.20
458.	Install and fit top	2.00	.80
464.	Replace back curtain	1.50	.60
465	Install celluloid lights in side curtains, per light	.60	.25
469.	Replace windshield and line up windshield frame	1.00	.40
470.	Replace upper windshield glass	1.00	.40
471.	Replace lower windshield glass	1.00	.40

Special

530.	Trouble calls (from any point within city limits)	1.50	.60
531.	Tow-in (from any point within city limits)	3.00	1.20
536.	Inspect and prepare new cars for delivery, including stamping identification number, pasting sticker on windshield, and installing or adjusting any minor parts when necessary, each	3.00	1.20
537.	Deliver car to purchaser's address	1.50	.60
538.	Wash and polish Touring car or Runabout	1.50	.60
539.	Wash and polish Touring Car or Runabout—wire wheels	2.00	.80
540.	Wash and polish Coupé or Sedan	2.00	.80
511.	Wash and polish Coupé or Sedan—wire wheels	2.50	1.00
545.	Clean car for placing on show floor, each	1.00	.40
533.	Teach car purchaser to drive, each lesson	2.00	.80

Commercial Bodies

605.	Install slip-on body	2.00	.80
B.	Install any new commercial body	CONTRACT	

Electrical Accessories

650.	Install Ford alarm	.50	.20
654.	Remove battery from car for recharging and install rental battery, including recharging of battery	.75	.25
655.	Remove rental battery from car and install customer's recharged battery	.25	.10
656.	Install electric horn	.50	.20
660.	Install electric tail light on dry cells and magneto	2.00	.80
661.	Install electric dash light	1.00	.40
662.	Install electric dome light	2.00	.80
663.	Install electric spot light	1.00	.40
664.	Install headlight lens	.40	.15
667.	Install standard Ford electric starter, complete	7.50	3.00

Wheels and Tires

702.	Change tires, each	.30	.15
703.	Install side-tire carrier	.75	.30

		A	B
704.	Install rear-tire carrier	$1.50	$ .60
705.	Install rear holder for wire wheels	1.50	.60
706.	Install 30″ x 3½″ Ford wheels or demountables in front only	3.00	1.10
707.	Install complete set of demountable rim wheels	4.00	1.60
708.	Install complete set of wire wheels, not including holder	5.00	2.00

Miscellaneous Accessories

		A	B
751.	Install Ford fan belt	.25	.10
752.	Install leather starter belt	.75	.30
753.	Install tool box	.50	.20
754.	Install front and rear license plates when brackets are in place	.25	.10
755.	Install front license brackets and license plates	.40	.15
756.	Install bumper (front)	1.00	.40
757.	Install rear bumper	1.50	.60
758.	Install set of three pedal pads	.25	.10
761.	Install cut-out	$1.50	$ .60
762.	Install exhaust deflector	.25	.10
763.	Install set of C. & M. oil retainers (model "T")	1.50	.60
764.	Install set of C. & M. oil retainers (model "TT")	1.50	.60
766.	Install Buffalo oil gauge	1.00	.40
767.	Install foot accelerator	.75	.30
768.	Install steering-gear lock	1.00	.40
769.	Install Yale lock on one door, catch on other door, Sedan or Coupé	2.00	.80
770.	Install Yale lock on both doors, Sedan or Coupé	2.50	1.00
771.	Install mirror	.25	.10
772.	Install rubber step mats (two)	.50	.20
773.	Install odometer	.50	.20
778.	Install carburetor control	.75	.30
777.	Install speedometer	2.50	1.00
1500.	Charge for work according to actual time spent on job.		
2000.	Special contract-price jobs.		

CLEANING ENGINE

We will now take up the usual and common work required on all engines. We will first start with cleaning and lubricating the engine and greasing a car. About every nine cars out of ten require cleaning and greasing.

Clean old oil from the engine as explained in the illustrations, Figs. 1, 2, and 3.

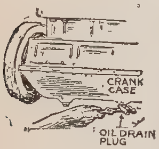

Fig. 1

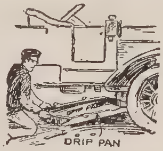

Fig. 2

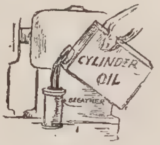

Fig. 3

Fig. 1. Remove the drain plug at bottom of oil pan and drain out the oil.

Fig. 2. Remove the oil pan and clean it thoroughly with gasoline; also clean the oil strainer.

Fig. 3. Replace the oil pan, and pour fresh cylinder oil into the engine.

It will be found that, when oil stops dripping, if the starting crank is turned a few times by hand a little more oil will flow. The best time to drain oil is after the engine has been run and heated and the oil is thinned.

When the oil has ceased to come from the crank case and the oil pan has been removed, cleaned, and replaced, the drain plug is replaced. It is not screwed tightly home, as it is soon to be removed again. Now **pour some light lubricating oil into the breather pipe** (Fig. 3) and run the engine again for about 15 seconds; then drain this out. It is better to flush out the parts with light cylinder oil in this manner, than to use kerosene, for reasons stated on page 167. Replace the drain plug and draw it tight, as well as the cap screws holding the oil pan to the crank case; also see that the gasket is replaced properly and does not leak. **Refill with good cylinder oil.** A gauge alongside of the engine is usually provided to show how much oil to place in the engine.

Note. If the engine is not in running condition, after replacing the oil pan as directed above, open the compression cocks on the cylinder and spin it rapidly by hand. The longer this is done the better, but it is an arduous task and if kept up for a minute or so it will be all that is necessary.

If the drain cock does not permit the oil to flow freely, when draining, run a wire through it to open it up.

The outside of the engine can be cleaned with gasoline. A brush dipped in gasoline to reach inaccessible places, and also an oil gun to shoot gasoline in inaccessible places, will suffice. The lighting of a match or any kind of flame, however, while cleaning should be prohibited.

A modern method for cleaning the engine is by means of a sprayer. In large shops compressed air is used quite extensively for all kinds of cleaning.

Home-Made Engine Cleaner

A gasoline or **kerosene spray,** acting under **air pressure,** will quickly remove dirt and grease from the engine or chassis. A device for forming this spray is shown in Fig. 4. It comprises a metal tank,

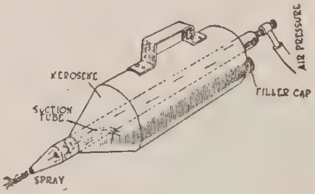

Fig. 4

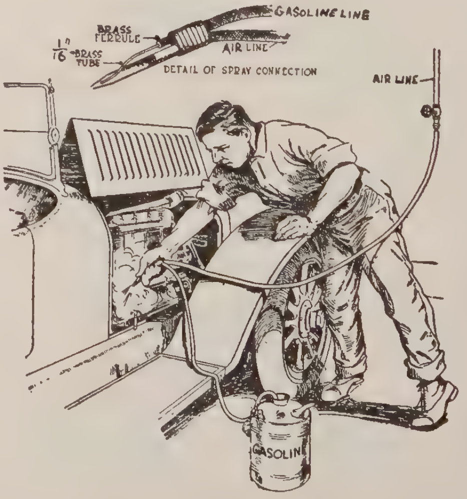

Fig. 5. Another engine cleaner. The parts may be readily cleaned by a **gasoline spray** or aspirator, actuated from the air-pressure line. This spray comprises a short length of copper tubing, about ¼″ in diameter, having a piece of 1/16″ brass tubing soldered to its side. The air line is connected to the larger tube, and the smaller tube is connected to the gasoline supply. When the air is turned on, a suction is created in the smaller tube, drawing gasoline from the can, and forcing it onto the part to be cleaned. (*Motor World.*)

holding the cleaning solution, and an aspirator for forming the spray. This aspirator is a copper pipe, passing through the center of the tank, one end being connected to the air line and the other being drawn down into a nozzle. A small copper tube connects this pipe, so that the solution is drawn from the tank and forced into a spray by the passing air. A foot pump can be used to inject air if pressure is not available.

Cleaning Engine Exhaust System

This cleaning should include the **exhaust manifold, pipe, and muffler.** The latter should be taken apart and the **parts soaked in kerosene** over night. The pipe and manifold may be cleaned by drawing through a pack of kerosene-soaked waste attached to a long wire.

Keeping Oil off the Radiator Hose

To prevent oil from rotting the inlet hose from the radiator to the engine, give the hose a **coat of shellac** and then a **couple of layers of tape** and shellac over that. This will assist in preventing leaks. The shellac keeps the oil away from the rubber and makes a good joint.

Cleaning Parts of a Car

While on the subject of cleaning an engine, we give below a few **home-made devices** which can easily be constructed for cleaning other parts of the car.

In large shops vats are provided in which engines are dipped into a potash cleaning solution, by means of a chain hoist.

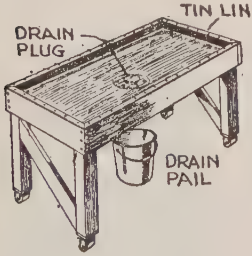

Fig. 6

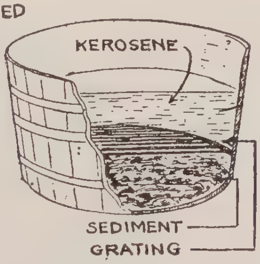

Fig. 7

Fig. 6. **A washing table for parts.** This is large enough to permit any part of the car to be cleaned. But, more important, it may be moved to the job. A wooden basin, or sink, 5 ft. long, 2 ft. wide, and 6 in. deep is mounted on legs, and lined with tin. A drain plug is placed in the center, permitting the dirty cleaning solution to be drawn off into a pail hanging beneath the stand. Gasoline may be used for cleaning parts, but kerosene is cheaper and safer.

Fig. 7. **Kerosene tub:** A large tube of kerosene will be found convenient for washing parts. The tub should have a metal grating 4″ or 5″ from the bottom, so that whatever sediment settles is not stirred up each time a part is washed. The presence of the grating insures clean liquid for a considerable length of time, for just as soon as a part is washed the grit and dirt settles below the grating, leaving the liquid clean.

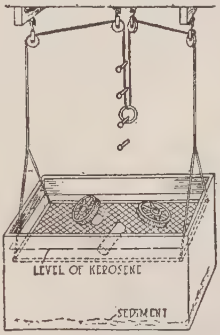

Fig. 8

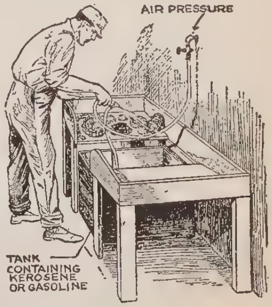

AIR PRESSURE
TANK CONTAINING KEROSENE OR GASOLINE

Fig. 9

Fig. 8. **Combination cleaning tub and drainboard** for removing the dirt from parts. It is usual to make the tub and drainboard separate, but by installing a screen in the tank whose height may be readily raised or lowered, all the advantages of a drainboard are obtained, together with considerable economy of space and some added conveniences.

Fig. 9. **Gasoline or kerosene, forced by air pressure on to the parts to be cleaned,** quickly removes all dirt and grease. A system for doing this is illustrated. The cleaning liquid is held in a metal tank placed beneath the inclined cleaning troughs in the manner shown. An injector type nozzle, connected to the air line and to the liquid, permits the liquid to be drawn from the tank and forced on to the part to be cleaned after which it drains back to the tank, to be used over and over again. During periods when the cleaning outfit is not in use the dirt settles to the bottom and may be scraped out. (*Motor Age.*)

For cleaning small brass aluminum, and metal parts, see Index.

GREASING A CAR[1]

One of the first things to do when starting to grease a car is to screw down on the grease cups, which forces out all grease therein. The cap is then unscrewed, the grease cup refilled, and the cap placed back—but do not cross-thread the caps or they will work loose and be lost.

The modern method of greasing a car is with the pressure system, such as the Alemite (page 174). If the car is not equipped with this system, a good grease gun should be provided. A type of grease gun which can be recommended is shown on page 663 (Fig. 9).

The Townsend grease gun is an excellent device for greasing such places as the shaft of a cone-type clutch (through a plug hole), the universal joint and other places on a car where a grease cup is not provided, but where grease plug holes are provided. You can grease the universal and the other such parts of the car in a few minutes' time, without removing the nuts or bolts.

Lubrication of Springs

A detail which, if attended to, conduces much to the easy running of a car, is the **oiling of those parts of the springs upon which the leaves move.** It is becoming the practice to make provision for proper lubrication at this point. This is easily done by drilling a hole through each leaf; otherwise it is not easy, when the weight of the car is on them, to introduce any oil into the interstices. Very frequently, however, rust is seen along the joints, show-

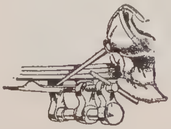

Fig. 10

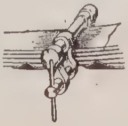

Fig. 11

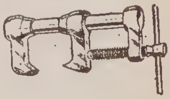

Fig. 12

Fig. 10. Lubricating the surface of the separated spring blades.

Fig. 11. The same tool used as a temporary cramp to secure a broken spring.

---

[1] See Index for "Greasing rack."

ing that water can get in, at any rate, and oil will work its way in, too, if applied at the edges, but it will probably be found that this can be more easily done if the blades are separated by means of the special appliance illustrated herewith (Figs. 10, 11, 12).

Rust in the springs affects their proper movement, and causes mysterious squeaks as well. The joints of the links connecting the upper and lower portions of the springs at each end should also have a little oil applied occasionally.

If a car is overloaded much beyond its normal capacity, extra work will be thrown on the springs which may give rise to breakage when the car is being driven over bad roads. An **extra leaf added** to the springs is advisable **for overloads.** Considerable advantage to the life of the springs is obtained by having shock absorbers. See Index under "Spring repairs."

Other parts of a car to lubricate and grease are shown on pages 172 to 174.

Spring Covers[1]

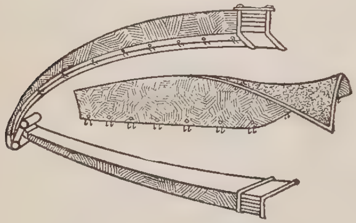

Fig. 13. **A spring cover and lubricator** which laces over the spring, preventing any danger of moisture or dirt getting between the leaves. The cover is lined with a felt wicking which is saturated with oil before the cover is put on, and will hold enough oil to lubricate the springs for 10,000 miles. The smooth gliding effect is obtained which is so noticeable in a new car with perfectly lubricated springs. (Woodworth Specialties Co., Binghampton, N.Y.)

Tightening Springs

When lubricating the springs, it is a timely opportunity for observing defects of loose nuts or broken leaves in the springs.

The nuts belonging to the **clips** which hold the spring on to the axle often display a tendency to work loose, and if this is not remedied the axle will be thrown out of line, with more or less serious consequences to tires and driving gear generally; or, if the front axle is in question, the steering may be affected, thus causing "wobbly wheels."

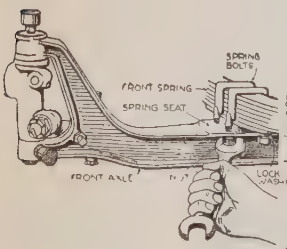

Fig. 14

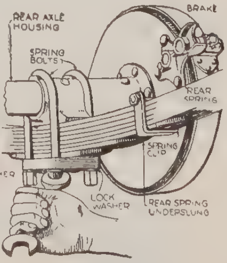

Fig. 15

The springs, like the engine bearings, have to take a sort of set before they are permanently tight. Hence it is desirable to tighten up the spring clips at the end of the first one hundred miles of running and then to inspect them occasionally until they remain tight.

A Spring Lubricant

A spring lubricant, known as "Spring-eez" is recommended. It is applied to the sides of the springs with a brush and chemically accomplishes that which by mechanical or other means, is either an arduous or impossible task, in that it **penetrates** between the leaves without the necessity of spreading; it disintegrates and eliminates rust; it deposits a lubricant, and causes the springs to perform their function properly, without squeaking about it. In the same manner its application makes the removal of "rust-frozen" nuts, bolts, screws, spark plugs, valve caps, etc., a simple matter.

Spring Shackles

Many of the makers now are putting on **adjustable** spring shackles, so that wear can easily be taken up. This is especially desirable in cars using a Hotchkiss drive, where a great deal of stress and wear is put on the shackles of the rear spring at its rear end and on the spring bolt attaching the front of the rear spring to the bracket on the frame.

With the Hotchkiss drive the rear spring supports have to take not only much of the weight of the car, but also the driving and braking strains. Hence, the better the design of the shackles and bolts at this point, the longer the life of the parts.

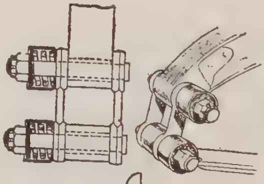

Fig. 16

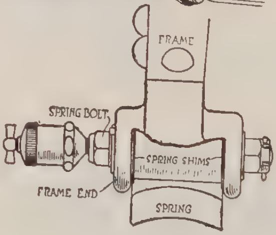

Fig. 18

Fig. 17. The **adjustable shackle bolts** used on the Hudson and Essex.

Fig. 18. Method of **taking up side play** in spring links with shims.

Among the cars using adjustable spring shackles are Jordan, Hudson, Cole, and Locomobile; the latter, by the way, has used this for some time. The Jordan shackle is shown in Fig. 16.

This shackle is of the type which automatically takes up the wear. The Hudson and Essex shackle (Fig. 17) is made so that wear can be taken up by a slight turning of the nut and locking it with a cotter pin.

REMOVING CARBON FROM CYLINDER, COMBUSTION CHAMBER AND PISTONS

Before taking up this subject, refer to pages 169, 170, and read the explanation of the **cause of carbon** and the **relation of carbon to lubricating oils.**

This is a job usually attended to before valves are re-ground. The frequency with which the job should be done depends upon the service, and quality and quantity of lubricating oil used.

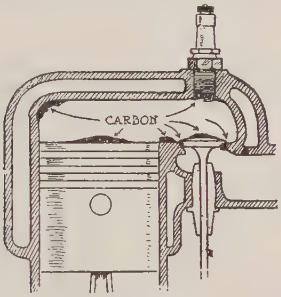

Fig. 19. Carbon usually accumulates at the points shown.

Methods of Removing Carbon

There are five methods employed in removing carbon. The most effective is that one which removes the carbon most completely—probably by hand. But to remove a piston is sometimes an expensive job, and other means are resorted to, as will be mentioned.

1. One plan is to **remove the piston** as shown in Fig. 20.
2. To **remove cylinder head** as shown in Fig. 21.
3. To **scrape with special scrapers,** as shown in Fig. 22.
4. To **chemically dissolve** the carbon.
5. To **clean by the oxygen decarbonizing** process.

This last-mentioned method is the one most generally used, and is conceded to be one of the best.

Note. **In using oxygen for carbon removal,** the piston should be placed at the extreme top of the cylinder, as the intense heat tends to roughen the cylinder walls. Both inlet and exhaust valves should be closed to prevent pitting of valve seats. The flames should not be directed so as to strike the threads of the spark-plug hole. See that the water system is kept full of water. The torch should be moved constantly, to cover as large an area as possible.

Questions Sometimes Asked Relative to Oxygen Decarbonizing Outfits

Q. **Where can oxy-decarbonizing outfits be secured?**

A. The Prest-O-Lite Co., Indianapolis, Ind., makes a good serviceable outfit, as does also the Imperial Brass Co., Chicago.

Q. **Can the Prest-O-Lite tank be used for this purpose?**

A. The oxygen tank of this company's welding outfit can be used, but lighting gas cannot.

Scraping Method

To scrape carbon fron a piston in the manner shown in Fig. 20, it is necessary to remove the piston from the cylinder.

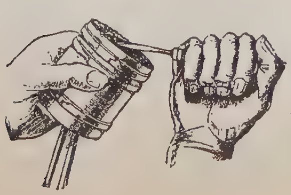

Fig. 20

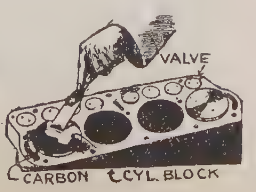

Fig. 21

Another method (Fig. 21) is to **remove the cylinder head, if it is a detachable type,** as on the Ford. Access can then be had to the tops of the pistons and to the walls of the combustion chamber in the head.

Special Scraping Tools

Scraping tools of special design (Fig. 22) are necessary for scraping the inside of a cylinder, a combustion chamber, and the head of a piston when the cylinder head is not detachable and where the pistons are not removed. The work can be done through the valve cap or plug holes.

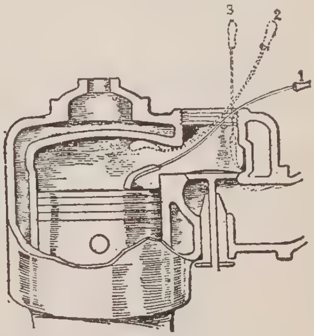

Fig. 22

Tool No. 1 is for scraping the piston head; **No. 2,** for the cylinder head, as shown by dotted lines, and **No. 3** is for the cavities over and around the valves and such other surfaces as have considerable curvature.

Scraper No. 1 should be used first, and worked back and forth with considerable pressure across the piston head until the scratching sensation disappears and the tool seems to glide over the surface. Care should be taken not to gouge grooves in the metal.

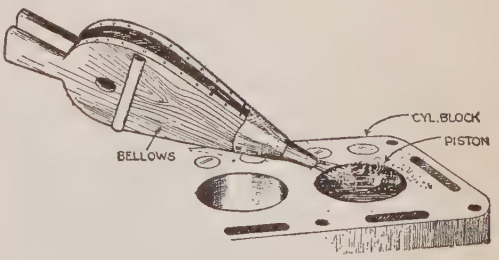

Fig. 23

After scraping, blow out the free carbon, using a hand bellows as shown in Fig. 23, if compressed air is not available. Continue scraping until the blast of air does not blow out any more carbon dust. Be sure to scrape the entire surface, for if jagged patches are left, they will become incandescent from the heat of explosion and cause pre-ignition.

It is important that none of the carbon gets into the cylinders, valves, or other parts of the engine. Therefore be sure that the valve is well seated in the cylinder you are cleaning, and be careful to blow out all carbon deposit thoroughly with an air blast.

After as much carbon as possible has been taken from the cylinders, a half-tumblerful of kerosene poured into each cylinder with the air blast applied, will often give good results. Another half-tumblerful of kerosene should be poured into the cylinders, and the engine should be turned over a few times.

The oil reservoir should then be drained and cleaned thoroughly with a clean cloth previously soaked in gasoline, and fresh oil should be put into the oil pan (after cleaning and using kerosene), as kerosene will thin the oil and cause it to lose its lubricating qualities and is liable to cause the bearings to score or cut. If any of the kerosene is left in the engine combustion chamber, it will eventually work into the crank case.

It is customary to grind the valves after having scraped carbon, and after grinding, to adjust valve clearance.

Oxygen Decarbonizing Method

The oxygen decarbonizing method is a process of cleaning the carbon from inside the cylinder and head of the piston, without removing the cylinder head, by means of an oxygen flame, as shown in Fig. 24.

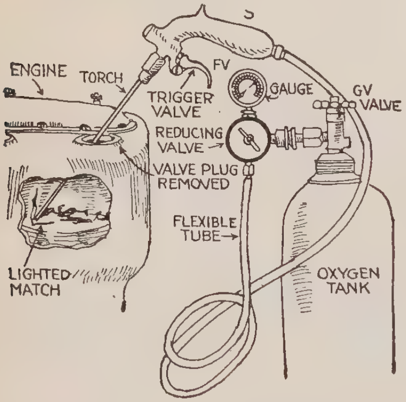

Fig. 24. Oxygen decarbonizing outfit.

The outfit (see also, page 751) consists of an oxygen tank, at an initial pressure of about 1,800 lbs. per square inch, fitted with an adjustable reducing valve that brings the pressure down to 10 to 20 pounds. The oxygen is applied through a torch or copper tube about 18″ long, with a rather fine, flexible delivery jet, communicating with the reducing valve through a flexible tube and fitted with a trigger valve (FV). The delivery jet of the torch when inserted through a valve-plug orifice, can be manipulated to reach all parts of the combustion space, if it is slightly bent and cleverly turned and twisted by the operator.

To Operate Oxygen Decarbonizer

1. **Turn off the gasoline at the tank,** and let the engine run until it uses up all the gasoline in the carburetor. If the pan is greasy, remove it, to avoid the possibility of a fire.
2. **Remove the hood and cover the air intake of the carburetor** with sheet asbestos, so that no spark can drop into it.
3. **Remove the large plugs into which the spark plugs are** screwed, and clean the cylinders, one at a time, being sure **that the piston is at its extreme height in each cylinder** and that both intake and exhaust valves are closed before starting to clean it.
4. **Start on the valve chamber,** first putting a few drops of kerosene oil or alcohol into it; ignite with a match or wax taper; insert tip of torch and direct a jet of oxygen against the carbonized surface. The jet of oxygen almost instantly consumes the carbon where it strikes, so move the tip around until the incandescence dies out, when it will be necessary to inject more kerosene or alcohol, and to repeat the operation until the chamber is thoroughly cleaned. When the burning starts the carbon will burn with a whitish flame and a shower of sparks will come out of the spark-plug hole.
5. **Clean the piston head.** When it is impossible to see portions being cleaned, continue the operation until the series of sparks stop blowing out, as sparks will cease as soon as the carbon is entirely consumed.

To clean the top and sides of the cylinder combustion chamber it is necessary to bend the flexible copper tip of the torch so as to direct the jet of oxygen upwards. To inject the kerosene or alcohol, use an oil gun or ordinary oil can with a curved nozzle.

Alcohol leaves the surfaces much lighter than kerosene, but when the oxygen strikes it there is quite a sharp report. **Kerosene** is rather more quiet than alcohol.

Some operators simply **drop in a lighted match** and then turn the jet upon it, but this method requires much more frequent igniting than when kerosene or alcohol is used.

It is important that **kerosene should not be mixed with the lubricating oil** as it will lose its lubricating qualities. The crank case should be wiped out before putting in fresh oil. When using the method described above, the flame must be handled cautiously, otherwise the parts inside of the cylinder combustion chamber will be overheated.

Chemical Method for Removing Carbon[1]

There are **several preparations** on the market for this purpose. It comes in powder form which, the makers claim, if mixed with the gasoline, will prevent carbon formation.

Another agent is known as a **liquid decarbonizer.** This chemical, the manufacturers claim, will dissolve the carbon accumulation in the combustion chamber and on the piston, and will also loosen the rings if they are gummed and stuck to one side of the piston.

When giving the engine the first dose, and where carbon is well accumulated, start the engine and run until warm; then shut down the engine and pour the decarbonizer into each cylinder, say about ⅛ pint in each, where it can act on the piston and rings. Also pour it over and around the valves. Leave the engine over night, or for at least three hours. After this time, start the engine up, and the carbon is supposed to pass off through the exhaust.

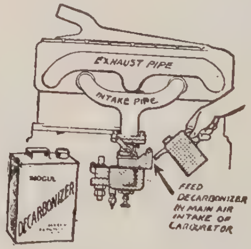

Fig. 25

After once cleaning in this manner, about once every two weeks feed the decarbonizer to the engine by placing about ⅛ pint in an ordinary oil can and let it pass in the air intake of the carburetor (see illustration), while the engine is running. The decarbonizer will suck into the engine, and will be sufficient to keep rings and valves clear and to keep carbon from forming.

Note. **It is not advisable to use liquid decarbonizing mixtures which contain kerosene,** as the kerosene tends to work its way into the oil pan, thus thinning the lubricating oil. The best plan to remove carbon is by the oxygen decarbonizing process, providing it is done properly and providing the parts inside of the cylinder combustion chamber are not overheated.

---

[1] **A carbon preventive** called "Woodworth Carbon-Clear," manufactured by Woodworth Manufacturing Corp'n., Niagara Falls, N.Y., is mixed with the gasoline, one spoonful to five gallons. It is claimed that this will prevent the formation of carbon.

WHY AN ENGINE LOSES POWER

There are four main causes for this. When an engine fails to develop its usual power the cause is frequently one of the following:

(1) loss of compression;
(2) deranged valve action;
(3) faulty ignition;
(4) improper carburetion mixture.

1. **Loss of compression** means more than simply failure to compress the charge to a specific extent; it is a common name for a condition which not only means low initial compression and consequent weak explosion, but also that a smaller charge is taken into the cylinder, that a portion of the diminished charge escapes during the compression stroke without doing even a small amount of work, and that a part of the explosive force (the only source of power that an engine has) escapes through unauthorized channels —altogether a threefold loss.

Faulty compression comes from a variety of causes: Cylinders may be worn, scored or cracked; pistons may sometimes crack, or rings become gummed, worn or broken; valves need grinding when pitted or warped; their stems are sometimes bent so that the valves cannot seat perfectly, or the stems and guides considerably worn. Valve stems become gummed and the springs sometimes weaken, so that a portion of the charge escapes before the valve shuts it in.

Leaks occur around spark plugs and valve caps, but are readily found by applying a little oil, while engine is running and noting if it bubbles.

2. **Valve action** is disturbed by wear. Usually this results from the valve tappets not having been given sufficient opening, or having been set to give too much opening, or from the valves not being properly timed. Valves that do not seat come of course under the subject of loss of compression.

3. **Faulty ignition** is occasioned by insufficient or unsuitable sparks, or by a spark at the wrong time, which may result from imperfect setting of the spark, from a weak battery, or from demagnetization or some other trouble peculiar to the magneto.

The ignition timer should come under suspicion and should be carefully examined for defects which lead to irregular action. Lack of synchronism means loss of power, and it is plain that missed explosions are fatal to efficiency. It is not always easy to detect missing or weak explosions, and no doubt they pass unnoticed many times. If vibrator coils are used they probably need adjusting, or their contacts need dressing.

4. See page 117 for suggestions regarding the **carburetion mixture.**

Other Causes of Loss of Power

Air leaks around the inlet valve stems make it impossible for even the best carburetor and the most careful regulation to supply a right mixture, as the leakage fluctuates and is greatest at the very time when the volume of gas used is the smallest, because there is stronger suction when the throttle is nearly closed. This completely upsets the right proportions at all throttle openings except the one adjusted. This is true also of air leaks around the carburetor or intake connections.

Weak valve springs will also cause loss of power, as explained on page 776.

The muffler may have become clogged by soot and charred oil, thus preventing a free exhaust and consequently a full charge, besides causing back pressure and undue heating.

Gasoline passages may have become clogged.

The oiling system may fail to supply the needed amount of oil, or the oil used may not be of the former good quality.

Carbon may have accumulated in the cylinders; the air valve in the carburetor may be working badly because of dirt or wear.

Dragging brakes will consume a lot of power.

Sometimes the addition of a top, etc., is not duly allowed for, though every driver must have observed what a difference the weight of one passenger makes.

In conclusion, it is suggested that **if a car does not run with its former power,** the cause is probably not the result of any one thing, but of a number, each contributing in proportion to its importance.

MEANING OF COMPRESSION, EXPANSION, AND MEAN EFFECTIVE PRESSURE

Compression pressure is the pressure of the gas after being drawn into the cylinder and **compressed in the combustion chamber** by the up compression stroke of the piston. This varies with the quantity of gas drawn into the cylinder, the speed of the piston, the size of the combustion chamber, and the condition of the valves and rings, and the tightness of the parts. See also, page 116.

The expansion pressure (often termed explosion pressure) would be the maximum or the **greatest pressure immediately following the combustion** or burning of the gases. This pressure is many times greater than compression pressure. This expansion pressure (gas expands when ignited and heated) continues, but diminishes throughout the entire power stroke.

The explosion pressure runs from three to four times that of compression pressure. If the compression drops one-half, then the explosion pressure drops, but the loss is in more than direct proportion. It would seem that if the explosion pressure was one-half, the power developed would be one-half. But one must realize that it takes a certain amount of power merely to keep the engine moving, that is, to overcome the inertia and friction of the moving parts. This amount is constant. All power developed beyond this amount is available to run the car. If the compression and power drop to one-half, just as much power is required to run the engine, so that the available power drops in much greater degree.

Mean effective pressure (M.E.P.): During the entire cycle of a gas engine, the cylinder is subjected to many variations of pressure. We have seen that during the power stroke, the pressure decreases as the piston proceeds along its stroke. All of this pressure causes the engine to deliver power. In the same way, during compression stroke the pressure gradually **increases** as the piston travels upward. All of this pressure hinders the engine from delivering power, and should therefore be considered as a negative power.

Now, if we average up all the pressures during a cycle and subtract those which hinder the engine from those which help it (the power stroke is the only stroke which helps), we shall arrive at the M.E.P., that is, the **average or mean pressure which is effective in producing power.**

The advantages of high compression are: greater engine efficiency at high speeds and greater economy in fuel.

The disadvantages are lack of flexibility at low speeds, greater strain on bearings, and greater tendency to burn valves and plugs, as well as a tendency to over-heat.

A greater compression can be carried in an over-head-valve engine, regardless of stroke or bore; therefore larger valve openings are permissible.

Naturally this increases the heat, but as the valves are in the head, the discharge is rapid. The explosion pressure is generated directly above the piston center, which receives no side thrusts.

The spark plugs in an "L"-head type are usually over the inlet valves where the inrushing gas keeps them cool and where the fire is most certain—since they are in the most perfectly scavenged part of the cylinder, i.e., the direct path of the fresh charge.

In the overhead type, on the contrary, they are exposed to the full heat of the explosion. In a high-compression engine, therefore, only well-made plugs should be used. One method of protection is to surround the plug with a water jacket as much as possible.

Abnormal compression is prone to cause over-heating. Results however can be obtained with high-compression ratio which cannot be approached with average compression.

If a high compression is desired in an "L" or "T"-head engine, in order to take advantage of the high compression, the cylinders must be designed with a sufficiently long stroke, to enable the desired ratio to be obtained without raising the piston appreciably above the floor of the valve pockets, as at (L) in the illustration (Fig. 26).

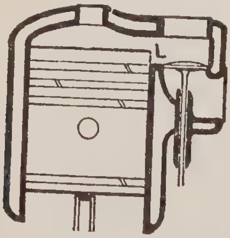

Fig. 26. This illustration shows the type of piston referred to. It will be obvious that the explosion will develop in the valve pocket (L), and that part of its expansion or pressure value is lost when the piston projects above the top of the cylinder to any great extent.

Average Compression of Engines

The usual compression pressure for touring-car engines is about 55 to 75 lbs. on four and six-cylinder engines, and 60 to 85 lbs. on eight and twelve-cylinder engines, per square inch, without the additional effects. This, when running at average road speeds, probably increases. The compression on a Hudson six-cylinder engine is approximately 70 to 75 lbs. The tendency is to decrease compression as the diameter of bore increases.

A six, eight, or twelve-cylinder engine, having a much more continuous torque than a single-cylinder engine, will obviously stand a higher ratio of compression.

The maximum compression is determined when the throttle is wide open and all pet cocks are closed. For instance, the compression in the cylinder of a Packard should show 75 to 85 lbs. pressure at cranking speed with pet cocks closed and a wide-open throttle.

Compression at the time of the explosion, at the instant when the piston is at top of stroke, is very hard to determine. Factors which would have to be taken into consideration are: character of fuel, degree of mixture, and speed of engine. In the average engine, pressure at explosion would probably be about 250 lbs. See also, page 116.

At higher speeds of the engine a slight compression leak is not so noticeable as at low-engine speed. If it is desirable to have the engine throttle down to a very slow speed, then be sure that there are no compression leaks in any part of the engine, including rings, as one leaky cylinder will affect the others.

The compression of airplane engines is somewhat greater than on automobile engines. As a rule the explosion pressure is four times the absolute compression pressure based on the assumption that the cylinder is filled with the charge to atmospheric pressure at the beginning of the compression stroke.

The compression on a motorcycle engine, as a general rule, is also rather high where speed is desired, but on the U. S. A. motorcycle engine, used during the war, the compression was slightly lower than the average. This somewhat depresses the power curve, but the engine will run better on a wide-open throttle at lower speed, enabling the machine to "hang-on" with great tenacity and to pull with power through sand, mud, etc.

An open throttle fills the cylinder with gas, which of course increases the compression pressure. Therefore an engine would pound or knock at low speeds with a wide-open throttle, as when climbing a hill slowly.

Increasing Compression in an Engine

This means that by **reducing the space in the combustion chamber** from the head of the piston to the inside top of the compression chamber of the cylinder—when the piston is in its uppermost position—the gas would be compressed tighter, therefore there is more explosive or expansion force on the piston when combustion takes place.

High compression gives more power, but it is harder on the bearings and makes the engine more liable to knock and produce heating, and is less flexible at low speeds.

It is true that different compressions affect the power of explosions, and that an uneven compression ratio in different cylinders will consequently cause an engine to jerk. If the compression is excessively high, it can keep the spark from jumping the gap in the spark plug, unless the latter is closed up slightly.

Decreasing compression. See Index.

TESTING THE ENGINE COMPRESSION[1]

The compression is much easier to test than the carburetor or ignition apparatus.

To test the compression of the engine one has but to crank it slowly (with switch off) and note the comparative resistance of each cylinder and the resistance of all in general. If the resistance of the compression of one or more cylinders is less than in the others, then this particular cylinder is leaking compression through one of the many causes previously enumerated. If the resistance of all of the cylinders is below the regular standard, then, perhaps, all are leaking compression.

MOVABLE HAND
MAXIMUM HAND WHICH IS LEFT IN STATIONARY POSITION BY MOVEMENT OF LONG HAND
FITS IN SPARK PLUG HOLE

Fig. 27

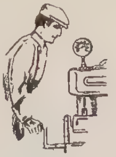

Fig. 27A

Fig. 27. A special gauge designed for testing the comparative pressure of each cylinder. It is attached to the engine cylinder by removing a spark plug and fitting the gauge, called **a compressometer**, instead. The engine should be cranked two or three times with the hand crank. (Fig. 27A).

Compression of the cylinder to which the compressometer is attached is indicated on the instrument as the maximum hand (short one) remains at the highest point so indicated. Note the two hands: the short one remains fixed at the highest point reached during the test. This test does not give the maximum pressure, as the maximum pressure is obtained only when the throttle is wide open and the cylinder is filled with gas. With this test the throttle is not opened, the idea being to see if there is a good spring resistance offered to the movement when the engine is quickly cranked.

As you test each cylinder separately, enter the reading on a slip of paper, and then compare the results. Those cylinders showing low compression are leaking, and the cause should be found and remedied.

A cylinder with good compression cranks with a springy resistance. If it cranks very freely, it may be considered an evidence of poor compression, and the cylinders should be tested for compression one at a time, as follows:

The compression relief cocks (in a six-cylinder) on five of the cylinders, say Nos. 2, 3, 4, 5, and 6, should be opened and the compression of No. 1 noted when turning the engine over. Then close relief cock No. 2, open cock No. 1, and crank again to test No. 2, and so on until the six cylinders are tested.

A leak through one or more valve seats is generally accompanied by misfiring and loss of power. A slight leak through all of the valves is accompanied by loss of power, but often without misfiring.

Grinding the valves will probably remedy this, if the leak is not due to leaky piston rings.

Leaky piston rings are often the cause of compression leaks and may be due to the rings being gummed in the grooves. A little kerosene poured into the top of the cylinder, and then cranking the engine several times may loosen the rings, as explained under "Piston rings."

Poor Compression; Effect and Cause

The subject of compression is one of the most important subjects connected with a gasoline engine. If an engine lacks power, nine times out of ten it will be traced to poor compression.

The compression space in an engine is the space between the end of the piston and the top of the inside of the cylinder at (L), Fig. 26. In drawing in a charge of gas into the cylinder, the piston travels downward, but after drawing in the gas through the intake valve, the valve closes and the piston on its up-stroke pushes the gas up into the head of the cylinder and compresses it (see page 32). If the valve leaks, or if there is a leak otherwise, then the gas will not be compressed to as high a pressure as if there was no leak.

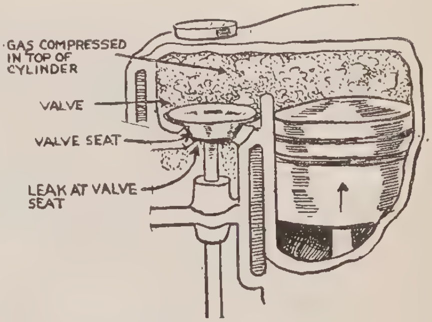

Fig. 28. If compression is poor, the probable cause is that the valves are leaking at the seat.

These joints must be tight at all times. For instance, if the cylinder-head gaskets or the small gasket in the spark plug, or the spark plug itself is not tight, gas will leak out and cause loss of compression and lack of power.

When the gas is compressed to the highest point, then the spark ignites the compressed gas and forces the piston down with great force. If the compression pressure is **low the force will be less.** If the compression power is **high the force will be greater.**

Leaks will affect the operation of the engine, by weakening the compression, diluting the fresh charge by the air that enters, by the escape of the pressure during the power stroke, and by the igniting of the mixture in the inlet pipe. Therefore **the power of an engine depends on good compression,** and good compression must be maintained.

A frequent cause of leakage is pitted valves (see page 769), which by not closing tightly, permit the pressure to escape. If the valves are in good condition, and the spark plugs and other openings in the cylinder head are tight, leaky piston rings may be causing the loss and should be examined.

The spark plug and the relief cock may be made tight by the use of copper-asbestos washers, or by a copper washer, that metal being soft enough to be forced into the rough places.

Leaky valves may be ground in as described under "Valve grinding."

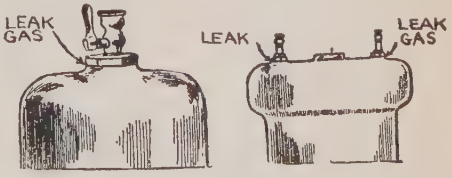

Fig. 29. Other causes of leaks may be in the spark plug, gasket, or piston rings.

There are many places where compression leaks may be looked for: through the valves not being set right, or through the **valves leaking** at the seat, through the **valve caps** not being screwed down tight, through the **spark plugs, relief cocks** and **piston rings, cylinder-head gaskets, etc.** Leaks have also been known to occur through a small sand hole in the end of the piston.

Compression leaks in valve caps, spark plugs, and priming cups (relief cocks or pet cocks) are usually due to a failure to draw them down tight in the threads.

A leak in the gasket connecting the intake pipe is a very common cause for missing at low speeds, and is best detected by allowing the engine to run at the missing speed. Take a squirt-can full of gasoline and squirt around all the intake pipe joints. If you detect any difference whatsoever in the running of the engine, there is a leak. The remedy is obvious.

Cylinder-head gaskets, if not properly tightened and fitted, will permit a compression leak, and will also admit water to the cylinder on those cylinders fitted with detachable heads.

Asbestos gaskets, when replaced, are first coated with shellac or soaked in linseed oil (not used on automobile engines). Copper gaskets are soft and give; therefore they do not require this treatment. See Index under "Gaskets."

Where cylinder-head gaskets are replaced without thoroughly cleaning them, as well as the surfaces on which they are fitted, or if they are not drawn down tight after the engine is warmed up (second tightening), a compression leak is likely to occur.

When cylinders are **not cast en-bloc,** care must be taken that gaskets are of exactly the same thickness, otherwise the cylinder with the thickest gasket will be raised higher than the others and will consequently have larger combustion space. As a result it will have lower compression. This in turn disturbs the running balance.

In two-cycle engines conditions would be even worse, for here we not only increase the combustion space and enlarge the lower space (which in two-cycle engines is an important feature), but we also change the port timing, as a little thought will prove.

If the cylinder wall, the cylinder head, or the piston head is cracked, compression will be affected.

A crack in the cylinder wall will admit water to the cylinder from the water jacket. If a hole is suspected, a test can be made on the cylinder to see if there is a leak by putting a foot-pump connection to the water jacket of the cylinder. Fill the water jacket with water and apply the air pressure, and see if bubbles of water ooze through, inside of the cylinder. If this is the case, then these holes must be made tight.

If water is found in the crank case, it results from one of three general causes: (1) water in the gasoline or lubricating oil; (2) loose cylinder-head gasket; (3) a cracked cylinder, or a sand hole in the cylinder from the water jacket. It is possible, sometimes, to stop a cylinder sand hole leak with salammoniac. See Index for this subject.

To detect a crack in the piston head, the latter must first be scraped clean of the carbon deposit and examined carefully.

Sometimes there will be a discharge back into the carburetor; this indicates a leaky intake valve, providing it is not first found to be the result of faulty carburetor adjustment, due to lack of sufficient gasoline, or to too much air, termed a "lean mixture."

Sometimes a discharge in the muffler indicates a leaky exhaust valve, but not always. It will require an experienced ear to detect the difference between an unfired charge being exploded in the muffler, due to carburetor adjustment and that of a leaky exhaust valve

Piston and Rings Cause of Leaks

When the piston rings or cylinders have been cut and scratched by long use, or running without oil, the compression leak will be into the crank case, and when the crank case heats so that it is uncomfortable to touch, it is an indication that the leak exists. The only remedy is the reboring of the cylinders, and the fitting of oversize pistons and rings, or, if the pistons are not too badly scratched, new piston rings may suffice.

When piston rings work around in their grooves so that their split ends are in line, this will often give the compression an opportunity to escape. Therefore, see that the split ends are not in line.

If the piston rings are in good condition, they will be smooth and shiny, as will also be the cylinder walls. If the rings are dull and dirty in spots and streaks, it will indicate that the flame passes between them and the walls, leaving a sooty deposit.

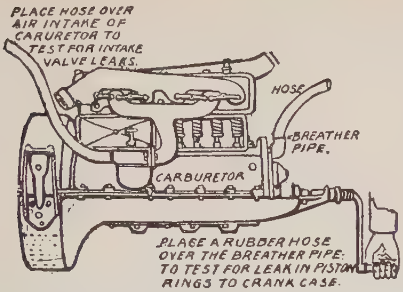
Badly fitting piston rings may be caused by the rings sticking in their grooves, because of gummy deposit from the lubricating oil; rings that are stuck in their grooves will not press against the cylinder walls and will cause loss of compression. Kerosene oil will cut this gum, and free the rings. If this is suspected, just a little kerosene poured into the cylinder and distributed by cranking the engine will cure it.

To test for a leak at the valve cap, spark plug, or relief cock: Pour oil over the cap on top of the cylinder block, and if bubbles occur when the piston is moving upward, it is an indication that there is a leak. It can be corrected by simply tightening, or it may be necessary to renew the gaskets. Pour water into the valve cap to detect an air leak, if the spark plug or relief cock is screwed into a valve cap with a depression in it. If there is a leak, it will bubble through the water when the engine is being cranked. This can be remedied by merely tightening up or by fitting new gaskets.

Before Grinding the Valves See if the Valves Leak

The loss of compression may be elsewhere than in the valves. To save time, therefore, first test for various other probable causes of leaks as described. A good plan is to use soap suds and apply it at all points where there is likely to be a leak, as, for example, around the cylinder head gaskets, spark plugs, priming cocks, etc. Then have someone crank the engine with the priming cocks closed and the switch off, bringing it up to compression, and hold it there for an instant. If air bubbles form there, you may know there is a leak. Test each cylinder. Remedy leaks, if any, before proceeding farther.

A compression leak between the piston and cylinder walls is rather difficult to test. Probably the best way is first to correct compression leaks as described above; then, if the compression is still poor, the leak must be between the piston and the cylinder wall. See Fig. 30 for one method of testing. The remedy for leaks past the piston rings is to put in new rings, if they are not merely gummed and cannot be loosened with a little kerosene. Usually they are worn or out of round. See also the subject "Piston rings."



PLACE HOSE OVER AIR INTAKE OF CARURETOR TO TEST FOR INTAKE VALVE LEAKS.
HOSE
BREATHER PIPE.
CARBURETOR
PLACE A RUBBER HOSE OVER THE BREATHER PIPE: TO TEST FOR LEAK IN PISTON RINGS TO CRANK CASE.

Fig. 30. One method of testing for piston-ring and valve leaks.

To test for inlet-valve leak: Knowing that the minor leaks above referred to are corrected and that all the parts are tight, the next step is to test for leaks of the inlet valves, if any. Place a piece of garden hose over the carburetor air intake, as in Fig. 30. With throttle wide open, have someone crank the engine with switch off. Place the hose to the ear; if a hissing sound is heard when the piston is on compression stroke, the inlet valve is leaking and needs grinding.

To test for piston-ring leaks: Place the hose at the breather pipe; crank as before; if a hissing sound is heard as the piston moves up on compression, the pressure is escaping past the piston ring, down the wall of the cylinder into the crank case. In this case new rings are required, or maybe a little kerosene to loosen up the ring will suffice.

If no hissing sound is heard, and you are still losing compression, the trouble probably lies with a leaky valve. The only way to find it out in such a case is to remove the valves of this cylinder and examine them.

If you are able to hold against the compression of a cylinder for half a minute without perceptible loss of compression, the compression is good in this cylinder. Test each cylinder.

Note. A bulletin on lapping out cylinders, grinding pistons into cylinders, removing score marks, etc., is furnished free to readers of this book by the Clover Mfg. Co., Norwalk, Conn.

Spark Plugs Indicate Condition of Valves and Piston Rings

When spark plugs are constantly oily and fouling, this is an indication of oil passing from the crank case past a **leaky piston ring.**

It is also indicated by excessive lubricating-oil smoke (blue) passing out of the exhaust, as the oil works up past the rings.

The condition of the spark plugs will sometimes indicate the condition of the valves. If the end of the spark plug is **oily,** it indicates too much lubricating oil or leaky piston rings.

If **black soft soot** is present, like that which accumulates in a lamp chimney, this indicates that too much gasoline is being fed to the cylinder through the intake, causing too rich a mixture. This may come from improper carburetor adjustment or from an air leak in the intake manifold.

If the ends of the **plugs are oily and sooty,** this would indicate that the valves leak, as this permits burned gases being drawn into the mixture, with the result of poor combustion and lack of pressure in the cylinder, and also of permitting oil to pass and foul the plug.

Prussian Blue for a Valve Leak Test

To test a valve-head seat: Buy a ten-cent tube of Prussian blue at any paint store. Loosen the valve spring, and **blue the face of the valve.** Then turn it one-quarter around in the valve seat. If the seat shows a clear clean line of blue, you have a perfectly fitting valve. If there are points where the blue does not touch, you have a worn or warped valve or a faulty seat.

If, after these tests, compression is not restored, the trouble is a serious one, requiring removal of the cylinders or cylinder head. The piston rings may be broken, scored, or badly worn, or the cylinders may be scored also. To remedy such troubles as scored cylinders, where they must be reground, requires special machinery, and this sort of repair is done by those who specialize in this class of work. Such work as fitting rings and grinding valves, etc., can easily be done in any shop.

Keep in touch, so to speak, with the compression in your engine if you wish to obtain best results.

A piston may sometimes have a flaw in the casting, and a small hole will permit loss of compression. See Index under "Testing piston for a leak."

Causes of Leaky Valves

A valve and its parts, as used on engines with valves on the side, is shown in Fig. 31.

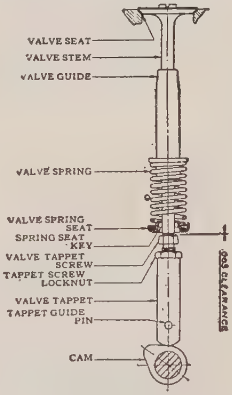


Fig. 31. A valve and its parts. The Ford valve has no tappet adjustment. When worn, new valves should be installed.

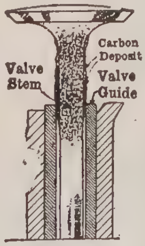

Fig. 32

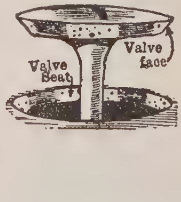

Fig. 33

Fig. 32. Note the black spots on the valve face and valve seat. This permits the escape of gas. If the valves are ground or reseated, the spots will be removed and the valve will seat tight, provided the pitting is not too deep and the valve spring is not too weak.

Fig. 33. Exhaust-valve stems often become carbon coated, and when the engine is driven at high speeds the temperature increases, causing expansion, with the result that the valve will be given a taper effect which will not permit it to seat properly. Often this is the cause of a leaky valve, and the stem should be cleaned thoroughly and sufficient clearance allowed between the valve stem and the valve guide. Clean by placing the valve in a vise, and use a strip of emery cloth.

To determine if valves need grinding or reseating: Valve grinding will ordinarily remove small pits, but if badly pitted or if the valve head is warped (caused by excessive heating), out of line with its seat, or if shoulders appear on the valve face or valve seat, they should first be re-seated with a special re-seating tool and then ground to a smooth surface.

Valve stems become worn in time and permit air to be drawn in through the valve guide when the inlet valve is open, thus admitting more air to the carburetion mixture, which sometimes causes missing. The remedy for worn valve guides is discussed on page 774.

The subject of worn valve tappets and guides is discussed on page 775.

GRINDING ENGINE VALVES

Valve grinding is necessary when either the inlet or the exhaust **valves leak.** The exhaust valve has a tendency to leak more than an inlet valve because it is more exposed to the heat.

To test whether valves need grinding, see the "Prussian blue test," explained on page 769; also try the compression. Weak compression usually results from leaky valves as well as from leaky rings; therefore be sure that the leak is in the valve and not in the rings.

To grind valves is not a difficult process. It is merely a slow and **painstaking job,** and is better done the more patient and untiring the operator is.

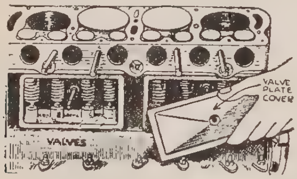

Fig. 34. Valve cover removed on an engine with valves on the side exposing the valve springs and valve stems.

To Remove Valves on Engines with Valves on the Side

First **remove the intake pipe** (if it is in the way) and then the **valve-plate cover** (Fig. 34). Remove the **valve cap or cylinder head,** if of a detachable type.

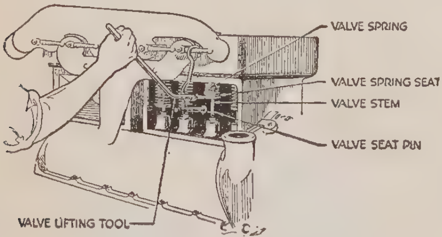

Fig. 35. Method of compressing the valve springs on a Ford to remove the valve.

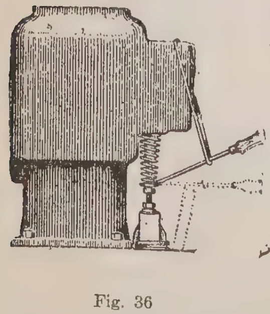

Fig. 36

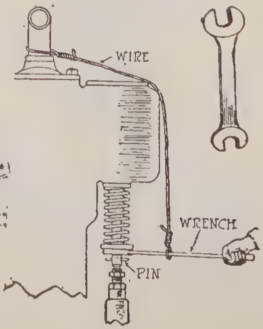

Fig. 37

Figs. 36 and 37 show two methods of releasing spring tension to remove the spring-seat key.

Remove the spring-seat key from under the spring. These springs are very stiff and will require a special spring lifter of some form which can be secured at any supply house, or you can make a serviceable tool, as explained in Figs. 36 and 37.

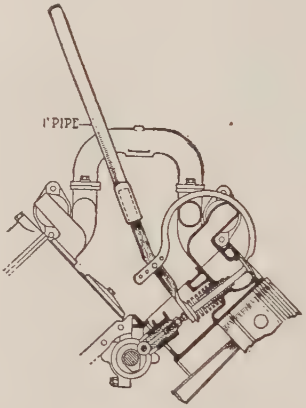

Fig. 38

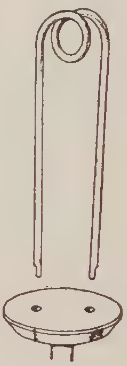

Fig. 39

Fig. 38. A method sometimes used on V-type cylinder-block engines for compressing valve springs.

Fig. 39. After the spring-seat key is removed, the valve is lifted out of its seat, which is not always as easy as it would appear. Valves may be lifted from their seats by means of a **valve lifter** made from a spring steel rod. A piece of 3/16" round rod, about 14" long, is heated and bent in the form illustrated, after which the coil is spring tempered. The points are filed down until they are a snug fit in the holes in the valve top. Valves may be readily lifted out for inspection by means of this device.

Grinding Valves on an L-Head Cylinder with Valves on the Side[1]

First, remove the valve cover, as shown in Fig. 34; then remove the valve caps or cylinder head (if detachable), and then the valve-spring key, by one of the methods shown in Figs. 35 to 38 and 40. **Next remove the valve** (Fig. 41).

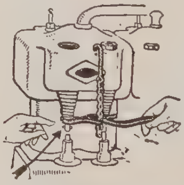

Fig. 40.

Fig. 40. Remove the pin in the end of the valve stem. A spring lifter will make this easy.

Fig. 41. Lift the valve out of the cylinder.

Fig. 42. Smear the valve-grinding compound around the edge of the valve.

---

[1] "Clover Grinding Compound" for grinding valves, grinding pistons into cylinders, lapping out cylinders, grinding crank shafts into bearings, polishing crank shafts, etc., is manufactured by the Clover Mfg. Co., Norwalk, Conn. This concern issues a very instructive free bulletin on valve grinding.

Second, place some valve-grinding compound on the face of the valve. The usual procedure is to apply first a coat of oil on the seat, and then to distribute it with the tip of the finger; then dip the finger into the emery (flour of emery), and apply this to the seat. Put on an even coat and don't plaster it all around the surrounding metal parts. Take your time.

There are specially prepared grinding compounds which can be secured at supply houses. They usually come in three grades: No. 1, No. 2, and No. 3. The first is coarse and cuts heavily; the second does not cut so much, and the third polishes.

Third, place the valve back into its seat; then use a screwdriver or a brace with a screwdriver bit, placing the point in the recess, with which most valves are provided.

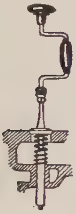

Fig. 43

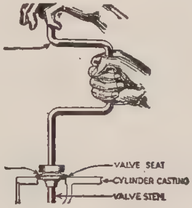

Fig. 44

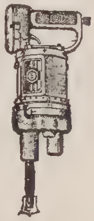

Fig. 45

Fig. 46

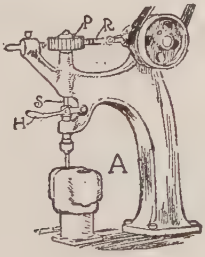

Fig. 47

There are various ways of grinding valves: with a brace and a screwdriver bit as in Fig. 43, or by hand, with a regular screwdriver as in Fig. 50, or by means of a special hand-grinding tool (Fig. 46) with a reciprocating motion, or by a specially made valve-grinding tool operated by power (Fig. 47), or with an electric valve-grinding tool (Fig. 45). There are numerous valve-grinding tools on the market.

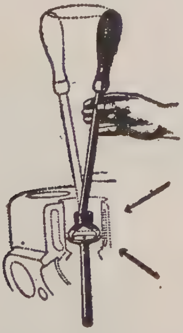

Fig. 48

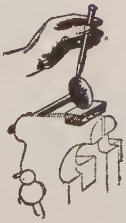

Fig. 49

Fig. 48. **"Anderson" universal valve grinder.** To use this tool it is necessary to make two light impressions or center-punch marks on the flat surface of the valve (Fig. 49), at an angle, or in the sides of the holes already there. The "pinch-ing-bug" hardened-steel jaws are then inserted, and securely held by turning down the knurled nut. Grind by rotating between the palms of the hand. The rod is fastened in such a way as to give a swivel action, permitting the rod to be held at any angle while grinding—the valve remaining true on its seat. (Stevens & Co., 375 Broadway, New York, N.Y.)

A spring should be placed under the valve as shown in Fig. 43. This will allow the valve to be raised from its seat occasionally for inspection.

Place a cloth in the opening to the cylinder to prevent the grinding powder and dirt from getting in; and be sure and take it out when through.

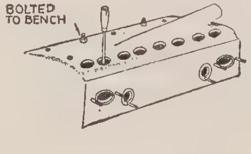

Fig. 50

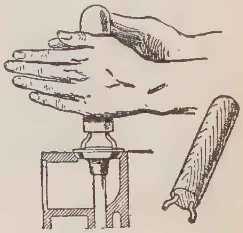

Fig. 51

Fig. 50. A plain screwdriver can be used for grinding valves and can be operated in the manner shown in Fig. 51.

Fig. 51. **A tool for grinding Ford valves** may be made from an 8″ length of broom handle and two nails. The two nails are driven into the sawed-off end of the handle, until only about one inch of the nail is left. The heads of the nails are then filed off and bent until they will fit into the drilled holes in the valve top, which are usually found either in the form of holes or of slots to take a screwdriver.

Fourth, turn the valve half a revolution back and forth in its seat, and occasionally lift it from its seat and shift it around. Don't turn it round and round. See the reason for this, as explained on page 772.

When the pits on the valve are almost removed, continue the operation with flour of emery of a finer grade, instead of the coarse grade; remove the valve oftener, applying more oil and less emery each time, until a good seat is obtained all around; then finish up by polishing the seats with oil. Kerosene is most effectively used in finishing, and the smoother the finish obtained, the less the chance for a leak. Be sure that the valve stems are free in the guides.

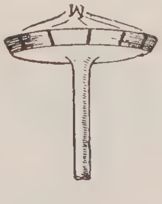

Fig. 52

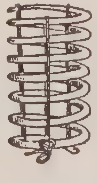

Fig. 53

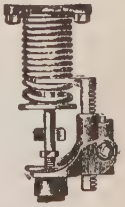

Fig. 54

Fig. 52. **To test the finish of a valve face after grinding:** mark it with a lead pencil as shown about ½ in. apart or less. If, after putting the valve in place and after oscillating it about a quarter-turn, all marks are erased, the job is satisfactory. (The marks on valve (W) are the pencil marks to be erased.)

Fig. 53. **Replacing a valve spring:** Tie the valve spring before trying to replace it. A simple method is to compress a valve spring between the jaws of a vise. While compressed, it is tied up with a loop of wire or string in two or three places. When the spring is thus tied up under tension, its replacement is easy. This is not necessary, however, if a valve-spring lifter is at hand.

Fig. 54. **"Bryant" valve-spring compressor.** The upper engaging device is inserted between the coils, thereby raising the spring away from the disk, leaving the disk and key free to be removed. The valve may be "ground in" and replaced in position without removing the spring or the lifter from their places. (Can be obtained of Stevens Co., 375 Broadway, New York, N.Y.)

Remove the valve and clean both head and seat with kerosene, and don't overlook cleaning the valve stem.

If a polished seat is desired, finish as follows: When the valve is ground to a dull, smooth surface, remove and clean the valve face thoroughly. Do not clean the valve seat, but leave upon it the compound which remains from the last grinding. Replace the valve and give it twenty or thirty turns. Remove again, clean the valve, but not the seat as before. Replace the valve, and repeat until the desired polish is obtained The polished seat may look somewhat better, but the **dull smooth seat gives much better results,** as has been proved by test.

For grinding valves, a pressure of about 3½ lbs. is sufficient. More pressure than this will cause the grinding compound to cut rings in the valve or seat.

A valve that is properly seated will bounce back when dropped into its seat. If it stops with a dull thud, either the grinding is not perfect or the valve stem is bent.

To Test Valve Seat After Grinding

Test a valve to see if it has been properly seated after grinding. As a rule, the grinding of a valve should not be carried too far. After completing the grinding operation as described above, clean the face of the valve thoroughly; place a light coating of oil on the valve face and then place the latter on the valve seat. Turn it back and forth a few times.

Then remove the valve and clean it, holding it to the light and observing if there are fine polished lines on it. These lines are the points at which the valve-head seat makes contact with the valve seat.

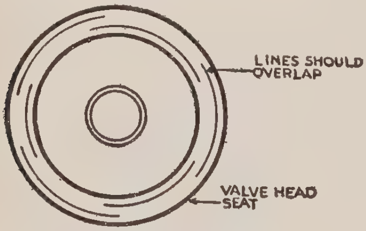

Fig. 55. Correct valve face.

It is not necessary that the lines continue all the way around the valve face or seat; in fact, this is rarely found to be the case. They are usually as shown in Fig. 55 when properly seating. Note that it is necessary that one line overlaps another line, so that there is no break all the way around the face of the valve.

If, on the other hand, there is a break at any point where one line does not overlap another, the gas will escape, and the entire operation should be repeated until the lines make a complete overlapping circle as shown in Fig. 55.

The reason why a valve should not be turned continuously in one direction when grinding, is that it is liable to result in a spiral cut in the seat which would be hard to grind out.

An ideal valve seat is a very fine, narrow edge, as it will last longer than a wide one, and, furthermore, a wide seat tends to permit carbon to collect in the seat, and thus heats the valve, while a narrow valve seat cuts the carbon, thus assisting in keeping the seat clean.

If difficulty is met with in grinding some of the valves, owing to the fact that the abrasive cuts the surface very slowly, it is because that particular engine has a very hard alloy steel Tungsten valve.

Tungsten metal valves have Tungsten heads electrically welded to nickel-steel valve stems. Valves are also made with **cast-iron heads** welded to steel stems.

The Webster laminated valve is another type of valve, the manufacturers claiming that the flexible action of the head makes it possible to use this valve without having to grind it in and that it will keep the face of the seat clean. Another feature claimed, is the smoothness and quietness of operation. This valve is made up of seven laminations, the bottom one of which is chrome-vanadium steel. The laminations are locked together on a 3½ per cent nickel steel stem by a patented method of swagging, making the stem an integral part of the valve head.

To grind valves in an engine with valves-on-the-side, with a detachable cylinder head, see also page 56.

After grinding the valves, replace the valve caps (Fig. 56), then adjust the valve clearance, and put on the valve cover (Fig. 34).

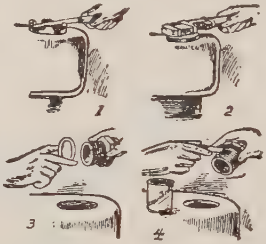

Fig. 56. **Valve caps** are placed over each valve and are finely threaded and provided with a copper gasket (3). When **replacing,** the threads should be coated with graphite or one will have difficulty in removing them the next time. (1) shows a castellated type which sometimes is sunk into the head of the cylinder and requires a special tool to remove.

Grinding Overhead Valves

The foregoing instructions are for grinding valves in an "L" or "T"-head type of cylinder.

Valves placed overhead, are either in **cages,** as shown on pages 53, 71, or in **cylinder heads which are detachable,** as in Figs. 112 to 115, page 57. The process of grinding is similar to the method of grinding valves explained on page 771 and also page 57.

Where valves are in cages, the cages are usually removed as shown by Fig. 57 below and the valves are ground in the cage. The method of grinding

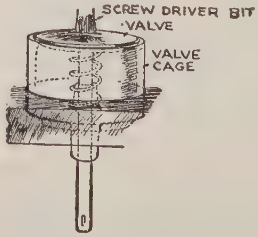

Fig. 57

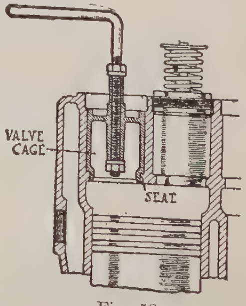

Fig. 58

Fig. 58. A simple way of **grinding a Buick valve cage** to a perfect seat is shown here. Through the center of the cage insert a round iron rod which has been threaded for a nut at the two places shown. Then tighten the nuts. With the rod as a handle, the cage can be rotated easily. See also page 71.

is similar to that of grinding valves explained on page 771.

The cage (Fig. 57) is placed in a counter-sunk hole in the bench, with a spring under the valve to raise it. In fact, it is a good idea to place springs under all types of valves when grinding, as shown in Fig. 43.

To tell when a valve is ground to a perfect seat, see Prussian blue test (pages 769, 772, and Figs. 52, 55).

REFACING VALVE-HEAD FACES AND RESEATING VALVE SEATS

When valve-head faces or valve seats are badly pitted or cut, or where shoulders appear, they will require more than mere grinding.

Valve-head faces are beveled, at either 45°, 30°, or 60°—usually 45°.

As an example of the contruction of a valve, a Ford valve will be used as shown in Figs. 59 and 60. Valves can be secured in the form of blank forgings and can be turned up on a lathe to size. Usually it is more economical to purchase valves finished.

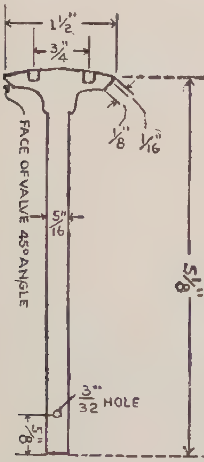

Fig. 59

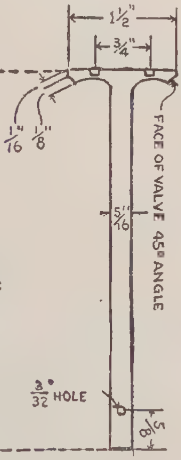

Fig. 60

Fig. 59. Dimensions of a finished Ford valve with a cast-iron head.

Fig. 60. A Tungsten valve. The Tungsten valve, of course, is much harder. Note that the face of the valve is beveled at a 45° angle. The exact dimensions of a Ford valve in thousandths of an inch are as follows: diameter of valve head, 1.422″; valve stem diameter, .311″; length of valve stem, 4.976″.

Refacing Valve-Head Faces

The valve head face is **refaced** with a special refacing tool, as shown in Figs. 61 and 62.

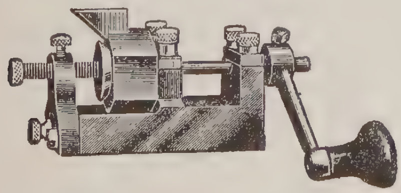

Fig. 61. The Sioux valve refacing tool; to be held in a vise. It is made with cutters for valve faces with 45°, 60°, and 30° angles.

Where Tungsten valves are used, they can be ground if a good valve-grinding compound is used for the purpose; but if they are badly pitted, they should be refaced, because the Tungsten metal is very hard, and the labor in this case is considerable. The usual practice is to place them in a lathe and emery them down with special devices for the purpose, or to use fine emery cloth on a block, while a valve is rotated at a high speed. A valve refacer designed for Tungsten or other valves is shown in Figs. 61 and 62.

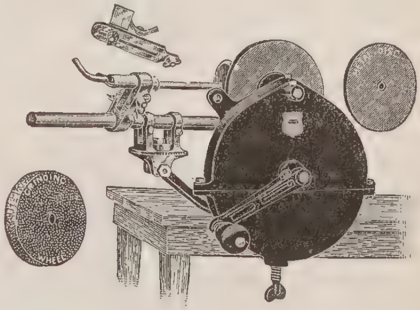

Fig. 62. **The McCullough valve grinder or valve refacer** is guaranteed to grind all makes and sizes of gasoline-engine valves with absolute accuracy and to any bevel desired. It will grind with ease, and perfectly, the hardest tungsten valves without affecting the temper. The hardest valve can be cut to shape in a few minutes, and it does not require a skilled mechanic to accomplish it. When not being used as a valve grinder this machine can be quickly converted into a tool and drill grinder, thus making it a most necessary tool in any auto repair shop. Manufactured by B. L. Fry Mfg. Co., St. Louis, Mo.

Reseating Valve Seats

Truing up a valve seat in the cylinder is usually done with standard sizes of valve reseating cutters or valve seat reamers, as they are usually termed. One type is shown in Fig. 63.

When reseating valve seats, the novice must be careful not to cut too deep into the seat and thereby lower the valve stem. In fact, it is advisable to adjust the valve clearance after either grinding or reseating valves. **After reseating, always grind the valve in order to make a good tight seating.**

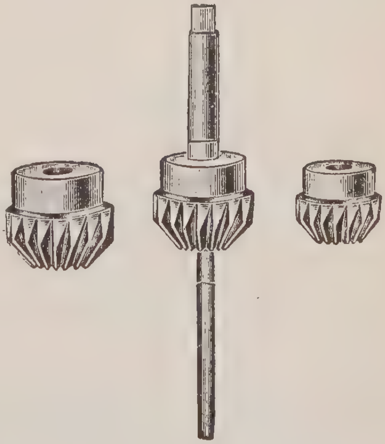

Fig. 63. The Sioux valve-seat reamer for refacing valve seats.

A perfect seat is assured when a white line extends clear around both the valve and the seat, when giving the Prussian blue test. The width of the line is immaterial, but the narrower the line, the better the compression will be, because there is less area for the pressure of the valve spring to act on. However, it is not well to have the ring less than ⅛″ wide.

A valve seat should have a bevel of not less than 45°. With less than this the valve will stick. Another good angle is 60°.

Q.: I have a ——— model car. Valve seats have been ground till the valves drop a ¼″ into seat and the valve head is not level with the combustion chamber till the piston has descended one-half of the suction stroke. Valves are 2¼ ins. Cylinder bore 4¼, stroke 6 ins. Is it advisable to reseat and use slightly larger valves?

Ans.: Yes. Leave the seat narrow so it will last longer. 1/16 to ⅛ inch is wide enough for the seat in the cylinder. You can secure the valve blanks at most any auto supply house.

It will be noticed that some valve stems seem to wear very much on one side. This may be caused by one or more things, viz.: (1) the hole is not concentric with the valve seat—which can be remedied by reseating in a radial drill press; (2) the top of the valve lifter is not at right angles with the valve stem, wedging it off to one side; or (3) the same may be true of the valve head on the stem of the valve. These two latter troubles can be remedied by the judicious use of the file.

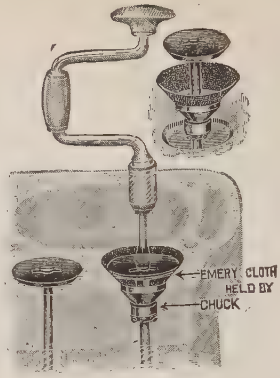

Fig. 64. **The McCullough valve reseating tool** consists of a carborundum cloth cone held to the face of the valve as shown. The valve is used just the same as a reamer, the cloth cutting the seat in the valve seat of cylinder at exactly the same bevel as that of the valve face. No reamers are required. There is nothing to replace but the carborundum cloth. Emery cloth or sand paper will do quite as well, but will not last as long. Manufactured by B. L. Fry Mfg. Co., St. Louis, Mo.

VALVE-STEM GUIDES, OVERSIZE VALVE STEMS, AND VALVE TAPPET GUIDES

When valve stems become badly worn, it is almost a certainty that the **valve stem guide,** or hole through which the valve stem passes, is worn out of round. This permits air to be drawn through the inlet valves when they are open, which causes an **imperfect mixture,** resulting in bad starting as well as noise.

Sticking valves are also sometimes caused by worn valve guides, causing the valve stem to stick at the top and bottom of the guide, with the result that air is drawn into the cylinder, causing missing.

On some engines there are valve-stem guide bushings which can be renewed when worn by putting on a new bushing and reaming out the guide for a new valve, which is fitted at the same time, and by then grinding the valve to a seat.

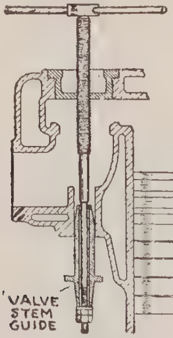

Fig. 65

Replacing valve guides: Where engine cylinders are fitted with removable valve guides, the old valve guides may be driven from the cylinder casting. The fitting of new guides must then be done with more care, however, as a slight distortion of the guide will cause the valve to stick. The puller illustrated in Fig. 65 is ideal for this work, as it applies a steady, even pull to the guide in a manner that cannot spring it out of shape. This tool can be made by taking an old cylinder cap and drilling and tapping it to carry the threaded rod, which may be made on the lathe in a few minutes. The valve guide, it will be noticed, is drawn in from the bottom.

Many valve guides are not bushed, but are simply drilled passages in the metal of the engine, as, for example, on the Ford.

In this construction, the **guide is reamed larger, and an oversize valve is put in.**

Ford valve guides (as well as those on many other engines) are a part of the cylinder casting, and cannot be renewed. Reaming and fitting oversize valves is a better method than to ream the guide large enough to put in a bushing. Unless a great deal of metal is removed, the bushing would be so thin that it would not last long.

A reamer 29/64″ is used to ream the push rod or tappet holes 1/64″ oversize, and a 21/64″ reamer for reaming the valve stem guides 1/16″ oversize on the Ford.

Oversize Valve Stems

Oversize valve stems are necessary when worn valve guides are reamed out. The standard oversize valve stem is $\frac{1}{64}$″ (or, in other words, the valve guide is reamed that much larger). If the standard valve stem was $\frac{5}{16}$″ in diameter, it would be $\frac{1}{64}$″ larger, or $\frac{21}{64}$″ in diameter.

If valve guides are badly worn, it will be necessary to ream larger and to fit larger oversize valves.

On older models (Dodge cars), the valve guide was integral with the cylinder, and a 35/64″ drill bored out the worn guide. Then a .556″ reamer is run through. Then a finishing cut is taken with a 9/16″ reamer.

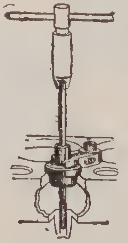

Fig. 66

Fig. 67

Fig. 66. **A valve-guide reamer.** When reaming the valve guides it is necessary to ream true; therefore a guide is necessary. The guide is shown clamped to the cylinder head. The reamer is then passed through the guide and turned by a hand tap-wrench.

Fig. 67. **An oversize valve stem which must be fitted when** a valve guide is reamed.

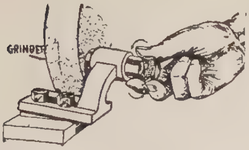

Fig. 68

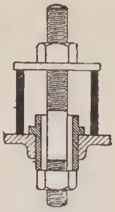

Fig. 69

Fig. 68. **The method of truing valve tappets, when worn,** is shown in this illustration.

Fig. 69. **Valve-tappet guide puller** is made of a short section of 2″ iron pipe, or any size larger in diameter than the guide. A washer is then placed over the top of the pipe. A bolt which will go through the guide hole, and two nuts, will complete the puller.

Noisy Valve Action

Noisy valve action: Difficulty is frequently experienced in locating noises in and about the engine, probably because there are so many of them that it is difficult to determine where to begin.

There are **three points** in connection with valve operation where a clicking noise may occur, as follows:

1. Worn valve tappet guides.
2. Too great a clearance between valve stem and valve tappet.
3. Valve springs too strong.

The best way, perhaps, is to go about it in a systematic manner, starting with the most likely sources, as, for instance, in the valve tappets.

Worn Valve Tappets and Guides

Valve tappet guides usually wear out of round, as a result of the cam striking the lower end of the valve tappet in one direction. Thus in time the wear will be such that each time the cam strikes the tappet to raise it, the tappet is thrust to one side of its guide, and a clicking noise will result.

The remedy is either to put in new valve tappet guides and tappets, or to ream out the tappet guide and to fit oversize tappets.

On the Ford, the tappet holes can be reamed to 1/64″ oversize with a 29/64″ reamer, and oversize tappets can be fitted.

VALVE-STEM CLEARANCE

This subject is fully dealt with on pages 58 and 73, therefore only the resultant effects produced by improper valve clearance will be dealt with here.

Proper adjustment of the valve tappets will help in reducing the noise which invariably occurs when there is any wear, as a result of the increased space between the valve stem and the valve tappet.

The proper space between the ends of the push rods and valve stems is as explained on pages 58 and 59. The smaller the space, the less the noise; but sufficient space must be allowed to provide for expansion when the engine is warm and for irregularities in the shape of the cam or roller.

Sometimes only one or two valves may need adjustment, while others may be in good shape; in such cases there will be a clicking sound at regular intervals.

The repairman can generally find a tappet that is badly out of adjustment in a very short time by simply working the tappets of each cylinder up against the valve stems and down again, with his fingers, while the pistons of the respective cylinders are on their compression strokes.

Another plan is to place a thin piece of metal as a thickness gauge under a suspected valve stem, as shown in Fig. 72, and when the noisy one is found, the insertion of the tool will cause the clicking to cease abruptly and the valve will remain quiet until the tool is removed.

Valve-Clearance Adjusting

Adjustable valve clearance is where there is a valve-tappet adjusting screw (Fig. 2, and Fig.1, page 58).

To test valve clearance, the best plan is to use a thickness gauge and follow instructions given on page 59.

In the absence of a thickness gauge for regulating the valve space, many repairmen use a piece of paper as shown at (C) Fig. 71. It is folded once and slipped between the ends of the stem and tappet; the lock nut (N) is loosened, and the stud (S) is screwed up or outward until it just begins to pinch the paper and prevents it from sliding about as readily as at first. The paper is then removed and the lock nut is tightened.

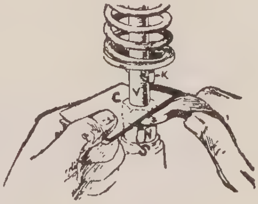

Fig. 71

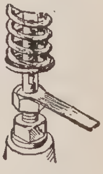

Fig. 72

Fig. 71. Valve adjusting.

Fig. 72. Thickness gauge inserted between valve stem and tappet to find out the existing valve clearance.

When both the inlet and exhaust valves have been adjusted in this manner, each one should be individually tested with a single thickness (a thickness gauge is best; see page 73 and see also, page 58 for the adjustment or gap necessary for leading engines), to see if the valves remain tightly closed throughout their required period.

This is best done by sliding the single thickness of paper back and forth as the engine is being turned slowly from the closing to the opening points of each valve. The marks on the fly wheel may be used to advantage in this operation if accessible, but they are not necessary. One can slide the paper under a stem and turn the engine over until the paper is seized, which indicates the valve opening. Then turn it a little farther until it is free again, which marks the closing of the valve. Now, if the paper is turned still farther, and is continually slid about, if it is not seized before the regular time for the valve to open (according to either the position of the piston or the crank handle), the adjustment is about right, but if the paper is prematurely seized the space is insufficient. The valve in each cylinder should be adjusted in the same manner.

When adjusting valve clearance, remember that if no space at all is left between the valve and the plunger, the valve will not seat properly; therefore, it is important to get the distance exact.

Non-adjustable valve clearance is where no adjustment nuts are provided, as on the Ford. Therefore when the clearance is too great, new valve stems and often tappets also must be installed, or valve adjusters can be used as explained below.

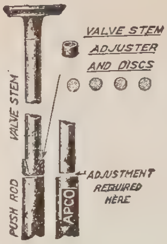

Fig. 73

Fig. 73. **Valve-clearance adjusters.** When the space between the end of the push rod and the end of the valve stem is more than 1/32", then a clicking noise is the result. As the Ford valve has no means of adjustment it is remedied by either installing new valves and 1/64" oversize push rods (tappets), or by using adjusters, as shown in this illustration, which are made of steel lined with fiber. These can be secured of supply houses. The clearance on a Ford valve should be .022" to .028". See Index under "Valve clearance, Ford."

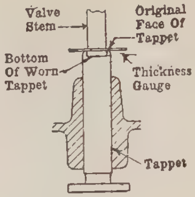

Fig. 74

Fig. 74. **If a valve tappet becomes worn with a depression** in the end of the tappet, this would throw the valve out of time if clearance was measured with thickness on the top or sides of the depression. **Install a new tappet, and also a new valve stem.**

VALVE SPRINGS

If the springs of the exhaust valves become weak from use or heat, the pistons will draw burned gases into the cylinders, past the valves with the incoming gasoline charge, **giving an improper mixture.**

The valve springs should be tested when overhauling, to see if they are full strength (see Fig. 76). They are usually made of chrome-vanadium steel. The average strength of a valve spring is about 30 lbs., but varies. On the Franklin series "9B" engine, when supporting a weight of 25 to 28 lbs., the springs should have just enough tension to seat the valves properly. A 1/32" washer under the spring will increase the spring tension by 1 lb.

Exhaust valve springs are stronger than the inlet spring, and at high engine speed the exhaust valves nearly always permit some leakage.

The reason why an explosion from a weak exhaust spring misses is, that when the throttle is closed, the piston cannot get much of a charge, and consequently it sucks the exhaust valve open and draws back some of the burned gases, which spoils the small charge in the cylinder, causing mis-fire.

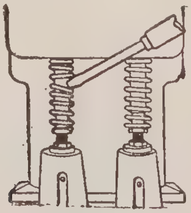

Fig. 75

To test for a weak exhaust spring, insert a screwdriver between the coils (Fig. 75), thereby increasing the tension. If missing stops, then remove the spring and stretch it about an inch, or put in a new one.

Valve springs that are too stiff are to be avoided, because they may close the valves with so much force as to break the stems at the key, or the heads from the stems, and it is a certainty that the seats will be pounded out of shape, even if the valves do manage to stand the constant hammering action. An **excessively stiff** spring consumes power which might be used to a better advantage, and there is also considerable **noise.**

A weak inlet valve spring also makes itself evident by the mixture back-firing into the carburetor. Springs too weak to hold the valves on the cams will also produce clattering noises, owing to belated seating of the valves.

To increase the tension of a weak valve spring, stretch the spring a mere trifle by slightly opening up the coils with a screwdriver (Fig. 75), or by securing one end coil of the spring in a vise and tying a cord or the like to the other end, so as to get a grip. Then stretch it a little in the ordinary way.

Another way to increase the tension is to place a couple of **washers under the lower end of the spring.**

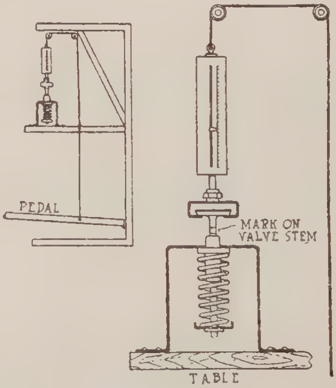

Fig. 76. When the engine is overhauled, the **old valve springs can be tested** to see that they have not weakened, and whenever a new spring is put in, it can also be tested. The illustration shows a simple means of determining whether a spring is in good condition or not.

The apparatus consists of a bracket in which is mounted a valve guide, valve, spring, spring seat, and retaining key. Two marks are placed on the valve stem, one indicating when the compression of the spring is zero, and the other when it has been compressed a certain amount, say ½". The number of pounds required to compress the spring ½" may be ascertained by testing a new spring known to be of the proper tension; then compare the test of the good spring with the old one. The pedal is depressed and the valve is raised until the lower mark on the valve stem is on a level with the top of the valve guide, at which time the pull as registered by the spring scales should be that of a good spring tested previously in the same manner.

One of the most important features necessary to obtain increased power is good valve action. Valve springs are cheap, and it pays to install a new set of valve springs occasionally, even if the old ones do not seem to be worn out. Lively springs close the valves promptly, and this is especially necessary if the engine is to be run at high speeds. If it is to be used for racing and the last ounce of power is desired, it may be advisable to use special valve springs that are stronger than the regular type, but such springs are more prone to break the valves and are more noisy.

ENGINE KNOCKS[1]

Knocks are usually caused by the following parts being loose or worn, or otherwise in poor condition:

1. Lower connecting-rod bearings.
2. Upper connecting-rod bearing or wrist pin.
3. Cam-shaft bearings.
4. Main crank-shaft bearings.
5. A loose piston which produces a piston slap.
6. Timing gears.
7. Cam shaft.
8. Fly wheel.
9. Carburetion adjustment not correct.
10. Running too far advanced on the spark.
11. Worn valve stems and valve guides.
12. Pre-ignition.
13. Badly worn or broken piston rings.
14. Too great a compression.

Troubles which commonly cause a knock that develops on a hill, and that is not perceptible on level ground are as follows:

1. Lean mixture.
2. Magneto set too early.
3. Valves seat poorly.
4. Carbon in cylinders.
5. Poor valve adjustment.
6. Loose wrist pin bushing.
7. Loose magneto shaft coupling and sticking valves.

The cures for these may be taken up in order. They are as follows:

Lean mixture can be cured by opening the needle valve slightly, or by closing the air valve. The former is preferable, as it is easier to make a correct fuel adjustment than an exact air adjustment. This adjustment should be made on the road. Take the car out on a hill and run it up in its present condition. Return to the bottom of the hill and make a change in the mixture, by turning the fuel adjustment. When this is done run the car up the hill again and note if there is any decrease in the knock. If there is none, or the change is only slight, it is time to pass to the next cause.

Climbing a hill with spark too far advanced will always cause a knock. See Index under "Ignition knock."

Loose cylinder nuts will cause a knock and vibration, and in some cases a knock has been caused by the engine being loose on the frame.

Timing gears: Lack of proper lubrication causes most of the worn-out knocks which are heard, while many come from natural wear. The timing gears, for example, run in a bath of oil, and yet, in time, the teeth become worn and, with the excessive backlash or play, a rattling and sometimes a knocking is heard.

Knocks are frequently caused by connnecting rods being slightly bent or out of alignment, which sometimes happens when fitting the cylinders down over the pistons. This will also cause a "piston slap."

Locating Engine Knocks

Minor causes: Before making tests, first determine if the cause of the knock is not one of several minor causes, which are easy to locate:

1. See if the cylinder is free from carbon, and if the knock is not caused by pre-ignition (see pages 170, 780).
2. Find out if the knock is due to running with the spark lever too far advanced.
3. See if carburetion is properly adjusted.
4. Ascertain whether valve clearance is correct, and if the valve tappets are not badly worn.

After determining that the minor causes enumerated above are not producing the knocks, then test from the outside of the engine with a sounding bar, so that the **location** of the knock will be determined or at least that its approximate position may be learned.

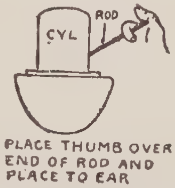

Fig. 77

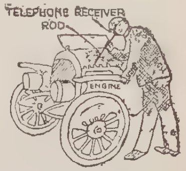

Fig. 78

Fig. 77. **A sounding rod** (of iron or steel) can be made useful to locate the source of knocks. Place the thumb over the end of the bar and then place the ear close to the thumb. The closer you get to the noise, the louder it will be.

Fig. 78. Detecting noises in the engine by sound, with a **Sonoscope,** on the same principle as the sounding rod above shown in Fig. 77. (Made by American Elect. Co., Chicago, Ill.)

It is particularly important to learn at just what point in the engine the trouble exists, and what the cause is likely to be. With this information to start with, no unnecessary parts need be removed, and much time will be saved. Aside from this, it is well known that an engine is always more or less marred by tearing down, and this unnecessary expense should be avoided as much as possible.

We have often seen good automobile mechanics stand around a knocking engine, and have heard each one name a different cause for the trouble. Taking an engine apart is a costly piece of work, and often much labor and expense could be saved **if the cause could be accurately located before the parts are disturbed;** in fact, the knock is not always in the engine itself, although it may sound as if this is the case. It may be found in some of its attachments or fittings, and could perhaps be easily remedied by the operator if only he had the means of locating it. For this reason, the use of the sounding bar is recommended.

First examine the valves: Noises from worn valve stems, push rods, or guides are usually caused by too much space between the end of the valves and the push rods; these conditions, too, are usually the cause of most clicking noises. They can easily be detected by "testing for noisy valves," as explained on page 775.

Wrist-pin knocks can be tested as follows: While the engine is running, short-circuit the spark plugs, one cylinder at a time, to cause it to miss, with the engine running slow or idle. While this is being done, if the piston pin is loose there will be a noticeable knock. The surest method is to remove the piston and connecting rod, and to test on the bench by "feeling" for the looseness.

---

[1] See also Index

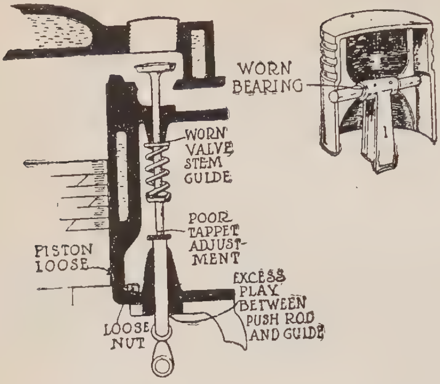

Fig. 79. **Although not all are shown above, most of the common engine noises and knocks** are caused either by poor tappet adjustment, by a worn valve-stem guide, by play in the push-rod guide, by a loose piston or a worn cylinder or loose cylinder nuts. Any of these will cause the engine to knock, and they should be remedied immediately to prevent further complications.

To test for loose pistons: Remove the spark plugs and put ⅛ pint of heavy oil in each cylinder; crank by hand slowly until the oil works to the piston rings. Replace the spark plugs and start the engine; see if the same noise occurs. If it does not, the heavy oil has cushioned the piston from the cylinder and has stopped the knock temporarily. The oil will soon get hot and run from the rings and piston, and the knock will occur again.

If the piston is loose, or if the connecting rod is bent, it has a tendency to cause the piston to strike the cylinder wall at an angle, causing a "piston slap." The rings may be tight, yet if the piston itself is loose, this knock is very likely to occur.

The cam shaft and timing gears can easily be detected with the sounding rod. The timing gears will have a sound or growl that is entirely different from a knock.

To test for loose fly wheel: Allow the engine to run idle at about 500 r.p.m.; then throw off the switch and wait till it slows down to about 75 or 100 r.p.m., after which throw the switch on with spark slightly advanced. Repeat this a few times, and if the fly wheel is loose there will be one distinct knock each time the switch is thrown on.

Another method of testing for a fly-wheel knock is to rock it (remember that the fly wheel may be entirely all right, but some other part attached to it may be loose).

A connecting-rod lower bearing knock can be definitely determined by removing the hand plate at the bottom of the crank case, placing your finger on one edge of the bearing, and cranking the shaft. Have someone rock the fly wheel or starting crank gradually one way and the other (switch off). If it is loose, you will feel it.

Main bearings can be tested in the same manner. A main-bearing knock can also be determined when running the car, by suddenly throwing it into high speed or when pulling a stiff grade. If the main bearings are loose, a distinct knock can be heard.

How to Locate a Knock by the Sound Produced

To locate the cause, first drive the car until the engine becomes warm or reaches its average temperature; second, select a run of about half a mile, running into a grade of about 8 to 12 per cent, of whatever length may be had.

Drive the car at from 10 to 15 miles per hour on the level road, and maintain this speed up the grade if possible. At this speed the engine should run quietly.

But, if, on the other hand, **a slight but distinct metallic rap is heard,** whether it be one, two, three, or four times to a revolution of the crank, the **push rod** or rods will be found to have too much play.

Should it be a slight knock, which slightly increases as the car mounts the hill, mark it first as resulting from **worn piston rings,** which for the fraction of a moment stand still in the cylinders at the beginning of the power stroke, while the piston travels its first 1/64″, or whatever distance the wear may permit. Or it may result from **worn pistons** which are being driven against the cylinder walls at the beginning of the power stroke.

This knock may, on the other hand, have a distinct metallic sound which occurs once to every explosion and greatly increases as the throttle is opened or more gas is admitted into the cylinders. If this be the case, mark it **carbon deposit** in the combustion chambers and on the piston heads, which becomes very hot and ignites the gas, causing pre-ignition.

Should the knock be either heavy or light but with a muffled sound, occurring either one, two, three, or four times to two revolutions, this can be marked **connecting rod or rods,** which may be loose on the crank shaft, or the piston pins or bushings themselves may be worn. The one or more which are causing the knock may be located by holding down on the coil vibrator, or in any other manner that will discontinue the spark at the plugs separately. For example, if by preventing cylinder No. 1 from firing, the knock ceases or is one less in two revolutions, then the trouble lies in connecting rod No. 1.

Should the engine pound, having the sound of a block of wood striking the ground, which will occur once to every explosion, but may be heavier at the explosion of any one cylinder, mark this **crank-shaft main bearing.** In very bad cases this pound can be felt by the driver.

Again, a fly wheel that is loose on the shaft will cause the same kind of a pound (this, however, is very rare). But if the driver will listen very closely he will discover that a crank-shaft bearing has a double pound with the knocks occurring very close together, so close that when first heard it will sound like one pound.

A spark knock can be more readily felt than heard, because the power of the engine is being held back by its own ignition.

A spark knock is due to advancing the spark lever too far, causing combustion to take place before the piston reaches top.

A gas knock is due to an excess of gas, resulting, for instance, from suddenly opening the throttle wide open. This knock also results from too rapid combustion, but the gasoline we have today does not burn so rapidly as to cause a knock (see Index under "Gasoline)." For "carbon knock," see page 170.

A compression knock may result from anything which decreases the space between the head of the piston and the combustion chamber.

Detecting Location of Knocks in an Engine with an Air Pump

A device known as the "Chapman Trouble Finder"[1] is illustrated below. This device will indicate knocks and leaks.

Principle: It is equipped with the necessary connections to enable one to apply it to any make of car, and is a process consisting of alternately raising and lowering the air pressure within a cylinder causing all loose parts to rise and fall. Thus, in doing so, they produce a knock.

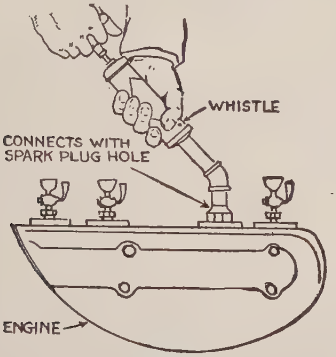

Fig. 80

How it is connected: It is to be used only when the engine is not running.

Remove all spark plugs, screw the device in place of a spark plug, and turn the engine with the starting crank until air escapes through a small whistle near the bottom of the device. Then turn slowly, giving the whistle a chance to operate.

When the whistle stops blowing for a short period, the piston is at top dead center of the compression stroke. Stop cranking the engine; push the handle of the finder down full length; grasp the finder with the hand so that the thumb or finger covers the hole in the whistle, and with the other hand on the handle of the finder you are ready for a test of leaky valves and rings, loose pistons, piston pins, connecting rods, and main bearings.

Procedure of Tests

Connecting rod: Bring the piston to top of the compression stroke. By the rapid movement of the handle all loose parts are caused to rise and fall, and can be plainly heard. By forcing the starting crank in against the end of the shaft, the jar can be plainly felt. This indicates a loose connecting rod, but if the noise is heard and no jar is felt, it is a loose piston pin. If two knocks are heard, it indicates that both are loose.

Piston side slap: If no knocks are heard or felt, turn the starting crank about six or eight inches, bringing the piston off center. Then move the handle rapidly up and down. If a clattering noise is heard it indicates a side slap, as pistons slap one wall and then the other.

Leaky valves: To locate leaky valves, bring the piston to top of compression stroke and move the handle rapidly up and down with a full stroke, which causes the air to escape through the part that leaks. By listening at the breathing tube, if you hear a wheezing sound, it indicates a leaky piston. Wheezing at the exhaust valves indicates a leaky exhaust valve.

Main bearings: To detect a loose main bearing, give the handle longer but equally rapid strokes up and down, placing your free hand on the crank or nub end of the shaft or upon the part nearest the main bearing. If the main bearing is loose you can feel a distinct rise and fall of the shaft.

If directions are carefully followed and none of the troubles described above are located, the trouble may be a carbon knock or advanced ignition, or a loose part not pertaining to the interior of the engine.

Piston Slap

The usual cause of knocks has been discussed in the foregoing pages. Another knock (which is caused by loose-fitting pistons or by connecting rods out of alignment) is explained in the illustration (Fig. 81), and is called **"piston slap."**

This is a knock that is very difficult to locate. About the only means of locating it is with the sounding rod and to have someone short-circuit the spark plugs at each cylinder while the engine is running, in order to determine in which cylinder the knock is. If the knock ceases when one cylinder is cut out by short-circuiting the spark plugs, then the cylinder in which the knock is occurring has been located.

The only remedy is to remove the pistons and to try them in the cylinder and to "feel" for looseness, or caliper the piston and cylinder wall to see what the clearance is. It is also well to see if the connecting rod and the piston are in perfect alignment. See Index under "Piston and connecting-rod alignment."

Bear in mind that a piston may slap when the engine is first started, but after it has warmed up and it expands, the knock may cease. Alignment of the piston and the connecting rod is an important factor also.

Oversize pistons and proper alignment of the piston and connecting rod is the remedy for piston slap. It will thus be apparent that this kind of knock can occur even though the piston rings fit tight.

Piston slap is the result of the piston striking first one side of the cylinder, then the other. The looser the piston is, the greater the slap. If the piston is a good fit, the slap is negligible, which is the case in the ordinary engine. The slap may be due to **worn cylinders,** to the connecting rod being out of alignment, or, in the case of **aluminum alloy pistons,** or slightly loose cast iron pistons, it may appear only when the engine is **cold,** when the pistons are contracted and are much looser than when they are hot.

There may be two or more distinctive piston slaps during the cycle. However, it is likely that the only one that can be heard is the one that occurs when the piston shifts from one side of the cylinder to the other at upper dead center just as the explosion is taking place, as shown in Fig. 81.

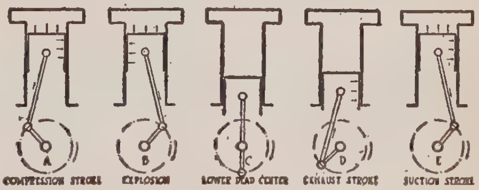

Fig. 81. **Piston slap** is a very common trouble with aluminum pistons, which, when cold, contract and leave a space between the cylinder wall and the piston. After the engine is warmed up the pistons expand and the noise ceases. Aluminum expands twice as much as cast iron. The Franklin car overcomes this by cutting three slots in the skirt of the piston with a spring ring placed in the bottom which holds the lower part of the piston to the walls. As the expansion increases, the ring tension gives accordingly. See also Index under "Pistons."

When the piston is on the compression stroke (A) (Fig. 81), it is in contact with the right side of the cylinder. As the crank pin swings by dead center, the inclination of the connecting rod is changed from right to left, thus forcing the piston to the other side. Under the full explosion pressure (B) the piston will strike a very heavy blow when it makes the change.

The piston remains in contact with this cylinder wall throughout the stroke, and when lower dead center (C) is reached, the pressure on it is entirely relieved, so that it is quite likely that the piston is then more or less able to float between both walls.

On the exhaust stroke (D) the piston is thrown gently to the right side of the cylinder, owing to the downward pressure of the inertia, as well as to the slight exhaust pressure. It is very doubtful that this ever causes an audible slap.

---

[1] Can be secured of A. L. Dyke, Electrical Department, Granite Bldg., St. Louis, Mo., Price $7.50.

The piston remains in contact with this wall throughout the suction stroke (E); then the downward pulling force of the connecting-rod is resisted by the suction on the piston as well as the inertia.

At very high speeds inertia may change some of the details of this explanation, but these can hardly be of interest or importance.

Pre-Ignition: Cause of Knocks

Sometimes it happens that the mixture is ignited before the ignition ignites it. This is termed "pre-ignition."

A rich mixture, or the burning of the lubricating oil, will leave a **deposit of carbon** on the piston head and combustion chamber. The intense heat of the explosions after long-continued runs, will heat the carbon which remains red hot, thus igniting the mixture before the proper time. This causes knock.

If the **points of the spark plug are too thin** and of poor material, they will get hot enough to glow in the same manner, and in such a case spark plugs with heavier points should be used.

Small points of metal, the result of rough castings or other causes, should be filed down, by using a fine file.

If the **water circulation stops,** or if the air cooling is not effective, the cylinder walls will get hot enough to ignite the charge, in which case the engine will continue to run after the ignition has been cut off. The remedy for this, of course, is to make sure that the engine is properly cooled, otherwise a "seized piston" will result. See Index.

Eliminating Compression Knock by Adding a Gasket

A knock caused by too high compression sounds like a carbon or advanced spark knock (see Index). The compression may be reduced by placing a thick gasket between the cylinders and the crank case. (This is seldom necessary on engines of modern construction.)

This is sometimes desirable when the car is equipped with a heavy closed body. In such cases a better job may be done by making the thick gasket of cast iron. It is made in a similar manner, but must be planed or milled to a uniform thickness and with a smooth finish. Otherwise the cylinders will be thrown out of alignment or the joints will not be tight. **Another method would be to use special pistons to decrease compression.**

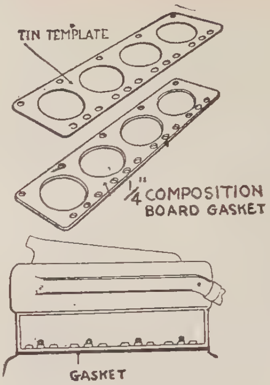

Fig. 82

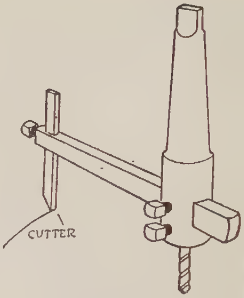

Fig. 83

Fig. 82. Tin template, and finished gasket. Lower cut shows gasket in position.

Fig. 83. Gasket-cutting tool.

Procedure of fitting a gasket: (1) Remove the cylinders. (2) Place the cylinders on a bench, and clean both the cylinder flange and engine base thoroughly. (3) From a sheet of tin, make a template (Fig. 82) which is an exact reproduction of the base of the cylinders, except that all the openings, such as piston and bolt holes, are about ⅛″ larger than those in the cylinders. The template is used as a pattern for marking out and forming the cylinder-raising gasket, and permits the gasket to be made without going to the cylinder each time to see if it is being done right. A copper asbestos gasket does not have sufficient clearance to be used as a pattern. (4) Procure a sheet of red composition board ¼″ thick. (5) Using the template as a pattern, scribe out the cylinder and bolt the holes and the outside form to the red composition board. (6) Using a gasket-cutting tool, as shown in Fig. 83, and a drill press, carefully cut out the piston holes. Make these ⅛″ larger than the cylinder bore. (7) Drill the bolt holes slightly larger than the diameter of the bolts. (8) With a band saw, or key-hole saw, cut the composition board to the outside shape of the pattern. (9) Remove all burred edges with a file. (10) Place the composition board on the engine base, and bolt the cylinders in place, as shown in Fig. 82. Shellac should be used sparingly to prevent leaks.

As a result of this the cylinders have been raised, giving a larger compression space and less compression. The result is that the compression knock disappears and the engine will pull much better on low speeds.

Note. It will be necessary to readjust the valve rods after the cylinders have been bolted down securely. (*Motor World.*)

Unless the compression is the same in all cylinders, the engine will not be in good balance and loss of power will result. The power lost when one cylinder does not fire is far more than one-fourth, and this is largely the result of a loss of balance.

To increase compression pressure: See Index.

INSTRUCTION No. 69

ENGINE BEARINGS: Main Bearing Adjustments; Fitting Bearings; Scraping, Burning-In, Boring, Reaming, Lapping, Etc.; Crank-shaft Alignment; Cam-shaft Adjustments; Connecting Rod and Piston-Pin Bearings and Alignment; Relation of Vibration to Balance

ENGINE BEARINGS[1]

With the exception of lubrication, the most important factor in the operation of an automobile is the condition of the bearings.

The most important bearings in an engine may be classed in four divisions:

1. Crank-shaft main bearings.
2. Lower connecting-rod bearings.
3. Upper connecting-rod bearings.
4. Cam-shaft bearings.

There are three different kinds of bearings: ball bearings, roller bearings and plain bearings. The last-mentioned is the type in general use. The ball bearings have been used to a limited extent on the racing type of engines, and the roller bearing is seldom used at all.

Ball bearings are sometimes used for main crank-shaft bearings, but very seldom.

To insure success, they should be large. On the Stutz racing engine the balls are over 1″ in diameter. It must be remembered that the surface contact of a ball with its race is practically a mathematical point. For this reason they are not found to be successful for connecting-rod lower-end bearings, for the impact is too great for such a small surface.

Where there is a whip, even of small degree, ordinary ball bearings should never be used unless they are of very great size. In a short, stiff shaft with a center bearing, ordinary sizes and types are satisfactory, but otherwise double-row bearings of the self-aligning order are used.

Where a crank shaft is fitted with ball bearings, the crank shaft must either be a two-bearing crank shaft, as, for instance, the Autocar truck engine, which is fitted with a crank shaft of very large diameter, so that the bearings can be fitted at each end of the shaft, or, if more than two bearings are used, then the crank shaft must be of the built-up-type, as it would otherwise be impossible to place the ball bearings over the center bearings of the crank shaft.

Roller bearings are likewise seldom used. These have, of course, a very much greater contact area than ball bearings, and have been used in the connecting-rod lower end, but not as a general practice.

Plain Bearings

The plain bearing: This is the type most used. Formerly, hard steel and phosphor-bronze bushings were regarded as the best combination, but in modern practice, where large bearing surfaces can be used, white metal or babbitt bushings are usually employed in preference.

In the case of small bearings which must sustain a heavy shock—such as, for example, the big, or lower ends of the connecting rods—white metal is scarcely hard enough to resist the spreading action of the impact. Phosphor-bronze, or a composition metal, is therefore necessary here; but where sufficient surface can be obtained to insure against this tendency, white metal—owing to its anti-frictional properties—is generally considered preferable. Since it is composed largely of lead, the result of a failure in lubrication from any cause is merely to melt it out without harming the shaft, which would probably occur if a tough metal like phosphor-bronze were used.

The secret, therefore, of a successful white-metal bearing, or indeed of a bearing of any kind, is a true and highly polished surface on the journal. The white-metal bearing can then be fitted comparatively tight, and will rapidly accommodate its surface to that of the steel, and long life will be insured if the lubrication is correct.

The essential requirements to be considered in a bearing bushing are that it should have anti-friction properties, so as to withstand the heavy impact or pressure against it during the hard pulls and high-compression impulses and at high speeds, without heating; it should be hard enough not to give, crack, or break under severe shocks and blows, and must be of such a construction as to be easily renewed when worn.

There are two kinds of bearing metals, (1) those which contain a greater percentage of copper and a small amount of softer metals, which are known as hard metals, such as brass or bronze; (2) those which contain a large proportion of tin or lead and a small percentage of copper, known as soft metals, as babbitt metal, anti-friction metal, and white metal.

The soft metal is generally used because the bearing can be renewed more easily. The soft-metal bearing does not have sufficient strength, alone, to sustain the weight and impact of the rotating parts; consequently it is usually used as a liner in a bearing and bearing cap, and is thus termed a "bushing."

The soft-metal bushing, or **babbitt,** can be run in a molten state into the bearing shell or cap, which is composed of tougher and harder metals.

White-metal bushings are usually die cast, and are placed into the bearings.

The bearings which are most dealt with on an engine are the crank-shaft main bearings, the upper and lower connecting-rod bearings, and the piston-pin bearings.

Crank-Shaft Main Bearings

The main bearings of an engine in which the crank shaft revolves are usually constructed as shown in Fig. 1.

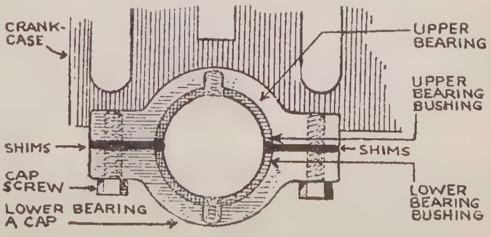

Fig. 1

---

[1] See Index under "Tractor and truck engine bearings."

The upper part of the bearing is a circular depression cast in the lower part of the crank case, into which is fitted an upper bearing bushing.

The lower part of the bearing, which bears the weight of the crank shaft and the thrust of the impact of explosions, is in the form of a cap, termed a lower main bearing cap, which is fitted with a lower main bearing-cap bushing. This cap is held securely around the crank-shaft bearing by being bolted to the upper half of the bearing by cap screws. It is made of steel or brass, or bronze.

Bearing Bushings

The upper bearing and lower bearing cap are lined, or bushed, with soft metal, such as babbitt or white metal.

There are two kinds of bushings: the **solid bushing** which is not removable, and the **die-cast bushing** which is removable.

The solid babbitt bushings are those where babbitt metal in a molten state, is poured, or run, into the upper bearing and the lower bearing cap, and thus they are lined with a stationary babbitt lining which cannot be readily removed.

When bearings which are lined with babbitt metal become worn, the bearing cap can be drawn up by filing; or, if shims are used, they can be removed and the cap can be drawn up as the wear increases; or, if they are too badly worn, new babbitt bushings are run into the upper bearing and lower cap.

The babbitt metal bushings as used on the Ford engine, for example, are of the solid type. In this case, the old babbitt is removed and the surface on which the babbitt is to be poured is tinned and the molten babbitt metal is run in around a mandril smaller than the shaft. A true bore slightly less than the shaft is then made with a boring tool and is reamed with a clearance for an oil film, after which the necessary oil channels are cut in the surface of the bushing.

Die-cast bearing bushings are removable. They are cast in separate dies, with either steel, bronze, or brass backs lined with white metal or anti-frictional metal alloy, similar to babbitt. These bushings are fastened to the bearings and the bearing caps by means of rivets and pins, or screwed with countersunk screws—usually the latter.

The split removable die-cast bushing just referred to is shown in Fig. 2. Another type of split removable bushing is shown in Fig. 3, known as the Ryerson reinforced bearing bushing, and consisting of a bronze or steel skeleton used in combination with babbitt or other bearing metals.

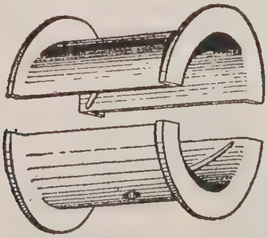

Fig. 2. **The die-cast split removable bushing.** The part above fits into the upper bearing and the part below fits into the lower bearing cap.

Die-cast bearings are usually constructed of a composition metal, die cast in a steel or bronze shell under pressure, then soldered and locked at both ends, thus eliminating the possibility of the babbitt coming loose from the shells. The bushings are also sometimes all die-cast babbitt, without the bronze or steel back.

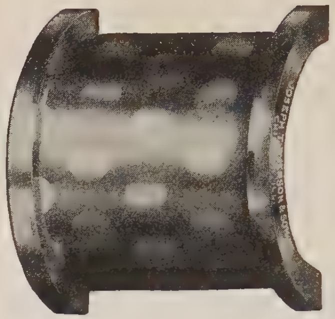

Fig. 3. The Ryerson bearing bushing—a die-cast split removable bushing.

When bearings which are fitted with die-cast bushings become worn, the bearing cap can be drawn up by removing the shims between the bearing and the bearing cap, or, if shims are not used, by dressing down the sides of the bearing caps.

If badly worn or burned, the old bushings can be removed and new ones can be substituted, or old ones may be scraped without removing. Usually all that is necessary is to remove the shims and tighten up the lower bearing cap.

Bearing Clearance

The space between the bearing bushing and crank-shaft main bearing pin, when the bearing cap is drawn tight, is about .002″, this space being divided on both sides of the crank pin, making a clearance of .001″ all around the circumference of the crank pin, which space is **occupied by a film of oil.** While this condition exists, and if the metal of the bushing remains hard without giving under the constant pounding of the power impulse and vibration, this oil film remains unbroken and the bearing remains in perfect condition. But the softer metal will, in time, give way to the pounding and vibration, with the result that the bushing will wear oval-shaped, because the weight of the crank shaft and the thrust of the power impulses will all concentrate on the lower bearing bushing. Most of the wear is thus at the bottom. In fact, practically all of the weight and most of the wear is on the lower part of the bearing, called the lower bearing cap. For this reason there is not much wear on the top. The 1910 Ford engine did not have a bushing in the top of the crank-shaft bearing at all.

If the bearing bushing is hard, or if a hard spot should develop in the bushing, the **crank pin** itself will wear flat on the pressure side.

Whenever a bushing in the crank-shaft main bearing has become worn until the inner surface is no longer absolutely round, it makes itself known by a peculiar **knock,** perhaps more like a heavy rumble, or vibration, than a sharp distinct knock. This rumble is usually more noticeable at speeds of 35 to 40 miles per hour.

On examination it will be found that the fit is loose and that the shaft has an excessive amount of "play" or lost motion; in the case of a main bearing, the shaft then is out of alignment.

The cause of bearing knocks: An article in the *American Automobile Digest* covers this point very clearly, and is as follows:

"As soon as the clearance between the bearing and the shaft exceeds the natural thickness of the film, the rod will begin to knock. The **oil film** thickness varies with the grade of oil used and the pressure on the bearing. Common usage and design allow from one to two one-thousandths of an inch to be taken up by the thickness of the oil film. Bearings should not be allowed to run loose for any length of time; when the knocking or pounding is first noticed, time should be taken to make a proper job of bearing fitting and replacement or adjustment, as the case may be. If the bearing is allowed to pound, it will wear the crankpin oval, making it impossible to fit a new bearing perfectly without removing the crank shaft and having the pin reground to the proper size."

Oil grooves in bearing bushings are treated on page 171. Do not forget, when taking up on bearings, to examine the oil grooves. They may be worn thin, and should be opened up.

MAIN BEARING ADJUSTMENT METHODS

Where main crank-shaft bearing bushings are only slightly out of round, or worn, the bearing cap can be drawn tighter by adjusting the lower bearing cap.

There are two methods for adjusting or taking up on a lower bearing cap so that it will be tighter on the shaft: (1) by removing the shims; (2) by dressing down the sides of the bearing cap.

Usually, the rear main bearing, owing to the increased weight of the fly wheel, is the one which wears first, and usually the bushing in the lower bearing cap wears most.

Adjusting a Bearing by Removing the Shims

Taking up main bearings: First, take down the oil pan. To do this remove all the bolts underneath, and all bolts at each end of pan. Then remove the lower oil pan. The bearings on most engines are fitted with brass or other forms of separators of a standard thickness, made up of thin shims in various gauges, .001" to .005" thick.

Shims: On modern bearings there are usually three shims of different thickness, under each side of the bearing cap, the thinnest shim being at bottom.

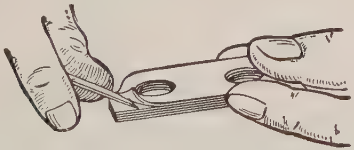

Fig. 4. **The laminum shim:** Note the **laminated layers of metal** similar to thin brass. In the illustration, the top layer is being started with a knife blade, enough to get a hold, then it can be peeled off. (Laminated Shim Co., 533 Canal St., New York.)

The type of shim generally used is the laminated shim shown in Fig. 4. It is made of thin layers (.001" to .005" in thickness) of laminum, which can be peeled off as desired. This type of shim can be used in the main crank-shaft bearings and also in the connecting-rod lower bearings.

To make proper adjustment, simply remove one or more thin shims from each side of the bearings.

The bearing cap, usually referred to as the lower bearing, must be drawn up tight, not against the shaft, but against the shim or spacing sleeve. If drawn tight against the shaft, it will burn out, and if left loose, it will pound and perhaps strip nuts off the cap screws. A really good mechanical job cannot be made without shims or their equivalent.

Adjustment of Reo Main Bearings; Removing Shims

As an example of a main bearing adjustment, the main bearings on the Reo models "T6" and "U6" are shown in Fig. 5.

The main bearings are adjusted as follows: Having removed the underpan from the chassis frame, unscrew the three small cap screws which fasten the cam-gear housing cover to the oil pan and the 18 cap screws which fasten the oil pan to the crank case. If care is exercised, the oil pan may be dropped down without necessitating the draining of the oil or previous disconnecting of the oil pump.

Fig. 5

Now remove the locking wires which anchor the nuts. Turning these nuts off their studs will permit the bearing cap to be taken off.

Remove one lamination from each of the metal spacing shims provided; replace the cap; tighten the nuts, and if the crank shaft still turns easily, repeat the operation **until a slight tightness can be detected.** It is good practice to adjust each bearing separately.

For example, let us suppose that with the spark plugs removed (thereby eliminating compression) the crank shaft can be turned over very easily. Commence with the first main bearing and adjust it properly, following the directions as given above. Were we to allow this bearing to remain properly adjusted, some difficulty would undoubtedly be experienced in detecting the exact tightness of the second bearing. Therefore, in order to ascertain this point, slack off on the first bearing just a trifle.

When the second bearing has been correctly adjusted, slack off on the nuts a trifle, and adjust the third bearing.

After the fourth bearing has been adjusted, the other main bearings should be drawn up snugly and the **locking wires** replaced.

Testing after adjusting: If the main bearings have been properly adjusted, no difficulty should be experienced in turning the engine over with the hand starting crank.

When testing the bearing, keep in mind that while it should have no appreciable amount of looseness, this does not mean that the drag on the shaft should prevent its free rotation, or so that you can spin the crank shaft with the hand crank, with the spark plugs removed. When all main bearings are properly adjusted and the caps are bolted in place, the crank shaft should be just loose enough in the bearing to permit revolving it by hand or turning it readily with the fly wheel, and without the assistance of a bar or pry.

Remember, there is a possibility of getting the bearings too tight, and under such conditions the babbitt alloy in the bushing is likely to cut out quickly unless precaution is taken to run the engine **slowly** for the first few days, with plenty of oil.

When bearings have been taken up, replace the oil pan, being careful not to damage the gasket, and do not forget to see that **all nuts** are securely tightened and that the cotter pins are inserted.

Note the Reo method of replacing the oil pan: Care must be taken in replacing the oil pan, as there is danger of damaging the gasket for the cam-gear housing cover and causing oil to leak from the front end of the engine. A thin strip of tin placed over the gasket will serve as a guide for the oil pan, and prevent damage to the gasket. Before fastening the pan in place, withdraw the tin strip. Best results can be obtained by fastening up the pan on the left side of the engine first. In this manner it is possible for one person to guide the pump plunger into its barrel while raising the right side of the pan in place. Before replacing the underpan, be sure that all cap screws are tightened securely.

If the bearings of an engine are not fitted with shims, which is unusual, then it will be necessary to dress the sides of the bearing so that it will make a closer fit.

Adjusting a Bearing by Dressing the Bearing Cap

Where there are no shims between a bearing cap and the upper bearing by which adjustment can be made, as previously explained, the bearing cap must be dressed down so that it can be drawn tighter around the shaft pin.

The bearing cap can be dressed off on the sides by filing (termed "draw filing") or by dressing the sides down on a sheet of emery paper. This work requires careful and painstaking effort, and frequent inspection or checking while dressing down.

When removing a bearing cap, always inspect the bushing to see if the babbitt is damaged to such an extent as to need scraping, or if the bushing is burned out or worn so thin that the bushings should be replaced. Usually the bushing in the lower cap wears most. If it is a solid babbitted bushing, a new cap with bushing in it can be used to replace the damaged one, or if it is a removable bushing, the bushings can be replaced. Usually, however, when this is the case, it will be found that all bearings must be replaced and properly lined up by scraping, or burning-in, or reaming, as will be explained farther on.

If the engine is on the bench, it is also advisable to **inspect the crank-shaft pins** and see if they are smooth and are not scored or cut, or worn oval or flat, or out of round, for if they are, then the attempt at adjustment will be time lost.

In this case, the crank shaft should be removed and tested (explained farther on), and bushings properly fitted.

If the crank-shaft pins are in good condition, and the babbitt bushings have not been damaged, the cap can be dressed down by draw-filing with a large mill file, as shown in Fig. 6. The repairman must exercise great care to hold the file squarely on the cap (see Index under "Draw filing").

When the cap has been dressed down sufficiently, try the surface of the cap for high spots, by holding a scale across it at several points and angles, as shown in **Fig. 7**, or try it on a surface plate (a smooth steel slab) by tapping the cap lightly with the fingers at several points to note any slight variation in the surface. If the cap is rubbed lightly over the surface plate and dark spots appear on the surface, these are the high spots and they should be dressed off with the file until they are distributed evenly over the surface of the cap.

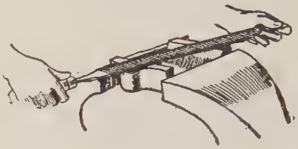

Fig. 6

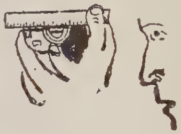

Fig. 7

Another method for dressing a bearing cap down on the sides, especially where one is not an expert with a file, is to cut the edges or sides of the cap down on a sheet of emery cloth glued to a perfectly flat hardwood block, a sheet of glass, or a steel surface plate. Any workman can perform the job successfully this way.

Unless filing is carefully done, the edges of the work are practically certain to be filed out of line, resulting in twisting when the cap is pulled down.

To test after adjusting: The bearings should not be fitted too tight or too loose. Follow the plan for testing the resistance of the crank shaft in the bearings after adjusting, as given on page 786.

Note: When removing bearing caps, be sure to **mark them** so that they can be replaced, and always put oil on the bushings when replacing a cap.

On most engines the main bearing caps, as well as the connecting-rod caps, can be taken up or adjusted by removing the oil pan and **without removing the engine from the frame,** or the crank shaft from the engine. On the Ford, the front and center main bearings can be adjusted without removing the engine; but in order to do any work on the rear main bearing, it is necessary to remove the engine.

Renewing Damaged Bearing Bushings

Where a bushing is damaged by being burned, scored, or worn thin, it must be renewed either by fitting new bushings, if of the removable type, **or** by rebabbitting, if of the solid babbitted type.

Crank-Shaft Alignment

When doing this work, the important point to bear in mind is that **the crank-shaft main bearing pins must be in perfect alignment with the bearings.** If one bearing bushing surface is lower or higher than the others, this will cause great vibration as well as wear. Thus the purpose of fitting the bearings is to align the bearing surfaces to the crank-shaft main bearing pins.

Inspect the crank-shaft bearing pins before fitting bearings: Before fitting the main bearings or connecting-rod bearings to a crank shaft, it is necessary to test the crank shaft to find out if it is out of alignment itself, by being bent or sprung, or if the bearing pins are worn flat or oval, or if they are scored, cut, or rough (explained farther on).

METHODS OF FITTING AND ALIGNING BEARINGS TO THE CRANK SHAFT

There are several methods of fitting and aligning bearings to the crank-shaft main bearing pins:

1. By "spotting-in" and scraping.
2. By boring, then reaming, then "spotting-in" and scraping, then "running-in" in oil.
3. By boring, reaming, and burning-in, which might be termed "melting-in"; then "running-in" in oil.
4. By boring, then reaming, then "running-in" in oil.

Either of these processes can be used, and all are intended to accomplish the same purpose, that is, to give a good bearing surface and to align the bearings with each other and to the crank-shaft main bearing pins.

Spotting-in and Scraping a Main Bearing (1)

Usually, for all ordinary wear, the adjustment of bearings is all that is necessary (for removing shims or dressing the sides of the bearing caps as the wear increases; more often by removing shims), and the removal of the oil pan is usually all that will be required.

Where bearings are spotted-in and scraped, it is necessary to remove the engine from the frame of the car.

To scrape and spot-in bearings: Remove the engine from the frame by means of a hoist or otherwise; remove the pistons; remove the oil pan and cylinders, or the cylinder head, if of a detachable type.

Mark each part when removed: Before disassembling the bearing caps to remove the crank shaft, the timing gears should first be carefully marked, as also the pistons, etc., that were removed, so that they can be assembled later on in their proper place. Usually, the connecting rods and caps are marked as shown on page 800.

Turn the crank case on its side, preparatory to removing the crank shaft. The crank case will then look something like that shown in the illustration (Fig. 8).

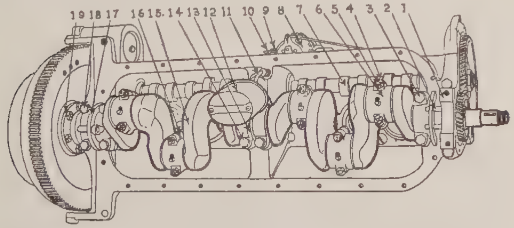

Fig. 8. Crank case with crank shaft in place (Nash "six," series 681 engine): (1) front bearing cap; (2) oil ducts to carry oil back in crank case; (3) crank-shaft front bearing screw; (4) connecting-rod lock nut; (5) connecting-rod bolt; (6) connecting-rod cap; (7) cam; (8) ignition distributor (Delco); (9) and (10) set screws for distributor; (11) oil pipe from pump to distributing tube; (12) oil-pump screen; (13) center bearing cap; (14) center-bearing lock screw; (15) crank shaft; (16) connecting-rod shims; (17) rear-bearing cap; (18) rear-bearing lock screw; (19) crank-shaft fly-wheel flange.

The oil-pump screen (12) is removed, as well as the fly wheel, by disconnecting it at the crank-shaft fly-wheel flange (19). Mark the fly-wheel bolt holes.

The connecting-rod caps are then removed and marked, as are also the connecting rods themselves.

The crank case is then turned up-side-down, and the main bearing caps (1, 13, and 17) are removed. Be sure to mark each one carefully.

The crank shaft is then removed and the work of spotting-in and scraping will be done on all of the upper bearings first, in order to have the crank shaft align with them.

Before proceeding further, **the crank shaft should be inspected for alignment,** etc., as outlined on page 792, and as will be explained farther on.

After determining that the crank shaft is in perfect condition, the next procedure is to "spot-in" and scrape the upper bearings.

Spotting-In and Scraping the Upper Main Bearings

Clean the crank-shaft main bearing pins and upper bearings with a soft cloth and wipe perfectly dry.

Then give the crank-shaft main bearing pins a very light coating of blue, or marking compound.

The marking compound is Prussian blue which can be secured at any supply house, and comes ready mixed (lamp black is also sometimes used). A little **dab** on the fingers is sufficient to wipe on the **shaft,** as a very light coat is required. If too much is given, it will run all over the bearing, and spots will show which should not be scraped.

Put the crank shaft in place, and revolve it several times in the upper bearings by hand.

Remove the crank shaft and note in what manner the blue has spotted the upper main bearings. The "high spots" inside the **bearing** will be found marked in blue, showing that at these points the crank touched; but the part which is white was not touched by the crank. Therefore the problem is to get the high spots down until the bearing will mark, or have a blue surface, all over.

This is accomplished by scraping the high spots down, as in Fig. 9, with the scraping tools shown in Fig. 10, which can be secured at any supply house or can be made of old files. This is a slow, tedious job, for if too much metal is removed it cannot be replaced.

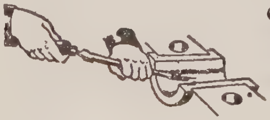

Fig. 9

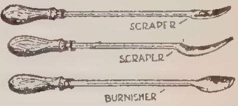

Fig. 10

This marking, or "spotting-in" and scraping process is repeated from time to time till the whole surface is marked, as shown in **(D)** (Fig. 11). In practice, it is not possible to get every white mark off the bearing; therefore continue the scraping and spotting-in until at least three-fourths of the total surface is blue, and the rest will wear in.

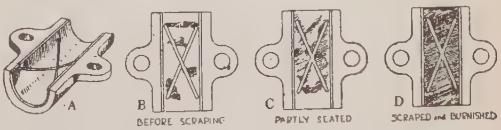

Fig. 11. Showing appearance of markings as the scraping proceeds.

After the scraping is done, the **burnisher** shown in Fig. 10 may be run over the entire surface of the bearing to shine it up and smooth the surface.

If, when first placing the crank shaft in the upper bearings, it is noticed that the end bearings are colored and the center one is not, it is an indication that the center bearing has received more wear than the end ones, and that the end bearings must be reduced in height to bring them down to a perfect line with the center one.

If the center bearing and only one of the end bearings is colored, it indicates that one of the end bearings has worn more than the other two, or that the center bearing has not received as much wear as both end bearings.

Whichever may be the case, the remedy is to scrape the babbitt bearing metal at the required points until the three (or whatever number of bearings there may be) **are in perfect alignment with the crank shaft.**

While marking or "spotting-in" these bearings, the weight of the crank shaft is sufficient. Do not put on the caps at all, as they would force or spring the shaft down and mark the low part of the bearings.

Spotting-In and Scraping the Lower Main Bearing Caps

After the upper main bearings are completed, the lower main bearing caps are treated in a similar manner, being scraped down to a perfect marking.

A very important point is to "spot-in" and fit the rear cap first and to test it for stiffness; then loosen it, then "spot-in" and test the next, and loosen it, and the other likewise. After doing this, tighten down on all. Otherwise, if each bearing is tightened as you proceed, the bearing being fitted could not be properly tested for clearance.

Clearance: After spotting-in and scraping the main bearing caps, the caps are tightened down and "run-in" by belt power, using plenty of oil. The caps are then removed, the bearing surface is examined, then replaced, and proper clearance is given by removing a shim, if necessary.

Adjusting and testing: When the lower caps are fitted and the nuts are drawn up tight, the shaft should turn with some resistance. Some repairmen judge the amount of resistance by being able to move the crank shaft with one hand as shown in Fig. 12. The bearings must not be so tight that they will overheat and seize.

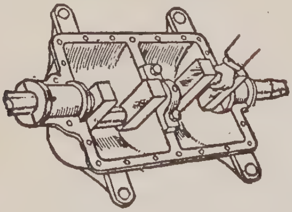

Fig. 12. Testing tightness of main bearings.

Care should be taken in setting up a scraped bearing not to have it as tight as a new bearing, as the metal in the old bearing has been compressed and will not seat itself and wear down, as in the case of a new one. The bearings should not be set up so tight that the crank shaft cannot be readily turned by the hand.

If the shaft turns too hard, do not think that loosening up the nuts is the remedy. In such a case an extra thickness of shim brass will have to be put in, so that the nut can set down tight and still allow the shaft to turn.

If the bushing or metal babbitt lining in a cap is worn badly or is very thin, then new bushings or a new babbitted cap will be necessary. The fitting process will be necessary just the same, however.

Bearing Pointers

After fitting the bearings, run the engine at moderate speed for the first 500 miles, using plenty of good oil to work the bearings in.

Before marking and after scraping, dust all the metal chips out with a small paint brush.

See that the oil grooves are not clogged, and are deep enough.

Wash all parts off with gasoline or kerosene.

Have the scrapers sharp, and never try to scrape with nicked scrapers.

In renewing bearing bushings, care must be taken to see that they are of about the same thickness of metal as the original ones. If too thick, the pistons will be pushed higher into the cylinder and will alter the compression and cause vibration. On two-cycle engines it would change the port timing.

If the crank shaft and timing gears do not mesh deep enough, after scraping the bearings, they will be noisy. Therefore this must be observed, and the upper half must be scraped more to permit a deeper mesh, if necessary.

After fitting bearings, never turn the car over to the owner with the bearings so tight that it is difficult to start the engine with the starting motor, otherwise he will run the battery down in cranking the engine. It is best to have them moderately tight, and then, after the car is driven for about 1,000 miles with plenty of oil, to examine the bearings and see if the cap should be adjusted.

End Play in Main Bearings

End play in main bearings is caused by wear, and the usual remedy is to put in new bearing bushings. Nevertheless, a fairly good repair can be made on the old bearings by building up babbitt at the ends with a soldering iron and some special solder.

The solder is made in the proportions of pure block tin, 1 lb., to half-and-half solder, ¾ lb. These are melted together and poured into sticks. Muriatic acid with zinc (see Index under "Soldering acid") is used to clean the surface, and the soldering is done with a well-tinned iron. After the end of the bearing has been built up, it is then scraped to fit.

On some engines the crank-shaft gear can be removed, and a large washer is placed between the end of the bearing and the gear.

Boring, Reaming, Spotting-in, and Scraping Main Bearings (2)

This is another process for aligning the bearings with each other and with the crank-shaft main bearing pins, which is similar to the scraping process, except that two other operations are added.

The main bearing caps are fitted in place (the crank shaft removed), and then the bearings are bored out on a **boring machine** designed for the purpose. They are then **reamed** with a special reamer, similar to that shown in Fig. 21, page 790, to about .001" larger than the crank shaft.

The crank shaft is then put into place, and Prussian blue is used for **spotting-in** the high spots, which are scraped down as previously explained.

After these processes are completed, the crank shaft is run-in by belt power, using plenty of oil, until the crank shaft can easily be turned by hand.

Boring, Reaming, Burning-in, and Running-in Main Bearings (3)

The burning-in process is supposed to take the place of scraping. By this process, the bearings are aligned with each other and to the crank-shaft pins.

The theory underlying the process of burning-in bearings is that if a very thin skin of the bearing metal next to the shaft is heated almost to the melting point while the shaft is revolving, it will form itself to a 100 per cent running fit. Such perfection is, of course, impossible of attainment. However, the process approaches it closely enough for all practical purposes.

There is some difference in the procedure, depending upon whether the bearing is die cast or of the plain babbitt cast.

In the first case, it is best to remove any gears meshing with the crank-shaft gear, for the reason that so much bearing metal may be shifted that the gears will not bind. If, after burning-in, gears mesh too deeply, the trouble can be easily remedied by placing shims under the upper bearing bushings.

If the bearing bushings are badly worn or thin or loose, then new bushings must first be fitted, either by installing removable bushings or casting the plain babbitt bushings.

If only the lower bearing is worn and it is a babbitt bearing, as on the Ford, a new cap with a babbitt lining can be secured. Usually the upper bearing can be used without rebabbitting.

The die-cast bearing bushings are of the removable type, with either brass or steel backs. They are fitted into the engine cylinder block bearing and cap. This type is most commonly used, as such bushings can be very easily replaced.

The other type is the solid babbitted bearing, which is stationary, being babbitted into the cylinder-block main bearing and cap.

Main bearings may be burned-in instead of replaced if the bushings are not loose or worn too thin, as the burning-in operation removes the worn surface of the bearing and refinishes it as good as new.

As an example, the process of fitting bearings to a Ford engine will be explained.

Babbitting: The first process is to rebabbitt the bearings if necessary. Usually, it is not necessary.

Boring: The main bearing caps are first fitted in place; then the bearings are bored out on a boring machine, as illustrated in Fig. 20, page 789.

Reaming: After the bearings have been bored out, they are then align-reamed to 1.249″ which is .001″ larger than the crank shaft (the crank shaft is 1.250″ in diameter). See also page 714, Fig. 76, for another type of an aligning reamer.

Fitting and testing crank-shaft and bearing caps: After the main bearings have been properly reamed with a bearing-aligning reamer, or roughly hand scraped, as the case may be, the crank shaft is installed by removing the bearing caps. Before installing the crank shaft, test it, as explained on pages 791, 792, 793.

Fit No. 1 bearing very tightly by shimming, leaving a "rock" of from .004″ to .006″, that is, in such a manner that, with the shims in place, it will be impossible to push the bearing cap down to them by hand. The proper distance can be measured with a feeler gage. For instance, a distance of .005″ on one side with the cap pulled down to the shims on the opposite side is equal to .0025″ on each side when the bearing is exactly centered on the shaft. Should it be impossible to fit closely enough by shimming, the bearings may be dressed off on the sides.

After fitting No. 1 bearing, loosen it, and proceed with the remaining ones, loosening each as it is finished.

Sometimes a small high spot in the bearing will deceive one into the belief that the hole is tight. This condition must be guarded against. If such a condition is suspected, the surfaces should be coated lightly with Prussian blue or lamp black and tried by installing the part, pulling it down lightly, and turning the shaft.

High spots should, of course, be removed with the reamer or by hand scraping. Errors had best be made on the side of looseness until experience is gained, as with all bearings pulled down tight, the shaft is subjected to a tremendous strain, which may spring it.

The bearing caps are then drawn down tight on the crank shaft, one at a time, and are then tested out with the turning bar or lever, approximately three feet long, which has two pins in it and fits into the flange of the crank shaft.

Burning-in the main bearings: Each bearing should be shimmed up to the same amount of tightness, and should then be put in the burning-in machine (Fig. 13), connected with coupling (**D**), then clamped tight with clamp rods (**CC**).

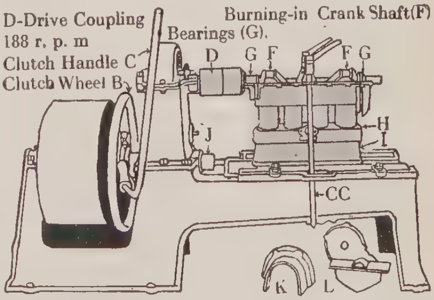

Fig. 13. **Fairbanks burning-in machine.** Burning-in the main crank-shaft bearings on a Ford engine. A belt drives the fly wheel. The power is then transmitted through a clutch to the gearing, thence to coupling (**D**), which drives the crank shaft (**F**) at 188 r.p.m. The same operation is used for burning-in the lower connecting rod bearings. The base (**I**) permits the pistons to pass the cylinder block slightly when burning-in the connecting-rod bearings. (Manufactured by the Fairbanks Co., Service Station Equipment Division, 3701 South Ashland Ave., Chicago, Ill.)

The machine is then started by means of the hand lever (**C**) which operates the clutch, and the crank shaft is revolved at 188 r.p.m., by belt power, for about 30 to 40 seconds, until the bearings begin to burn and smoke.

The hand wheel (**B**) (Fig. 13) is for the purpose of testing the bearings to see if the burning-in operation is completed. When this wheel can easily be turned by hand, the bearings are finished.

Usually, the main bearings are burned-in for about 30 or 40 seconds, then oil is poured on the bearings, and after about 30 seconds more, oil is again poured on the bearings. After about 2 to 5 minutes the clutch lever (C) is thrown out, and the bearings are then tested by means of the hand wheel (B). If the crank shaft cannot be turned by one hand, then the operation of burning-in is repeated for a few seconds.

If one bearing should not get as hot as the others, the operation should be stopped and either shims should be removed or the cap should be draw-filed to tighten on the bearing, thus insuring its being burned-in the same as the others.

After the burning-in of the main bearings, the engine is removed from the machine, all surplus metal is scraped out of the oil grooves of the bearings, and the caps are replaced and lubricated.

Burning-In Connecting-Rod Lower Bearings

The main and connecting-rod bearings had best be burned-in separately, the former first.

In order that no time need be wasted, the connecting rods should have been fitted to and aligned with the pistons and the whole assembly prepared in advance of the foregoing operation.

After the main bearings have been burned-in and lubricated, the pistons and connecting rods are assembled to the engine, after the pistons and connecting rods have been tested on the alignment device, as will be explained farther on. The engine is then returned to the machine; mounted on the same base (I) (Fig. 13), which permits the pistons to pass cylinder head block slightly. The operation is then the same as the burning-in operation on the main bearings just explained.

It is well to relieve the tension on the main bearing caps slightly while burning-in the connecting-rod bearings. When burning-in the connecting rods, it is important that, though the pistons and cylinders and main bearings are flooded with oil, the connecting-rod bearings should be kept dry until the running-in in oil process is reached. Should they get even a few drops of oil, they will remain tight and not burn.

Test with the hand wheel (B) to see if the work is completed, and when the hand wheel (B) can be turned over freely by hand, the connecting-rod cap is removed, the oil groove is scraped out, and the job is reassembled.

The engine is now ready for running-in in oil, or burnishing. The main bearing caps are tightened.

Running-in in Oil or Burnishing, Main and Connecting-Rod Bearings

The engine is returned to the machine in an upright position, and instead of base (I) being used, the upper half of the crank case is bolted to the oil sump on the machine at (M). The oil sump is filled with oil to the oil level (Fig. 14).

The engine is run at 550 r.p.m. until it is limbered up to the extent that it is possible to turn over the crank shaft by the hand wheel.

After this operation is completed, the engine is ready for complete assembly and for adjusting, testing, and inspection, before installing it in the car.

Testing, Adjusting, and Inspecting Engine on Machine

The next operation is to **test the engine under its own power on the machine,** as illustrated in Fig. 15.

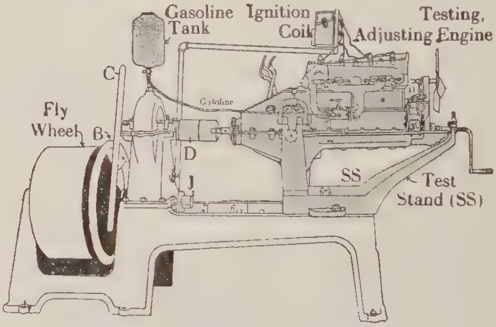

Fig. 15. Fairbanks machine being used for **testing, adjusting and inspecting engine under its own power,** before installing in car. Note that the stand (SS) has been attached to the machine for this purpose.

After the engine has been completely assembled, it is then connected to the machine with the fixture (SS), as shown in Fig. 15; it is then connected with the gasoline tank, which is furnished with the stand. The ignition system is then connected with the battery, and hose connections may be made for running water through the cylinder blocks for cooling. The exhaust should be piped out-of-doors to eliminate fumes.

After the engine is ready for this operation on the machine, the clutch (C) is thrown in and the engine is run until it starts under its own power. The machine is then shut off and the transmission of the engine is set at neutral point and the engine is run until freed up to the point of being able to crank easily by hand.

After all adjustments for oil leaks, ignition, valves, etc., are made, the engine is ready to be placed in the car. It is far better to exercise the several tests described, rather than to have to tear it out again for some trivial reason which could not be detected until the engine had been replaced.

As previously stated, the Ford crank-shaft bearing pins are 1.250″ in diameter. When the aligning reamer is run through the bearings, they are reamed to 1.249″ in diameter. When the burning-in operation is completed, the final clearance will be changed from 1.249″ in diameter to about 1.252″ in diameter, thus giving a clearance between the bearings and crank-shaft pins of about .002″, or approximately the amount which was melted down in the burning-in process. Thus a clearance is gained for the film of oil which is necessary to lubricate the bearings.

A Home-Made Running-in Machine

A very good home-made outfit can be made by using an old transmission to take the place of the clutch. The three forward speeds can be used to give different ratios of speed.

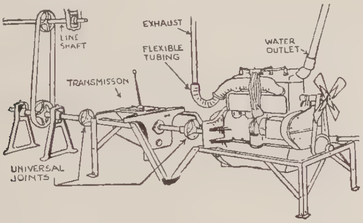

Fig. 16. Home-made running-in machine.

The outfit is shown in Fig. 16. The frame is constructed of heavy structural steel, riveted and welded together as shown. Universal joints of the flexible type are used. Two line-shaft hangers are bolted to the floor to serve as bearings for the driven pulley and shaft. The shop line-shaft is used to drive the device, and pulleys can be fitted to give the necessary speed of about 400 r.p.m.

The engine can be tested on the same stand, and if there is not too much line-shafting connected to the drive pulley, the engine can drive the shop machinery so as to assist further in testing it out under load.

Another simple method for running-in an engine after it is overhauled is to connect the front end of the crank shaft to a shaft driven by belt from the line-shafting. This coupling may be of the starter-crank type.

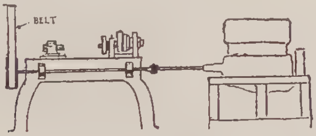

Fig. 17. Simple method for running-in an engine.

The engine should be supported on a low stand and the driving shaft should be provided with a universal joint. The shaft is mounted by bolting it to the legs of a lathe or planer, as illustrated (Fig. 17), and the shaft is driven directly from a pulley on the line-shafting.

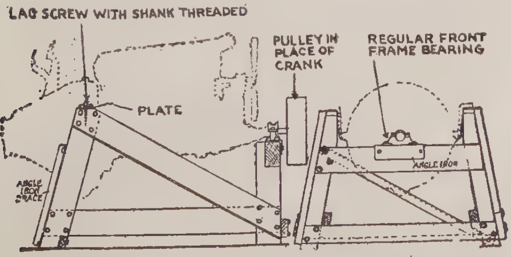

Fig. 18. Home-made Ford engine stand.

Another method for running-in a Ford engine is to construct an engine stand of heavy wood (Fig. 18). A regular front bearing-bracket of the Ford is attached to the stand to form the support for the front end.

Boring, Reaming, and Running-in Main Bearings (4)

In order to fit main bearings properly on a Ford without using the burning-in process, the K. R. Wilson method may be used to advantage.

Mr. Wilson has spent considerable time in research on this particular subject, and in doing so, has developed a combination machine that is well adapted for shops doing Ford work.

If we expect the same results from a rebuilt engine as we do from a new one, the following are essential: (1) new bearings and wearing surfaces; (2) perfect mechanical alignment. To make it possible to do this work quickly and accurately the appropriate machine tool equipment is necessary.

The K. R. Wilson process consists of boring out and then align-reaming the bearings to .001″ larger than the diameter of the crank shaft.

The fallacy of tight bearings: The common mistake of most mechanics is their desire to see a bearing "spot-in" all over even though it shall be so tight that it cannot be turned without a long lever. That idea is wrong owing to two considerations:

1. Expansion which results from the heating up of the motor after it is started.
2. Clearance must be allowed for the oil film.

A tight bearing means metal-to-metal contact. This, in turn, means that there is no room for oil, and the resulting friction will cause the bearing to wear until a .002½″ to .003″ clearance is created.

To prove this, fit up a set of bearings tightly by any known process, whether hand scraping, burning-in, or reaming. Put the motor in a car and run 200 miles. Pull the motor down for inspection; remove any bearing cap; lay a .003″ feeler-gauge on the crank shaft; replace the bearing cap, and tighten it down to its original position. Then see how easily you can turn the shaft by hand by grasping at the crank pins, without any increased leverage. The result proves that the time spent in trying to get a tight, perfect fit was wasted.

Procedure: We will first consider the method of fitting bearings to a new crank shaft. The case of a worn crank shaft will be taken up later.

Re-babbitting: The old babbitt is impregnated with grit and metal particles—so-called abrasives—and if "just tightened up," as in ordinary practice, will soon cut themselves out again and become loose. Therefore the bearings should be ruffed up with emery cloth and re-babbitted as shown in Fig. 19. The same treatment should be applied to the bearing caps if old ones are used. However, it is better always to buy new caps.

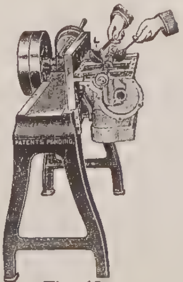

Fig. 19

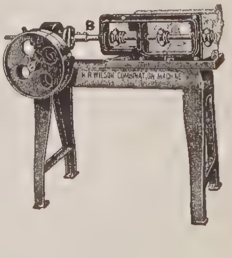

Fig. 20

Fig. 19. The Wilson combination machine being used to babbitt the upper main bearings on a Ford engine.

Fig. 20. The same machine boring out the babbitted main bearings, with caps in position.

Babbitt contains 86 per cent tin, 7 per cent copper, and 7 per cent antimony. The metal is usually heated to at least 800°, while the tin melts at a very low temperature of 450°. It will start to oxidize and to form a dross on top of the metal: a great many repair men think this is dirt, but it is tin. Consequently, each time you skim it, you are reducing the percentage of tin, and the babbitt becomes harder and harder.

Boring the bearings: After babbitting, place your bearing caps in position, bolt down tight, and bore them out **together with the upper half of the bearings.** This operation insures perfect alignment and correct cam-shaft gear centers. The boring is done with three fly cutters, as shown in Fig. 20.

The object of this operation is to prepare the bearings for align-reaming. To do this, the fly cutters are adjusted to bore the bearings so that they will fit the pilots of the reamer.

The main thing to remember in this operation is that the bearings should be bored so that with the pilots of the **main bearing reamer** in the bearings, and the caps on and pulled down, you should be able to turn the reamer by hand. It is also important that they be not too loose. The correct size is 1.244″.

Align-reaming: The boring of the fly cutters is dependent on the hardness of the babbitt. We have already seen that we change this hardness by skimming; therefore we cannot depend on fly cutters for accuracy.

It is therefore necessary to provide **some other means for properly finishing the bearings and bearing caps after they have been rough bored.** To do this a power-operated **aligning reamer** .001″ larger than the crank-shaft bearings is used (Fig. 21). The Ford crank shaft is 1.248″; the reamer is 1.249″. It is equipped with pilots ahead of each cutter.

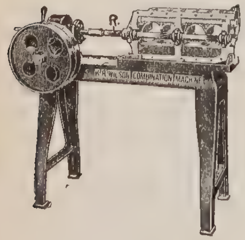

Fig. 21

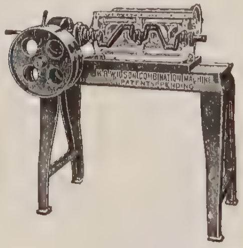

Fig. 22

Fig. 21. Alignment of bearings by reaming the bearings with caps in position.

Fig. 22. Running-in the bearings with the crank shaft in place.

Place the reamer in position; replace the bearing caps that automatically line themselves up; then **align-ream.**

When the reamer is removed and the fillets on all three bearings are touched up with a hand scraper, and the crank shaft is placed in position, draw down the caps tight, and you will have a perfect mechanical fit, .001″ larger than the crank shaft. One reason for running in the extra .001½″ required for an oil film, instead of reaming it, is to permit the bearing to conform to the shape and alignment of the crank shaft. The fit is snug, but not tight. **You should be able to turn the crank shaft with your two hands** without the aid of increased leverage.

In connection with the use of this reamer, it is well to remember that it should be kept well oiled because it will produce much better jobs and the life of the reamer will be increased.

Another point to bear in mind is that the maximum cut which can be made with a reamer is approximately .007″.

Running-in: The reaming process gave us a clearance of .001″; this is not sufficient. Oil the crank shaft (castor oil is preferable). Then the engine should be "run-in" with the Wilson machine (Fig. 22).

A half hour's running-in at normal speed creates the proper oil clearance, but does not destroy the babbitt or spring the crank shaft. With 20 to 1 worm gear and 3½ to 1 belt reduction, the total ratio is 70, and the machine may be driven with a 1 h.p. motor or a line shaft.

Worn crank shaft: In the case of a worn crank shaft, the very first thing to do is to take your micrometer to determine the exact size of the front crank-pin bearing. If you find it worn more than .006″ under size (or 1.242″), it is a good plan to measure at points 90° apart, and if you find it out of round more than .002½″, you might just as well discard it and save any possible trouble.

If it is not worn more than .006″ on the crank-pin bearing, it will never be worn more than .001″ to .003″ on the main bearing, and usually only around .001″ to .001½″ at the most, as the main bearings do not interfere in proportion to the crank-pin bearings.

Therefore bore out main bearings with your fly-cutter boring bar and jig, and, previous to reaming, **place shims underneath the bearing caps to raise them up equivalent to the amount of undersize of that particular bearing.** Proceed with placing the caps in position and draw them tight, then ream. After they have been reamed, **remove the shims,** replace the crank shaft, and draw the bearing caps down tight. You will then have a mechanical fit similar to that described for a new crank shaft.

Conclusion: Use plenty of good oil on the bearings while they are limbering up. Following this process, after the car is run for 300 to 500 miles, instead of a recurrence of the familiar thump, you will have a quiet motor and can be positive of having perfect, long-lasting bearings.

This operation of boring out the bearings and bearing caps simultaneously (Fig. 20) and then align-reaming (Fig. 21), as stated by Mr. Wilson, is the same method used by the Ford Motor Co. and many other manufacturers of automobile engines in the United States. The fact that their motors built by this process stand up is proof that the process is right in principle. It saves two to three hours over the common practice of boring out the upper half of the main bearing and then "hand-scraping" the caps into position.

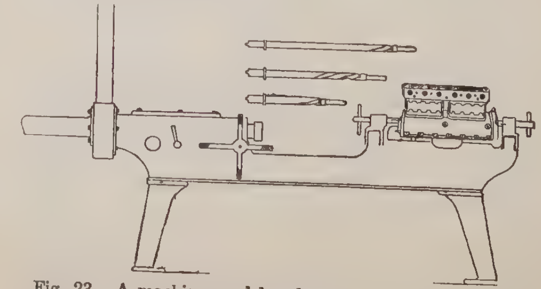

Fig. 23. **A machine used by the Ford Co. for boring and align-reaming bearings with caps in position. The top tool is the boring bar for the front bearing; the center tool is for the center bearing, and the lower tool for the rear bearing.**

A LAPPING COMPOUND FOR BEARINGS

Lapping the main and connecting-rod bearings instead of scraping or burning-in has not been the general practice, owing to the tendency of the hard abrasive to stick to the bearing material and thus to continue to cut the bearing or shaft after the lapping process has been completed.

A compound, known as **"Timesaver,"** can, it is claimed by its manufacturer, be used with perfect safety as it breaks down after it has been in use for a short time. It is composed of large and small crystals, the cutting surface being the large crystal and the small crystal being a neutralizing substance. When the large crystal has been worn down so that the short crystals are in contact with the rubbing surfaces, these are broken up and, owing to their neutralizing action, destroy the cutting qualities of the entire compound. This action generally requires about 10 min.

This product does not contain any form of emery, carborundum, or glass. It is stated that an 80 or 90 per cent bearing can be secured with it in about one-fourth of the time required to scrape the usual bearing. "Timesaver" is soluble in oil, or it can be removed with gasoline or distillate after the lapping operation is completed. It cannot be used for grinding valves, or lapping in pistons and rings, as it does not work on iron or steel.

The method of using this compound is to bore or cast the solid bearings or bushings to a light driving fit on the shaft and grind in with "Timesaver." This is applied very thinly and with plenty of oil. It is ground or lapped with a twisting and turning motion as of a coarse screw or thread. After a few twists have been given, the shaft is cleaned and fresh compound is applied.

A number of other methods can be utilized. Fig. 24 shows the car with the engine in place and the bottom half of the crank case removed. The connecting rods being fitted to the crank shaft are in the reverse position, that is, hanging down.

One shim is removed and the connecting rod is bolted up, just snug, with bearing compound and oil in the bearing, and is rocked back and forth a few minutes, tightening the nuts as the babbitt grinds out. If one application does not produce the desired surface, repeat the operation. A few minutes will generally produce the desired results.

All connecting-rod bearings can be fitted with the engine in one place, at one time, by removing the caps, taking out one shim, applying the bearing compound. Then assemble snug but not tight, rotate the engine by hand, by outside applied power, or by its own power at low speed for about two or three minutes. This will usually finish a set of old bearings, but possibly two or three applications will be necessary on new bearings.

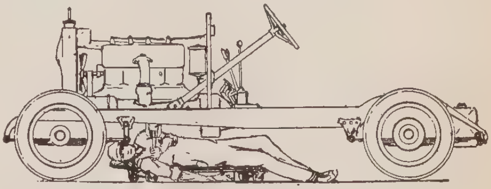

Fig. 24. Showing how the connecting-rod bearings of an engine can be lapped with the "Timesaver" compound.

The main bearings can be treated in a similar manner, and the engine crank case can be inverted and placed on a stand or block. A very good makeshift to turn the crank shaft over in its bearings is to drop the cone belt from the drill press and to use it to drive the crank shaft, using the foot clutch to start and stop the power.

It is claimed that bearings produced in this manner do not have to be assembled as tightly as a scraped bearing, as there are no high spots to wear off and the bearing, if properly done, is a finished job. This product is being marketed by the M. T. K. Products Co., of Seattle, Wash.

Another lapping compound is known as **"Kwik-ak-Shun,"** sold by Edward A. Cassidy Co., 23 W. 43 St., New York. It will eliminate scraping and works with bronze, babbitt, or brass.

The Clover Mfg. Co., Norwalk, Conn., also manufactures grinding compounds.

CRANK-SHAFT INSPECTION AND REPAIR

Before the main bearings, or the connecting-rod bearings are fitted, the crank shaft should be inspected. Some of the **disalignments of crank shafts** can be enumerated as follows:

1. Crank-pin bearings scored or cut.
2. Crank-pin bearings worn oval or flat.
3. Crank shaft bent.
4. Crank-shaft throws out of line with each other; that is, those throws which are supposed to be in line.

Scored Crank Pin

If the crank-pin bearing is **scored or cut** by ridges or rings on it (Fig. 25), it will cut the bearing, causing it to run hot and thus ruin the bearing. Fitting of bearings under such conditions will be a waste of time.

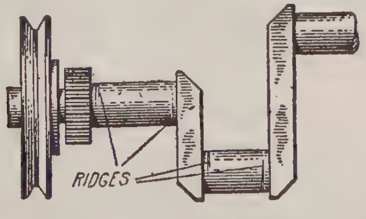

Fig. 25. Scored crank-shaft bearing pin. Note the ridges. This is only a slight score.

Where the crank pin is only slightly scored, the deep ridges or high spots can be removed with a fine Swiss file, and the rough surfaces can be polished off by encircling the shaft with fine emery cloth saturated in oil and making a steady, even motion up and down, as shown in Fig. 26, before lapping.

The strips of emery cloth should be about 1½" wide and well oiled. Emery tape is better, if obtainable. Unless the method shown in Fig. 26 is used, there would be a tendency to make the shaft oval.

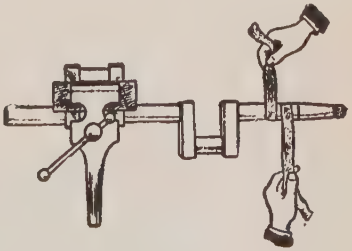

Fig. 26. Cleaning roughened surfaces of crank-shaft bearing pins with emery strips.

Another method is to lap the crank-shaft bearing pin, using a lapping compound and specially made clamps.

Lapping a Crank-shaft Pin

Lapping: Figs. 27, 28 show a form of hand lapper. This consists of a pair of hinged members with a

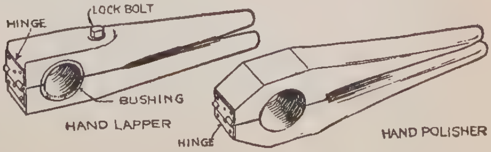

Fig. 27 Fig. 28

Figs. 27, 28. Form of hand-lapping device for crank-shaft pins.

central hole large enough to admit various-sized bushings to conform to the various sizes of shafts. A bolt is provided to hold the two halves together, and the flanges on the bushing prevent the bushing from slipping out the side of the frame.

The lapping is done by applying a fine emery grinding compound[1] and oil to the pin, and clamping the lapping tool to the work. The long handles serve as a lever for the work.

The pins are polished in practically the same way by a pair of long wooden clamps (Fig. 28) constructed on somewhat the same principle as the lapping tool.

The throws on the crank shaft can be lapped in the lathe by setting up the shaft between two centers for the main bearings, and with the use of a special flange for the connecting rod pins. It consists of a special fixture made from a large casting with a base to fasten to the face plate and a long extension arm having a split end for attaching and detaching to encircle the throw to be lapped. (*Motor Age*, by Mr. T. P. Bowman.)

If a crank shaft is badly scored, it will be necessary to put it in a lathe and true it up, or send it to a concern that has special crank-shaft grinding machines.

Crank Pin Worn Oval or Flat

If a crank pin is found out of true, that is, is not circular, by testing with micrometer calipers, and is more than .0015″ out of round, the best plan is to have it trued up on a lathe or ground true on a special grinding machine by a concern that specializes on this work.

If a crank shaft is worn more than .010″, it is usually discarded.

Where a crank pin is only slightly worn out of true and a grinding machine is not available, then file up the untrue part with a fine Swiss file to as accurately a circular shape as possible, testing frequently with the micrometer calipers. The crank pin is then lapped, as previously explained.

The cause of a crank-pin being out of true (where the lower part of the connecting rod fits) is often attributable to a flat spot, due to explosion pressure occurring constantly at one point. The result of this is that the connecting-rod bearing will not fit true and will bind, even though properly fitted. The only remedy is to have the crank shaft ground on a special crank-shaft grinding machine. (H. & H. Machine Co., St. Louis, Mo., grinds crank shafts.)

If a crank shaft (or a cam shaft) is out of true, it will cause the bearings to wear out of round in a very short time and create a knock; therefore, before assembling the crank shaft (or cam shaft) in an engine, they should be tested for concentricity. A machine especially adapted for this purpose is shown in Fig. 29.

To test a crank shaft (or any other shaft) for concentricity, the shaft is placed in the adjustable center posts (**CP**). The needle of the dial indicator is permitted to touch the crank shaft lightly (as at **B**) at various points, while the crank shaft is slowly turned by hand.

The **dial indicator** will measure from zero to one quarter of an inch, and will indicate it in half-thousandths.

The centers (**CP**), may also be used for testing the concentricity of armature shafts on starting motors, generators, etc.

This device is also used for pressing bushings and shafts out of gears, for straightening axles and propeller shafts, etc.

The concentricity of the crank-shaft main bearing pins could be tested as shown in (**B**) on the machine shown in Fig. 29, but the test of the connecting-rod bearing pins on the crank shaft, which are eccentric to the main bearing pins, would necessitate special dogs or jigs for holding it.

If a shaft is found out of true, it is put in the "V" blocks (**V**) (Fig. 29), under the press screw and straightened, then tested again in centers (**CP**) with the dial indicator.

Crank Shaft Bent; Alignment of

A crank shaft may be as much as .020″ out of alignment, yet, notwithstanding, if the three main bearings are perfectly true and straight, after a few revolutions of the crank shaft in the bearings, they will pull the crank shaft within .002″. But of course, this is hard on the bearings. Where a crank shaft is bent, it should be straightened on a straightening press. For instance, it may be placed in the centers (**CP**) (Fig. 29) and the press used on it. Another shaft-straightening press is shown in Fig. 30.

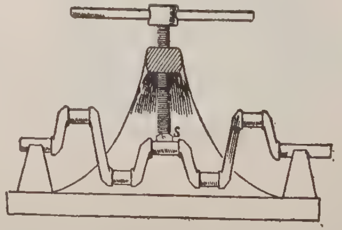

Fig. 30. **A shaft-straightening press.** Care should be taken not to apply too much pressure in the first attempt to straighten the shaft, as it may be bent in the opposite direction. A new test should be made after each attempt of straightening.

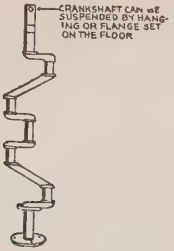
---

[1] The Clover Mfg. Co., Norwalk, Conn., supplies lapping compound for this purpose.



CRANKSHAFT CAN BE SUSPENDED BY HANGING OR FLANGE SET ON THE FLOOR

Fig. 31. When **storing crank shafts** it is advisable either to suspend them as shown, or to set the flange on the floor so that the crank will be straight. It is not generally known that a crank shaft will sag out of line when allowed to lean against the wall, but such is the case. Crank shafts have sagged as much as .002″ or more in this way.

Simple Method of Testing Crank Pin

The crank case may be used with little difficulty as a fixture for testing the alignment of the main bearings of the crank shaft. The case is placed on the bench in the position shown; a strip of pasteboard about 1 in. wide and 1/64 in. thick is placed beneath the front and rear bearings of the crank shaft. By these the shaft is raised from the center bearing and side play is prevented.

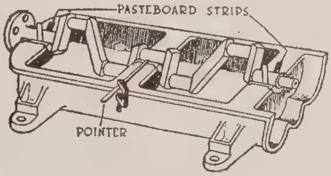


Fig. 32

A pointer is then clamped on to the side of the case at the center bearing, and by turning the shaft the amount it is out of true is determined. This method is not only better but quicker than testing in a lathe.

One Method of Testing for a Loose Bearing

Run the car over a pit, if possible, although the bare floor will do.

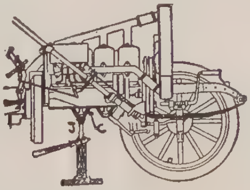

Fig. 33

Raise the car by means of a jack to suit the conditions for testing. If the rod bearings are to be tried, run a jack head against the lower half of the connecting-rod bearing and work the jack handle up and down. The smallest amount of play can be detected in this way, especially on the main bearings, where the pressure of the jack is applied on the crank shaft against the weight of the car and "play." This method is not exactly according to engineering practice, but with a sensitive jack and a sense of "feel," the amount of looseness can be determined to a certain extent.

To test for a bent crank shaft, place it in center blocks, as shown in Fig. 34. A gauge is used or indicator to locate the direction of the bend, if there is any; that is, in relation to the main bearing pins (**MP**), but as the connecting rod pins (CP) are out of line with the main bearing pins, this would require special jigs.

If the shaft is bent, there will be one point of the main bearing pin which will make a contact with the gauge, and as it is revolved the shaft will leave the gauge. This point which makes a contact should be marked with chalk, so that you will know where to apply the pressure to straighten it,

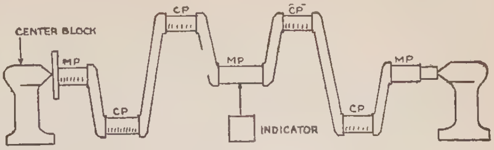

Fig. 34. Method of testing a crank shaft for a bent place. (**MP**) are crank-shaft main bearing pins; (**CP**) are crank-shaft connecting-rod pins.

In testing for a bent crank shaft, one should not be misled by a bearing surface of the shaft that is probably worn out of round; the test should be made at the side of the bearing where little or no wear is liable to take place.

There are few repair men who will undertake to straighten a bent crank shaft, and by many it is claimed to be impossible to make a lasting repair to a shaft which is out of true. However, as the repair man is occasionally called upon to "fix it up," and a straightening press is not at hand, one means employed is shown.

One method of straightening a slightly bent crank shaft is shown. This shaft is bent as indicated by the dotted line (**A**) (Fig. 36), only to a very much less extent, the bend not being visible to the naked eye except when the shaft is revolving in a lathe with a tool or other object held stationary, close to the center bearing surface or crank pin.

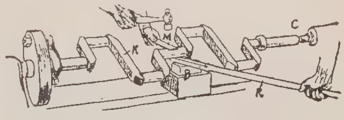

Fig. 35

The shaft (**K**) (Fig. 35) is fixed between the centers (**C**) of the lathe, blocks (**B**) are placed upon the lathe-bed for a fulcrum, and a bar of iron (**R**) or preferably of wood, is used as a lever. If an iron bar is employed, a piece of brass, wood, or lead should be placed between it and the bearing surface of the shaft for protection.

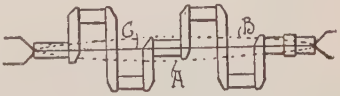

Fig. 36. Bent crank shaft.

Assuming that the shaft is bent as indicated by the dotted line (**A**) (Fig. 36), it is pried up with the bar till it assumes the position indicated by the dotted line (**B**), and while held in this position, an assistant holding a piece of brass (**M**) on the bearing surface with one hand, and with a hammer in the other, strikes the shaft a sharp light blow.

The bar and blocks are then removed, the lathe started, and the shaft tested again for results. This treatment is repeated again and again until the shaft is straight as indicated by the line (**C**). It is generally a long and tedious job, depending greatly upon chance and the ability of the operator of the bar to guess the proper amount of pressure to apply and the proper place at which to apply it.

Crank-Shaft Throws Out of Line

The crank-shaft "throws" are the parts (CP) to (MP). On a four-cylinder engine, the four throws (CP) should be in exactly the same plane or line. When out of line the crank shaft is sprung or twisted.

Such a condition will cause vibration, and may also throw the timing and the firing impulses out of line. In such a case, the valve events and spark would not occur in the correct relation to the piston positions.

One method of checking would be to learn the position in inches in which the piston is supposed to be from the top of the cylinder at the time of the opening and closing points of the valves and to see if it checks properly. On the Ford, these positions are shown on an illustration referring to valve timing. See Index.

CAM SHAFT ADJUSTMENTS

The cam shaft on some engines is a case-hardened drop forging of low carbon steel. It is usually mounted in die-cast bearing bushings.

The usual troubles are worn bushings which produce knocks and end play, and it thus often becomes necessary to replace the bushings.

If the front cam-shaft bearing has worked loose in its bearing, or is worn, the timing gears would be noisy.

If the wear is not too great, the bearing can be tightened by means of an adjustment screw which is provided on some engines, or by removing and copper plating the bearing to compensate for the wear, or by replacing the bearing bushings.

On the Continental engine (see Index) the end thrust, or end play is taken up by regulating an adjusting screw in the timing-gear case cover.

To replace cam-shaft bushings: First, it will be necessary to remove the radiator, then the gear-case cover. Be sure to note the marks on the gears, and if they are not marked, be sure to mark them. Remove the cam gear; remove oil pan; remove the springs and valves; remove the cam shaft, and also remove the carburetor assembly. Put in new bushings and ream them to a fit.

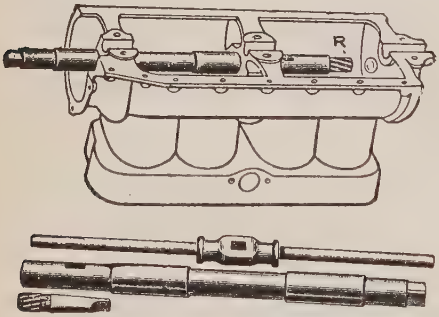

Fig. 37. A cam-shaft aligning reamer.

To prevent cam-shaft knocking, the rear cam-shaft bearings should be reamed in **perfect alignment** with the front and center bearings. An ordinary reamer is useless because the bushing is driven in and usually battered. A good form of cam-shaft reamer is shown in Fig. 37. It is manufactured by K. R. Wilson, Buffalo, N.Y. After the cam shaft is in place and the gears in position, check the valve timing.

If a cam shaft is sprung, it is necessary to remove and straighten it or to replace it with a new shaft.

On the Ford, the front and center cam-shaft bearings are held in place by set screws located in the right hand side of the cylinder-block in line with the cam shaft. The set screws should be removed from the cylinder in order to insure clearance for the cam shaft. The cam shaft is then withdrawn by means of a cam-shaft puller.

The front and center bearings are of the split-bearing type. They are held to the shaft by means of circular springs. These springs are removed by inserting a screwdriver under them, and forcing them off. The cam shaft may then be tried on the centers as shown in Fig. 29 at (B), page 792.

The cam shaft should not run out any more than .0015″. If bent, straighten it on the straightening press.

It is not good practice to remove cam-shaft gear from the cam shaft unless absolutely necessary. If it must be removed, the best plan is to remove the cam shaft and gear to an arbor press and to press the gear off.

Removing a Cam Shaft

(Dodge as an Example)

To remove the cam shaft, the radiator must be taken off and then the front gear-case cover. The cam shaft may then be pulled out after the valve push-rods are tied up, so as not to catch the cams as they slide by, and after the cam-shaft retaining pin (which will be found on the right side of the motor directly back of the ignition unit) has been removed. This pin fits in a deep groove in the center journal. In the first 40,000 or 50,000 cars the pin was held in place by a set screw, but the newer cars have a spring.

Oldsmobile (Model 45B) Cam-Shaft Bearings and Cam Shaft

Cam-shaft bearings: Several thousandths of an inch is left in the bearings which must be removed from the bore of cam-shaft bearings. It is advisable to leave a few thousandths for final reaming. They should be line-reamed when in place.

Cam-shaft bearing adjustments: It is rarely the case that the cam-shaft bearings require attention, because they are exceptionally large. The following is a method to determine **whether this attention is necessary.**

At idling speeds, play in the front bearing, or end play in the cam shaft, causes a dull rumbling noise which may be relieved by pressing against the vertical distributor-drive shaft with a screwdriver. This transmits pressure to the distributor-shaft drive gear and cam shaft, and temporarily removes the looseness causing the noise.

To replace the front cam-shaft bearings proceed as follows:

1. Remove the radiator, fan belt, and hose connection from the water pump to the cylinder blocks.

2. Loosen the retaining clip on the lower edge of the distributor-drive shaft and withdraw the splined shaft and gear from mesh with the cam shaft.

3. Remove the two front engine bolts and jack up the front of the engine about 3 inches.

4. Remove the cap screws from the gear housing, and remove the housing complete.

5. The cam-shaft gear may be removed by means of a special gear puller attached to two tapped holes in the face of the cam-shaft gear.

6. The cam-shaft bearing is thereby exposed to view. It is held in place by an offset lug and retaining screw, removal of which will allow the entire bearing to be extracted.

The new bearings provided are full in length, and may be filed on the end until of a length that permits no end play in the cam shaft. With the new bearing in position the cam shaft should be pulled forward so that its forward shoulder is firmly pressed against the inner end of the bearing, and the outer end should be level with the shoulder against which the cam-shaft gear locks. It should be understood that these cam-shaft bearings are not adjustable, and when looseness occurs, new bearings should be installed and fitted in the manner described above.

If it is desired to remove the cam shaft for examination, this may be done very easily. To do this proceed as follows:

1. Remove the push-rod assemblies carrying the push rods that rest on the cam shaft. These assemblies are located by dowels and bolted in position, hence are easily removable.

2. Draw the cam shaft out through the front, complete with the front bearing.

In assembling, one point is to be observed to obtain correct timing, and that is to crank the engine over until No. 1 piston is at the top of the compression stroke. In this position the fly-wheel marking will be 1-4 U-D-C, and the prick-punch mark on the crank-shaft gear will be at the top. Then if the cam-shaft gear markings be made to coincide with the crank-shaft markings, the valve timing will be correct.

Timing gears-45-B: These gears are matched up in sets to give a clearance of .008″ between the cam and crank gear when fitted, and will have slightly less clearance than this after some use.

These gears are marked "O" for standard, "1-L" for .001″ large, and "1-U" for .001″ undersize. The letters "L" and "U" always appear, but the figure will depend on the number of thousandths of an inch that the gear is over or undersize.

Questions and Answers on Crank- and Cam Shafts

The following questions pertain to the Continental engine (see Index), but are applicable to many other engines:

Question 1: How can the end thrust or end play be taken up on the crank shaft?

Answer: The end thrust of the crank shaft is taken against the front bearing. To adjust this end thrust shims are provided between the crank-shaft gear and the thrust surface of the crank-shaft front bearing. End play is taken up by removing one or more of these shims.

Question 2: How can the end thrust or end play be taken up on the cam shaft and timing gears?

Answer: End thrust is taken up by regulating the adjusting screws in the timing-gear case cover. These adjustments should not be disturbed unless it is plainly evident that they demand attention. To check the end thrust, release the lock nut and turn the screw in until it touches against the end of the shaft. When this contact is felt, the screw should be backed off one turn and the lock nut re-tightened.

Question 3. Can the piston and connecting rod be taken out from below without removing the crank shaft, and is that the best plan?

Answer: Piston and connecting rod assemblies can be removed from below without disturbing the crank shaft. This is decidedly the best arrangement. Not only can the pistons be pulled, but every bearing of a Continental engine can be got at readily by removing the oil pan. Engines are assembled and inspected in this manner during the process of manufacture in the Continental factories.

CONNECTING-ROD AND PISTON-PIN BEARINGS

There are two types of connecting rods in general use, as follows: (1) the connecting rod using a **stationary** piston pin (Fig. 38); (2) the connecting rod using an **oscillating** piston pin (Fig. 39).

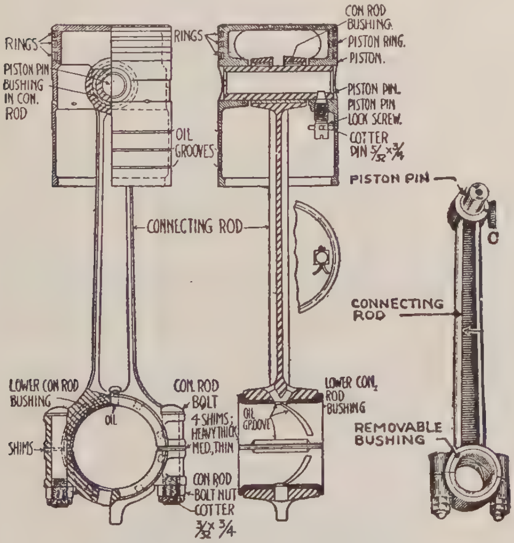

Fig. 38

Fig. 39

Connecting rods are usually made of I-section drop forgings of nickel steel. Bearings are usually die cast of special metal. Bearing-cap studs are nickel steel.

Connecting-Rod Upper End

The piston pin or wrist pin is the pin on which the upper part of the connecting rod swings. It is sometimes made of solid steel, but usually of hollow case-hardened steel tubing. It is also called a "gudgeon" pin. It is non-adjustable, and therefore, when worn, the piston pin or bushings must be renewed.

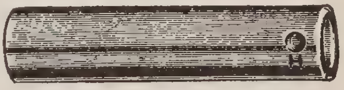

Fig. 40. Piston pin showing hole (H) where the lock screw (Fig. 38) holds the pin stationary.

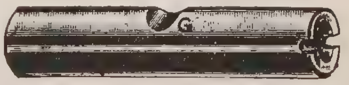

Fig. 41. Piston pin showing groove (G) where clamping bolt (C) (Fig. 39) is clamped tight to the piston pin.

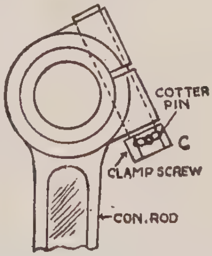

Fig. 42. Showing clamping screw which clamps the connecting rod to the piston pin. Oil holes are provided in the pins to lubricate the pin and bushing.

The stationary piston pin (Figs. 38 and 40) is used where there is one bronze bushing in the end of the connecting rod, which oscillates on the piston pin. The pin is held tight by a set screw at hole (H) (Fig. 40).

The oscillating piston pin (Figs. 39 and 41) is where the piston pin is clamped to the upper end of the connecting rod, as shown in (C) (Fig. 39) and more clearly shown in Fig. 42. The bronze bushings in this instance are pressed into bosses in the piston, and the piston pin oscillates in the bronze bushings.

The first bearings of an engine to manifest the effect of wear, in normal service, are the connecting-rod bearings. They are next to the piston and rings in importance.

Connecting-Rod Bearing Knocks

A method for determining a loose connecting rod is explained and illustrated in the *American Automobile Digest* as follows:

"After continued use they become worn, producing a dull thud or pound, especially noticeable when the engine is suddenly accelerated or speeded up. This is due to the fact that the bearing becomes elongated, as shown in Fig. 43, since the pressure is in one direction only. For this reason the knock is dull and is usually worse when the engine is idling.

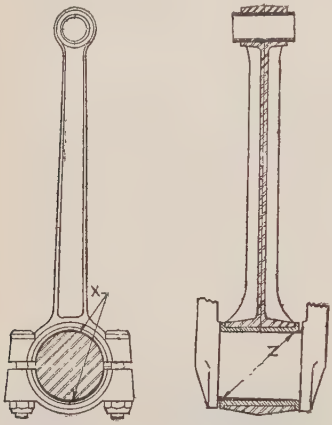

Fig. 43. This illustrates how the crank-pin bearing wears. At (X) is shown natural wear, while at (Z) is shown the wear caused by a bent or twisted rod.

"The best method of **locating a worn connecting-rod bearing** which has started to knock is by short-circuiting the spark plug, when two knocks will be noticeable, since the explosion pressure is eliminated. In addition to being caused by a worn bearing, the knock can also be caused by a twisted connecting rod, scored bearing, burned out bearing, or end play. In the case of a seized bearing or one that has been burned out, due to a lack of oil, the motor will also groan when starting cold.

"**A worn piston-pin bearing** can easily be distinguished by a sharp metallic knock occurring twice when the spark plug is short circuited. The knock will appear regularly, and is very sharp when the engine is pulling hard."

Removing Pistons and Connecting Rods from Engine

It is necessary to remove the pistons when working on the wrist pin.

The method of removing the piston (Overland, for example) is to take off the bottom half of the crank case and then remove the connecting-rod bearing cap from the rod attached to the cylinder which it is desired to remove. The bearing cap is held by two bolts fastened by castellated nuts. When these are removed the rod can be swung to one side out of the way of the crank shaft and the entire assembly can be withdrawn from the cylinder in the manner illustrated (Fig. 44). The piston pin can then be driven out with a punch, after which the bushing can be removed.

This method cannot be applied to all engines. Such work as this is usually done by removing the engine from the frame, and when engine is disassembled.

Be sure to mark all parts when removing them, so that they can be assembled in their respective locations, as before disassembling.

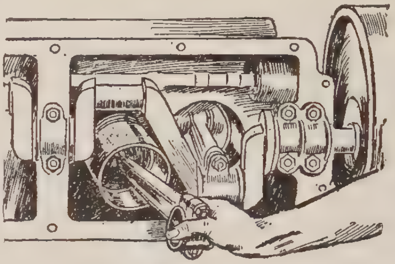

Fig. 44. Method of withdrawing piston and connecting-rod assembly after the bottom half of the crank case has been removed.

Removing Piston Pins and Bushings

To remove the piston pin of the stationary type, the cotter pin and lock screw (Fig. 38) is removed with a cotter-pin puller and a special socket wrench which will fit into the space.

The piston pin is then pressed out, which is not always an easy task. One method of removing a piston pin is shown in Fig. 45, and can be resorted to if the piston pin is hollow, so that the shaft can be run through it.

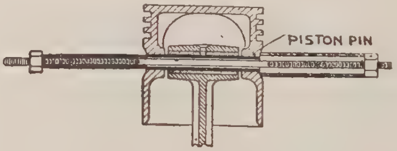

Fig. 45. **For removing piston pin or bushings,** a rod is turned to slide freely through the bushing and is then threaded S.A.E. standard. The pulling bushing is made slightly smaller than the hole in the piston.

To remove a piston pin of the oscillating type, loosen the lock screw (C) (Fig. 42) with a special wrench; then press the piston pin out of piston bushings.

Sometimes a tight piston pin can be more readily removed by plunging the piston in boiling water. This will tend to loosen the grip of the piston on the pin and will then permit it to slide out.

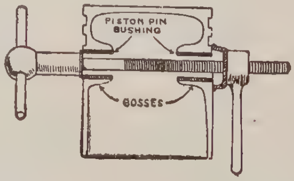

Fig. 46. Method of removing the two bushings from the piston bosses where the piston pin oscillates.

For removing the two bushings from the piston where an oscillating piston pin is used, refer to Fig. 46.

For removing the one bushing from a connecting rod (upper end), where the stationary piston pin is used, see Figs. 47, 48, 49.

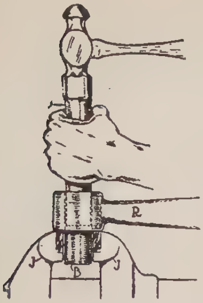

Fig. 47

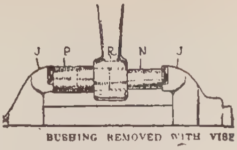

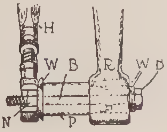

Fig. 48 (upper)

Fig. 49 (lower)

Fig. 47. **One common way to remove an upper connecting-rod bushing.** Jaws (J) of the vise are opened far enough so that the end of rod (R) rests upon them and at the same time gives sufficient clearance for the bushing to pass between, as it is driven out. To drive out bushing (B), a drift (D) (usually a bar of steel) and a hammer are required.

Fig. 48. **A better way:** Jaws (J) of the vise are opened wide; a piece of pipe (P), large enough to clear the bushing, is placed against the inner surface of one jaw; the rod is carefully adjusted and pressed against it to hold it in place until the drift or solid pin (N) is adjusted into place. Then draw the vise together to squeeze the bushing out of rod (R) into pipe (P). If no vise is at hand with a large enough opening, recourse can be had to the method shown in Fig. 49.

Fig. 49. **Another plan:** A bolt (B), some washers (W), a piece of pipe (P), a nut end, and a wrench (H) may be employed as shown. By this method, a bushing may be removed without danger of springing or burring up the connecting-rod end.

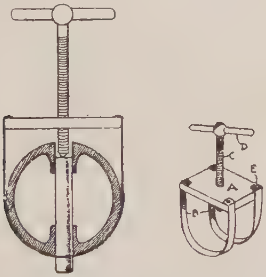

Fig. 50. **A piston-pin remover.** (A) is flat iron tapped to take screw (C). Flat iron bands are attached so that they can be placed around the piston, then the screw is forced against the wrist pin (piston pin).

Fig. 51. **Fairbanks Universal piston vise and press,** designed especially for removing piston pins and bushings.

If oversize reaming is necessary for bushings, the same device can be used to hold the piston for the operation. This device will also hold the piston while fitting rings to the piston, or for scraping carbon from the piston, or while the top, or upper part of the connecting rod is being clamped to the piston pin.

This vertical vise can be used for many other jobs, as the "V" jaws have a babbitted lined surface which will not injure the finish of the piston.

Fitting Piston-Pin Bushing[1]

Where the oscillating type of piston pin is used, the bushings are fitted in the piston bosses after the old ones have been driven out. Very often, instead of pressing out the old bushings, they are reamed oversize, and an oversize piston pin, usually .0025″ or .005″ oversize, is substituted.

To check the play between the piston pin and the piston bushings (Ford piston, as an example), hold the piston with the piston pin perpendicular to the bench with the left hand (Fig. 52), while with the right hand the connecting rod is forced up and down in such a way as to cause the pin to be forced against one side of the bushing and then the other. If there is any play, a new pin should be fitted and, if necessary, the piston bushings should be replaced.

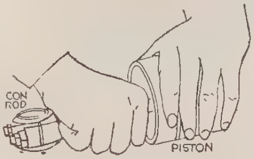

Fig. 52

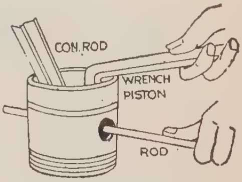

Fig. 53

The pin is removed by running out the connecting-rod clamp screw, after which the pin may be pushed out. Every repair shop should be equipped with a piston clamp, or vise.

If no clamp is available, the piston may be held by means of a rod (Fig. 53) through the piston pin while loosening or tightening the rod. The practice of holding the rod in a vise invariably results in a twisted rod and a scored cylinder.

The piston pin, when properly fitted, will wear very slowly, but when carelessly fitted, it will wear the bushing in a very short time, causing a noisy engine and excessive wear on the crank-shaft bearing.

The piston pins are usually fitted in the bushings by **selective fit.** A pin is tried in the bushing. If it turns freely, another pin is selected until one is found which requires a fair amount of effort to force it in and turn it. Since the piston pin is harder than the bushings, it is usually necessary to renew the bushings to insure a properly fitted pin.

The bushing is removed through the inside of the piston. The piston is then turned over, and the other bushing is forced out in the same manner. When pressing in the new bushings, it is important to have them line up properly with the hole in the piston, as a cocked bushing requires considerably more pressure to force it in, throwing the piston out of round.

The bushing should be pressed in until about 1/16″ of the bushing shows on the inside of the piston, or until it is 1/32″ inside the oustide diameter of the piston. When the bushings are in place, they should be line-reamed to size with a Ford pilot-type reamer "28Z-20," which may be purchased from the nearest branch.

Reaming the piston-pin bushings: If a reamer is used which has no pilot, only one of the bushings should be removed at a time, and the reamer should

Fig. 55. Die-cast removable bushings for the lower end of the connecting rod and cap. Where the bushings are babbitted in the lower end of the connecting rod and in the cap, they are not removable.

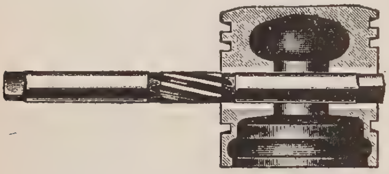

Fig. 56. **A self-aligning piston-bushing reamer with pilots** on each end to insure perfect alignment and a perfect fit the first time through. The spiral is fluted with steel blades. This type of reamer is furnished by K. R. Wilson, Buffalo, N.Y., for Ford, Chevrolet, Oakland, Oldsmobile, or Scripps-Booth cars.

be inserted through the old bushing to act as a guide in reaming the new one. The old bushing is then replaced and the reamer is inserted through the reamed bushing as a guide in reaming this one.

If there is no piston clamp (shown on page 797) available, the reamer should be held in a vise and the piston turned by hand, as shown in Fig. 58.

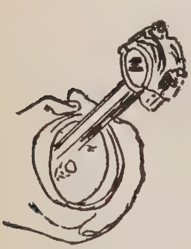

Fig. 57

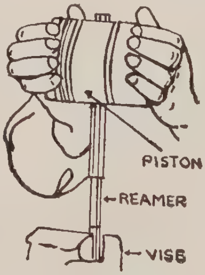

Fig. 58

When the new pin has been fitted, as described, it is removed and oiled. It is well to rub a little oil in the bushings as well. Hold the rod in the piston and force the pin into place. Turn the pin until the groove (G) (Fig. 41) lines up with the connecting-rod clamp-screw hole, and insert the clamp screw.

Run the clamp screw down with a socket wrench; remove the piston from the clamp, and press the rod from one side of the piston to the other to see that the pin does not extend outside the diameter of the piston. If it does, remove the rod and pin and press the bushing on that side in a little farther. If it does not, set the piston in the clamp and tighten down the cap screw with a "3-Z647" Ford wrench, and insert the cotter pin.

To test: The assembly may now be tried by holding the piston as shown in Fig. 57. The rod should hardly be able to turn of its own weight, but should drop gradually as the piston is jarred.

Where the stationary type of piston pin is used, the bushings are not fitted in the piston. The one piston pin bushing is fitted in the upper end of the connecting rod, as shown in Fig. 38, page 795, and the piston pin (Fig. 40, page 795) is held tight in the piston bosses by a set screw.

The same principle of removing, reaming, fitting, etc., to fit the piston pin is employed, as explained in the preceding paragraphs.

The piston pin may also be worn: therefore examine and replace it when renewing the bushings, if worn. As a rule, the wrist pin and connecting-rod bearings are prone to wear sooner than the main bearings.

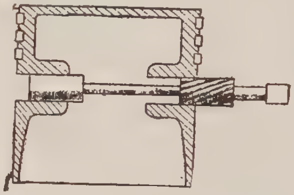

Fig. 59

Another reamer: The reamer is placed at one end of the tool there being a pilot at the other which slips into the opposite piston boss and thus guides the tool. When one boss is reamed the tool is reversed and the other one is done. Since the pilot is smaller than the finished hole, a bushing must be used to guide the pilot in the second half of the job.

Piston Pins

While the standard pins can usually be secured from stock in .003″, .005″, or .010″ oversize, it sometimes is necessary to order special ones. That there may be no confusion in ordering special sizes, be sure to give the oversize above standard, the make of car, model, motor, diameter and length, slot or set-screw hole, width and depth of slot, diameter of set-screw hole, distance from center of set-screw hole to end of pin; and also state if the pin has oil holes or oil grooves.

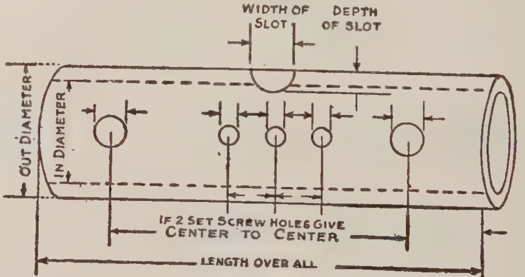

Fig. 60. A handy diagram to copy and fill in what is needed when ordering special piston pins. (By courtesy Heald Machine Co., manufacturer of cylinder grinding machines, Worcester, Mass. Copyrighted.)

Oversize Identifications

The practice of **painting the ends different colors** has been generally adopted by oversize piston-pin manufacturers, in order to identify them, so that they can be readily distinguished from one another. For instance, standard, no color; .003″ oversize, red; .005″ oversize, yellow; .008″ oversize, white.

Fitting Piston Pins

Use an accurate reamer, and be very careful not to remove too much metal. Remember that the clearance between the pin and the bearing should be .0005″ to .001″. A loose-fitting piston-pin with too much clearance will cause a piston-pin knock which will eventually mean that the whole motor will have to be pulled down and new pins inserted.

On the other hand, if it is a ringing fit, it will also cause trouble, because there must be room for a film of oil on the pin. A well-fitted pin will last for years.

Fitting Connecting-Rod Lower End

As in the case of the main bearings, there are caps fitted to the lower part of the crank-shaft bearing pins (see Fig. 38, page 795), which in this instance have removable **die-cast split bushings** in both the connecting-rod bearing above the crank shaft and in the cap below the crank shaft. This is the type generally used, with shims placed between.

On some connecting rods, the lower part of the connecting rod and the bearing cap are **babbitted,** and when the lower part of the rod is worn or burned, a new connecting rod is necessary (on the Ford); a new bearing cap also can be secured.

What has been said concerning the main engine bearings also holds good for the connecting-rod bearings. The two bearing halves may be brought closer together by the removal of some of the "shims" between them, or dressed down with a file, if shims are not provided. It is policy to take off enough metal to allow for a few shims, so that when taking up is again required, it will only be necessary to take out one or two shims.

In the majority of engines the removal of the lower half of the crank case gives access to the connecting rods.

Adjusting Connecting-Rod Lower Bearings

Loose connecting-rod bearings are detected by a kind of metallic sound or knock when the engine is running at idling speed.

To test, in order to determine which rod is loose, a good method is to run the engine at idling speed and to disconnect one spark plug after another. The knock will either cease or will sound as if there are two knocks, when the cylinder is found in which the rod is loose.

After determining that a connecting rod is loose, remove the oil pan. Turn the crank shaft (first remove the spark plugs to relieve the compression) so as to place the rod bearing in a convenient position for inspection. Take hold of the rod and, by a vigorous push up and down, ascertain whether there is end play. If so, the looseness can be felt.

Do not, however, mistake the side play for looseness, as there should be an appreciable amount of **side play.** At the same time, too much, or an excess of side play indicates wear on the sides.

If the bearings are found to be loose, pull the two cotter pins out and remove the nuts. The cap can then be removed.

Next, examine the bearing bushing and see if it is cracked, worn thin, or scored. If so, it will require new bushings and refitting by scraping or burning-in.

Note. It is not always necessary to scrape or burn-in on replacing die-cast bushings. Some repairmen shim them up and then run-in by not tightening too tight, and later on readjust again. It is best, however, to scrape them in to a fit. If new babbitted bearings are fitted, it is necessary.

At the same time that the bushing is being examined, examine also the crank-shaft bearing pin to see if it is scored or cut. If so, it will cut the bearings, and the crank shaft should be removed and the pin dressed down.

If the bearings are only worn and have a clean polished surface otherwise, then remove one layer of shims on each side and try the cap for tightness.

Replace the cap and tighten the nuts and then crank the engine by hand with the spark plugs removed (to relieve the compression), and test for tightness.

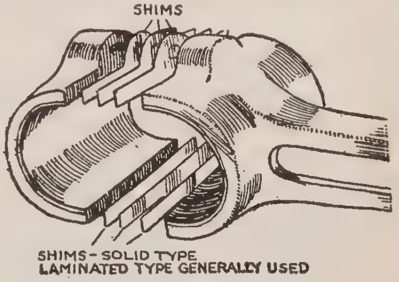

Fig. 61. **Connecting-rod lower bearing end** with cap removed to show shims placed between the upper bearing and cap. By removing a shim the cap is drawn closer to the upper bearing, and hence it would be tighter on the crank pin. The shims shown above are not the laminated type. The laminated type of shims is universally used, however.

When testing the bearing, keep in mind that while it should have no appreciable amount of looseness, this does not mean that the drag on the shaft should prevent its free rotation. Follow the same rule as given for the main bearing adjustment.

After adjusting and testing one rod, loosen up slightly on the nuts of the bearing adjusted, so that it will have no binding effect on the next one to be adjusted.

Adjust and test each rod accordingly, and after all are adjusted, tighten up on all nuts and replace cotter pins and spread the points.

It is a good plan, after about 1,200 miles of running, to **inspect and readjust the bearings again,** as they will then be set.

When replacing the oil pan, be sure the gasket is not damaged, and that the cap screws holding the oil pan to the crank case are tight, otherwise oil will leak.

If the connecting-rod bearings are not fitted with shims, then the bearing cap must be dressed down, as explained on page 784.

Note. **When removing caps and connecting rods, mark them.** Also be sure that the connecting-rod bearing caps are placed with the oil holes facing the direction in which the engine runs. This is important, especially with an engine using splash lubrication, because oil is forced into these holes when the engine is running.

Fitting Connecting-Rod Lower Bearings[1]

When the bushings in the lower end of the connecting rod and cap are badly worn, or cracked, or are loose, it will be necessary to install new bearing bushings if they are of the removable die-cast type.

If of the plain solid babbitted type, a new connecting rod and cap will be necessary, or they will have to be re-babbitted.

In either case, it is necessary to fit the bushings to the crank-shaft connecting-rod bearing pins.

---

[1] See also Index under "Fitting bearings on a truck engine."

In many instances, this work can be done under the car, by removing the oil pan, disconnecting the connecting-rod caps, and removing the rod and pistons from the engine.

The new bushings are then installed in the cap, and if it projects above the cap, it is dressed down.

There are various methods for fitting the connecting rod to the crank pin, which is similar to the main bearings: (1) by spotting-in and scraping; (2) by burning-in; (3) by lapping with a grinding compound. These methods were explained under "Fitting main bearings," and the process here is the same.

Where the work is done under the car, the connecting rod can be worked as shown in Fig. 62. It is best, however, to do this work with the crank shaft removed, because at that time the crank shaft can be tested for alignment and the crank pins can be examined more freely and the work will be done better.

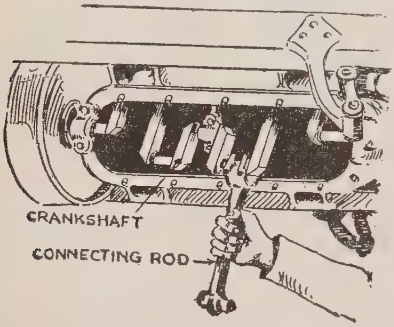

Fig. 62

Two methods are shown (Figs. 64, 65), for supporting crank shaft while fitting the connecting rods. The crank case can also be turned upside down and the work can be done while working on the main bearings and while the engine is on the bench and after the main bearings have been fitted.

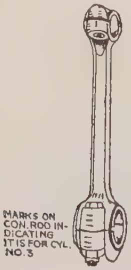

Fig. 63. Rod and cap should be marked.

When removing a connecting rod or cap, remember the position of the cap and examine it immediately for file marks. If the rod and cap are not marked, they should be, before the positions are forgotten. See also page 801.

Spotting-In Connecting-Rod Bearings

After sufficient shims have been removed from between the cap and rod, so that the bearing fits tight on the shaft, the rod nuts are taken off and the shaft bearing surface is given a very light coating of "marking" compound (Prussian blue or lamp black).

Put the connecting rod in place, and put on the cap and draw it up tight. Be sure that caps are fitted on according to the punch marks on the cap, and that the rod is on the right side forward. Then rock back and forth, or if the engine is removed, swing it around the shaft twice.

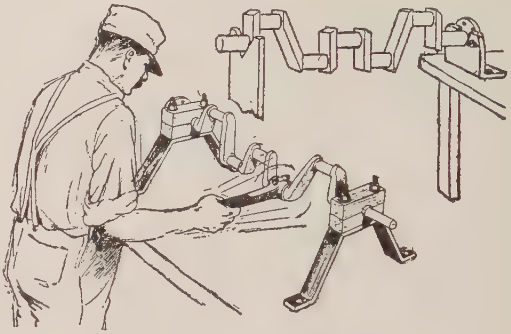

Fig. 64 Fig. 65

Fig. 64. A wooden crank-shaft support for fitting connecting-rod bearings to the crank shaft when removed from the engine.

Fig. 65. Another method.

Next remove the nuts and bearing. The "high spots" inside the bearing will be found marked in blue, showing that at these points the crank touched; the part which is white the crank did not touch. The problem is, therefore, to get the high spots down by scraping, until the bearing will mark for about three-fourths over its surface.

This marking or "spotting-in" process is repeated from time to time till the whole surface is marked as shown at (**D**) (Fig. 11, page 785). The upper part of the rod is scraped first, then the lower bearing cap.

Adjustment: When scraping is completed and all nuts are down, the connecting rod should be just **stiff enough to turn by hand,** and if placed in a horizontal position it should not fall by its own weight, but should move when pushed by hand. If fitted too tight, seizure will result.

After scraping is done, the burnisher shown in Fig. 10, page 785, may be run over the entire surface of the bearing to shine it up and smooth the surface.

Another method: When the rod shows a good bearing of about 30 per cent, tighten it to the shaft so that it will be hard to turn. When the engine is assembled (leave the oil pan off), run it for about 30 seconds; then remove it and examine the bearing. If it shows a good bearing, replace the cap. If not, remove the cap and repeat the operation.

When fitting a new connecting rod to an old shaft, the crank pin is usually undersize and it is not only necessary to remove the shims, but also to file off the sides (face) of the cap.

If a crank-pin bearing is badly under size, it is necessary to file the face of both the cap and the rod.

If, as already suggested, the shaft is badly undersize, and all connecting rods require replacing, it is usually less expensive to install a new crank shaft (on a Ford).

Oil grooves: Do not overlook the oil grooves when fitting the connecting-rod bearings. Remember that oil grooves wear thin in a worn bearing. See page 171: "Oil grooves in bearings."

How a Connecting-Rod Is Babbitted

Connecting-rod bearings are, as a rule, made from babbitt metal die-cast to size and shape, and in some cases these are backed by bronze shells, while in other designs the babbitt is cast directly into the rod and cap, the object of this being to reduce the weight of the reciprocating parts.

Babbitt as a bearing metal is very desirable, as it is soft and will not score the shaft in case the bearing should seize. It wears more rapidly than bronze, and consequently needs to be adjusted oftener. In order to prevent overheating and to allow for slight irregularities in connecting-rod alignment, these bearings must have a slight amount of end play.

Re-babbitting: In some of the older models and on some of the modern popular-priced cars, the bearing metal is cast in place, and is not in the form of removable bushings. In cases of this kind it is always best to have the rods re-babbitted at the factory or service station. Some makers even exchange the rods in order to facilitate service.

To pour and bore these bearings requires some skill, and it is a difficult job to set up. A simple method is depicted in Fig. 66, in which a machine table, such as that of a shaper or milling machine, is used, as these have T-slots to fasten the work to. To get the new bearing in line with the piston-pin bearing is not easy, but if the ends of the piston-pin hub are in good shape, one of these can be blocked up and bolted down on the machine table. Then with the babbitting mandril held vertically and located from the center of the piston pin, the bearing will line up within scraping distance, the setting being obtained by measurements.

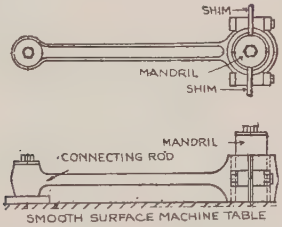

Fig. 66. A simple method of holding the connecting rod for re-babbitting the large end.

The babbitting mandril can be made of wood, which will leave a fairly smooth babbitt surface. It must be bolted down to prevent shifting when pouring the babbitt.

To form the two halves, a liner is inserted on each side that touches the mandril, both halves being run at the same pouring.

The babbitt can be heated in a ladle, using a slow heat and stirring frequently. For best results the babbitt should be poured at the proper temperature, which is that at which it will char a pine chip, but will not ignite it. When the metal has reached the pouring temperature, the rod should be heated somewhat. This prevents sponginess and blisters in the babbitt. Pour it slowly, and avoid the scum which forms in the ladle, or remove it before pouring.

After the bearing has cooled, the oil holes can be drilled, and then the final operation of scraping and fitting can proceed. It will be necessary to cut new oil grooves, which can be accomplished with a hammer and cape chisel, as shown in Fig. 67. (*American Automobile Digest.*)

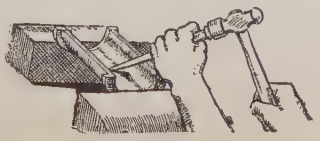

Fig. 67. Method of grooving re-babbitted bearings.

Pointers on Connecting-Rod Bearings as Usually Found on Tractor Engines[1]

Rods and caps should be marked: Before removing any of the connecting rods they should be examined for identification marks (Fig. 68). The marks referred to are placed on the connecting rod and cap, so that they may be reassembled in their original positions.

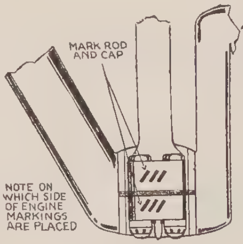

Fig. 68

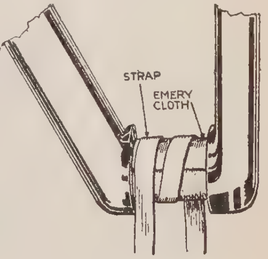

Fig. 68A

Fig. 68. The marks are put on the rod and cap when the engine is assembled. Note that there are three marks on the cap and three on the rod; thus they are for cylinder No. 3.

Fig. 68A. Dressing down a crank-shaft connecting rod bearing pin which is slightly scored without removing crank shaft.

If there are no marks on these parts it is a simple matter for the operator to put some there with a cold chisel or a file. The rod and cap should be marked with the same mark, but a different mark should be used for each rod so that they will be put back on the same cranks. A common and convenient way of doing this is to mark them 1, 11, 111, 1111—starting at the front end of the engine. With the rods properly marked and a note made on the side of the engine on which the marking was done, all parts should go back in place without any trouble.

Bearings must be fitted to a perfectly round bearing pin: When the connecting rods have been removed, the shaft should be tried for roundness. This is easily done with a pair of calipers carefully handled. If the shaft is found to be out of round or scored, there is no use fitting new bearings without first dressing down the shaft.

---

[1] *Canadian Power Farmer*, by D. R. A. Drummond.

This work may be done at the time, without removing the shaft if the shaft is not in very bad shape. Wrapping around the journal a piece of emery cloth which will cover it for the full length; around the emery cloth a strap is wrapped once, and the operator pulls back and forth on the ends of the strap (Fig. 68A).

Fit backs of liners or bushings first: If there is any difference between the two half-liners (bushings), they should be fitted to the rod and cap in such a way that the oil holes will match. When the liners are placed in their seats, it will sometimes be found that the **flanges** are a little too thick to allow them to seat properly (Fig. 69).

The sides of these flanges should be dressed down carefully with a fine file until the shell will almost seat. It is driven the rest of the way with a hammer and a round block of wood.

Liner riveted to prevent turning in shells: With the liner or bushing in place, the anchor rivets or screws should be put in and drawn up to place.

If screws are used, they should be screwed in tight and then riveted, to keep them from turning back and scratching the journal.

In some bearings neither screws nor rivets are provided, and the operator occasionally has trouble with the liners seizing on the shaft and turning in their seats. In this case it is just as well to drill the rod, cap, and liners, and to put in either rivets or brass screws (Fig. 70).

With the liners anchored in place, they should be filed flush with the top surface of the shells, and if they cover part of the bolt holes they should be filed to make the holes round.

Fitting the bearing to the shaft: To fit the bearing to the shaft each half should be fitted separately. It will probably be found that the bearing is a little too long to go down in place properly, and a little metal should be filed from each end of the bearing until it goes into position with the end play about equal to the thickness of a piece of ordinary writing paper. In doing this work, the edges of the shell should be rounded off with a bearing scraper to correspond with the rounded fillet on the crank-case journal. The shaft is coated with a very thin layer of Prussian blue, and the half-bearing is placed in position and worked back and forth on the shaft. The blue on the shaft will mark the high spots on the bearing, and these should be removed with a bearing scraper as previously explained under "Spotting-in and scraping bearings."

While scraping a bearing, care should be taken to scrape a very little at a time, as making deep cuts only moves the high spots from one place to another, and the job might go on indefinitely. The marking and scraping operations should be continued until the blue marks the full surface of the bearing.

Assembling the bearing: When both halves of the bearing have been fitted to the shaft, the whole may be assembled and this is where a great many operators fall down. There should be the same shimming in each side of the bearing, and there should be just enough shimming used so that when the bolts are drawn up tight the shaft can be turned by hand. This means that the rod, cap, shims, bolts, and nuts will form one solid piece.

If, when the bolts are tightened, the shaft cannot be turned, shims should be added until the proper fit is obtained. Under no circumstances should the nuts be slackened to obtain the proper fit, as this leaves a certain amount of play on the bolts, which soon causes the shims to wear out and the bearings to be badly damaged.

When the nuts have been drawn up tight, it may be found that the slots in the nut do not match the holes in the bolts. In this case, the nuts should be removed and enough metal filed from the bottom so that they can be turned up to match. The nuts should not be turned back even part of the whole width to get the pins in. New pins should always be used in reassembling these bearings, as old ones are liable to break, causing serious damage to the engine.

Main bearings:[1] The main crank-shaft bearings are fitted in much the same way, except that all the upper liners or bushings must be fitted at the same time. Fitting one bearing at a time would be pretty sure to result in getting one lower than the other, which would cause the shaft to bind when the caps were put on. The caps, on the other hand, may be fitted one at a time, the usual practice being to start at the center.

The job of fitting bearings is not a hard one, but calls for care, precision, and a certain amount of mechanical ability. The work outlined above may easily be adapted to almost any kind of tractor motor bearing.

ALIGNMENT OF PISTON AND CONNECTING ROD

What follows is not a part of the tractor engine bearing subject just treated, but refers to pistons and connecting rods in general.

After having fitted the bearings, as previously explained, the rod bearings should now be tested for **parallelism.** The piston pin and the crank-throw must be parallel, and the bearings that they move in must also be parallel, or binding and rapid wear will take place. This should be done before and after scraping the bearings.

If the connecting rod is distorted or bent, to even the slightest extent, it will cause a knock or "piston slap" and wear on one side of the cylinder wall, and will also cause the rings to stick and leak; therefore, before assembling, some means must be found of determining if the piston is in perfect alignment with the connecting rod, crank shaft, and cylinder.

Very often, knocks that develop in engines (after they have apparently been thoroughly overhauled), will be found to be due to the fact that the connecting rods are slightly bent sidewise, or got out of true when fitting the cylinders down over the piston, or when removing and replacing them. One cylinder will get a slight lead, or one ring does not properly enter, the cylinders are twisted, and in an effort to align them, the rods are bent. When the engine is finally assembled, it is very noisy, due entirely to the fact that one or more of the rods have been bent sidewise, and when the force of the explosion is exerted on the piston head, the wrist-pin end of the connecting rod is driven sidewise against the piston boss.

There are three disalignments possible in the piston and connecting rod: An offset in the direction of the crank shaft; the rods may be bent to right or left in the direction of the crank shaft; a twist in the connecting rod may exist.

Before replacing these parts, great care should be taken to have them in perfect condition before they are assembled. To make sure, they should be tested on a device as shown in Figs. 72 and 73.

Fig. 72. **A connecting-rod aligning jig.** Note that the test is for the purpose of ascertaining if the connecting rod is **bent sidewise.** If all of the side of piston comes flush with the face plate and if they touch at points (X), then the piston and connecting rod are in alignment. If, however, the piston touches at the bottom at (X) but not at the top, then the connecting rod is bent to the left. If it touches at the top and not at the bottom, it is bent to the right. Note that the test is made on a mandril. If bent, it can be straightened with a straightening bar, as shown at (M56).[1] This device is used for **straightening the connecting rod if bent or twisted.**

Piston Pin (PP) Should Touch on Each Side At Points X

Fig. 73. The same device as shown in Fig. 72 is being used to test the connecting rod to see if it is **twisted.** It is clear that if the piston pin (**PP**) should not touch the surface blocks at both points (**X**), the connecting rod is twisted and should be bent back with the tool (**M56**) (Fig. 72).[1]

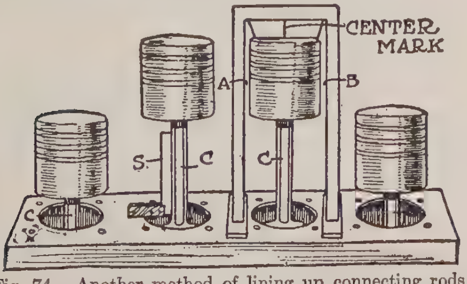

Fig. 74. Another method of lining up connecting rods of block-type engines with the base of the engine. (**S**) represents a square placed alongside the connecting rod (**C**) to determine whether it is true or not. If the rod is true and the piston is square, the space at (**A**) and (**B**) should be the same.

Another example which will illustrate to what lengths makers are going in order to insure the pistons working absolutely parallel with the bores is the method of checking the alignment of the piston and rod in the Rickenbacker engine. If a connecting rod is found to be slightly bent, instead of its being bent to shape while cold, it is faced off in a special fixture by grinding. This will insure no stresses being set up in the rod when it is heated while the engine is operating. Thus there is assurance that the pistons will at all times work correctly in the bores.

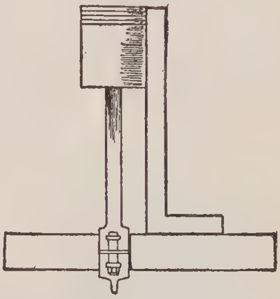

Fig. 75. A ground arbor and a square can be used to check up the alignment of the connecting rod and piston assembly. This should be done both before and after scraping the bearings.

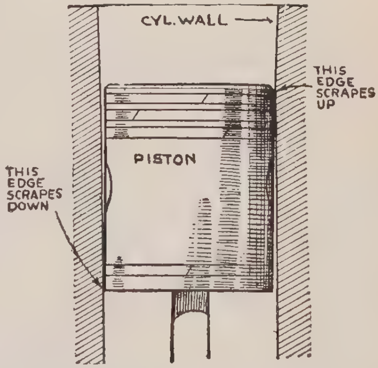

Fig. 76. The illustration is exaggerated in order to show how a piston that is cocked as a result either of the connecting rod being out of alignment with the piston or too great a piston clearance will scrape oil up on one side and down on the other side of the cylinder walls.

The connecting rod has come in for a good deal of attention during the last year or so. In nearly every case makers are now finishing their rods much better. Some go so far as to machine the rods all over, and take great care in balancing them. Heretofore some makers have weighed their rods, and if they were within ½ oz. of each other, they passed inspection. These same makers now carefully balance the rotating ends of the rods and the reciprocating ends, because it is of prime importance to get the rotating weights alike as well as the reciprocating weights.

In order to get a better distribution of the load on the connecting-rod bearings, many engine makers now are flaring the ends of the connecting rods. This naturally results in such a bearing wearing less, because the load imposed upon it by the explosion stroke is taken over a greater spread, than where the I-beam part of the rod is brought to the cap end in approximately a right angle, or a small fillet.

---

[1] These devices are sold by the Service Station Equipment Co., Chicago, Ill. The Continental Auto Parts Co., Columbus, Ind., also manufactures devices for aligning purposes.

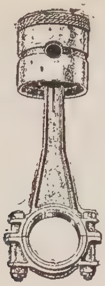

Fig. 77. The spade type of flared-end connecting rod now being introduced.

The Universal Crank-Shaft Support and Aligning Fixture

A device (Fig. 78) **for aligning connecting rods and supporting any make or size of automobile engine crank shaft,** so that the connecting-rod bearings can be fitted, and connecting rods and pistons can be tested for alignment at the same time, is shown in the illustrations.

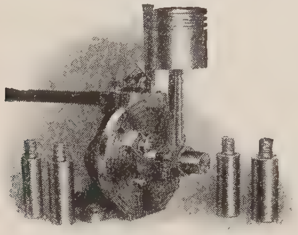

Fig. 78

Note that in Fig. 78 the crank shaft is clamped to the face of the fixture, the other end of the shaft being supported by the floor stand. The connecting rods can be fitted in this position; one advantage in fitting connecting rods in this manner being that the bearings are "spotted" to the shaft. The connecting rod can be turned a complete circle, thus insuring a more perfect marking, or, in other words, the entire circumference can be "spotted."

Fig. 79

After the connecting rods are fitted to the shaft, the connecting rods and pistons are both tested for alignment with the square. Thus each piston is squared on its own bearing.

When a shaft is not taken out of the engine, mandrels (see Fig. 78) are supplied to be used instead. The outfit shown above sells for $60 and is manufactured by the H. & H. Machine Co., St. Louis, Mo.

IMPORTANCE OF OIL PRESSURE IN RELATION TO CRANK-SHAFT BEARINGS

As an example, we will use the Oldsmobile eight-cylinder V-type engine, model "45-B."

Oil-pressure regulation: The oil regulator is shown in Fig. 80. Note the position of the oil-pressure adjusting screw and the ball-check valve. Dirt beneath this valve will cause a drop in pressure, and may be removed by snapping the ball up and down a few times with a piece of wire inserted through the oil passage.

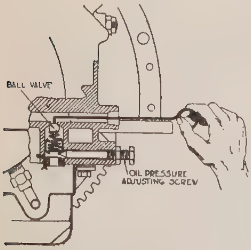

Fig. 80

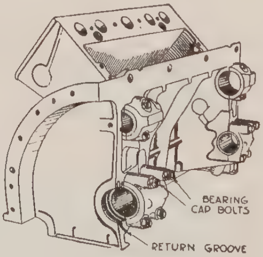

Fig. 81

Fig. 80. Oldsmobile (eight-cylinder, V-type engine) oil-pressure regulator.

Fig. 81. The main bearings are bolted to the left cylinder block. Note the return oil groove. This should be free to permit the oil return.

The oil-pressure regulator is on the front left-hand side of the engine, as shown in Fig. 80. If the oil-pressure gauge on the dash registers below 5 lbs. at 10 m.p.h., it is necessary to regulate the oil pressure. The following is the method:

1. Screwing the oil-pressure adjustment screw inwards should raise the pressure, and remedy the conditions. When the engine is steadily raced, a maximum pressure of 25 lbs. should be shown on the gauge.

2. If this is not the case, remove the oil line from the pump to the regulator, and also the elbow attached to the regulator. Then with a 3/16″ wire or rod, bent at right angles for ⅜″, reach into the oil passage and depress the ball valve a few times. This will release any dirt beneath the seat which has caused low pressure.

After replacing the parts, it will be necessary to adjust the oil-pressure screw as directed. It is also advisable to drain the crank case and flush it out with kerosene, when conditions are as described.

A medium-weight oil should be used, and, as is common with the present-day low-grade gasoline, it will be best to drain the oil, flush out the base, and replace new oil every 500 miles. Five quarts of oil are needed to completely replenish the oil supply.

Should a crank-shaft bearing ever burn out, it will be necessary to see that all oil passages are tested for clearness before replacement is made.

If any of the oil passages in the crank shaft are stopped, a ⅛″ twist drill may be used to remove the babbitt.

Testing should not be done with an air hose. The best method is to clean the end of the oil passage and blow by means of the mouth; the mechanic can thereby feel exactly the condition of the oil passage.

Cleaning oil lines: Usually a short-length twist drill is used for clearing babbitt out of the crank shaft after a bearing is burned out. Most tool stores carry long-shank twist drills, with which this work can be carried out better.

This precaution applies equally well if a connecting rod bearing burns out. Before the new bearing is installed, all oil passages should be **cleaned with**

compressed air. Very probably one will find a thick, black, pasty substance in the oil pipes connecting the crank cheeks, and also in the drilled passages in the crank shaft. This is carbon, road-dirt, and oil emulsion formed by the mixture of oil and water—the water being one of the products of combustion or having entered the crank case through a leaky head gasket.

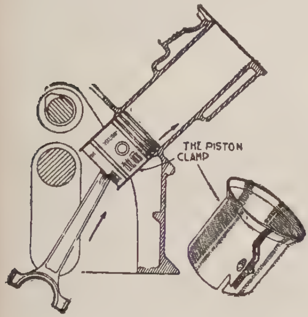

Fig. 82

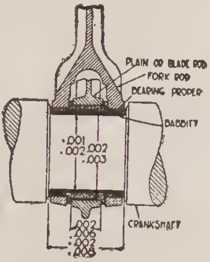

Fig. 83

Fig. 82. A piston clamp, as shown, facilitates piston and ring replacement through the crank case.

Fig. 83. These are the running clearances that should be observed when refitting the connecting-rod bearings.

If air is not available, use a tire pump by removing the connection and applying the end of the hose to the mouth of oil holes.

Connecting-rod bearing clearances: In fitting the connecting-rod bearings, it is essential that the correct clearance be observed in order to give proper action. If the mechanic uses those methods common in fitting the connecting-rod bearings on four-cylinder engines, the bearings will be drawn too tight and will cause future trouble.

The plain, or **blade rod** shown in Fig. 83 bears on a bronze bushing, which in turn runs on the crank shaft. If this bearing does not have from .002–.003″ clearance, the bushing will expand faster than the plain rod and cause binding. This condition will be indicated by a burning out of the babbitt around the center of the bearing proper.

The following is the proper method of fitting the plain or blade-rod bearing to obtain the proper clearance.

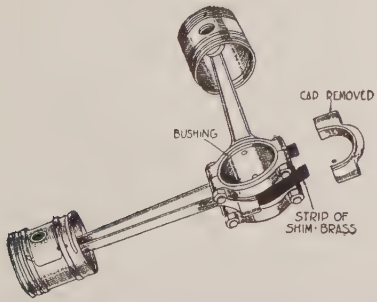

Fig. 84. A strip of shim brass applied in the manner shown above enables the mechanic to obtain the proper clearance between the blade rod and the bearing proper.

1. Fit the babbitted bushing to the crank-shaft bearing, and bolt the fork rod tightly in place.

2. Procure a strip of shim brass ¾″ wide and .001″ to .0015″ thick, just long enough to lap around the plain rod bearing on the bronze bushing (see Fig. 84).

3. Bolt the plain rod in position and adjust until, when the bolts are tight, the plain rod may be turned, but not loosely. Then if the brass shim be removed, the plain rod will have the proper clearance.

The side clearances may be checked up by means of a thickness gauge. It is essential that the clearance shown be followed. An absolute check on the bearing fits may be determined by using an inside and outside micrometer, and the careful mechanic will use this method instead of rule-of-thumb methods.

Adjustment of main bearings on the Oldsmobile model "45B" is described below and serves as an example of how bearings are adjusted on the average eight-cylinder V-type engine:

1. Remove the oil pan, place a jack under the flywheel "take the strain"—noting carefully if the crank shaft has any motion in the bearing. If such motion exists, remove the main bearing cap and take an equal number of shims from each side of the bolts, usually about two.

2. Examine the cap carefully to see that the crank shaft has a good bearing. In some cases the lining of the bronze bearing has been partially ruined, from lack of oil, which later causes leakage from the rear end of the engine.

3. Use air hose or a tire pump to blow through the drain hole which brings back the oil from the rear of the rear main bearing into the oil pan; this is a "cored" passage beneath the bearing, and connects with a groove in which a collar formed on the crank shaft revolves, throwing off the oil. There may be dirt or a stoppage at this point, preventing a proper return of the oil to oil pan.

4. When all of these points have been taken care of, replace the bearing cap and tighten up firmly. Crank the engine by hand. If it is not stiff, but has more "feel" to it than existed before you made the adjustment, this will indicate that the bearing is a close and proper fit. If it is still quite free, it would be advisable to check the bearing again, and see that it is not loose.

Note. In removing shims, be sure to take the same thickness from each side.

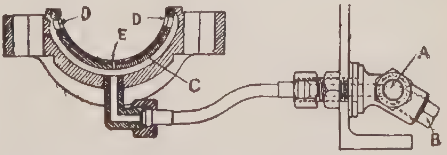

Fig. 85. Method of oiling the main bearings on the Mitchell. The space back of the bearing forms a reservoir, the oil being forced through holes (D) and (E) under pressure.

RELATION OF VIBRATION TO BALANCE

The detailed consideration of vibrations is very complex and is only of interest to specialized engineers. However, some of the factors that affect vibration are of interest to the mechanic and car owner and will be taken up in an elementary way.

Periodic Vibration

A vibration is said to be periodic when it recurs at equal intervals. Thus, during two revolutions of the crank shaft (one cycle), certain vibrations occur; if, during the next two revolutions (cycle), these same vibrations are repeated, they are said to be periodic, that is, they occur at every two revolutions of the crank shaft.

Balancing

Balancing may be considered as the effort to reduce the effects of vibration. It resolves itself into two main classifications: (1) balance of rotating parts; (2) balance of reciprocating (up-and-down motion) parts.

A part or combination of parts may be perfectly balanced when at rest, but may not be balanced when the engine is running at a high rate of speed. This leads to a further classification of balance as: (1) static balance, which means balance when at rest; (2) dynamic balance, which means balance when in motion.

Therefore we may say we have four classes of balance:

1. Static balance of rotating parts.
2. Dynamic balance of rotating parts.
3. Static balance of reciprocating parts.
4. Dynamic balance of reciprocating parts.

Balance of Rotating Parts

The rotating parts include the crank shaft and the flywheel.

It is obvious that in order **to obtain static balance of rotating parts,** it is only necessary to machine them so that the weights are equal in all directions from the center.

The dynamic balance of rotating parts is affected by a number of factors, the most important being distribution of weight along the length of the crank shaft.

One method of aiding dynamic balance is by placing counterweights on the crank throws. Another method is the divided flywheel (one in front and one in the rear), as used on the Rickenbacker engine. Here the flywheel strains are taken up, both at the front and rear ends of the crank shaft.

Whip

Suppose we made a crank shaft out of rubber. It is evident that during a power stroke the connecting rod would bend the crank shaft out of shape and cause it to **"whip"** around. While the steel crank shaft will not bend like rubber, nevertheless it has some elasticity, and it is this deflection (bending) that causes "whip." If the main bearings are out of line, the tendency will be to increase the whip. **Some methods of decreasing whip are:** (1) using a stiffer crank shaft; (2) placing the main bearings closer together; (3) placing counterweights on the crank throws.

Balancing of Reciprocating Parts

The reciprocating parts comprise: pistons and rings, wrist pins and connecting rods.

To produce static balance of the reciprocating parts, it is necessary only to have the parts equal in weight, that is, all pistons with rings and wrist pins equal in weight, and all connecting rods equal in weight.

INSTRUCTION No. 70

PISTONS: Types, Construction, and Fitting; Piston Clearance; Standard and Oversize Pistons; Piston Repairing; Lapping Piston and Rings in Cylinders; ENLARGING CYLINDERS: Different Methods of Finishing Bores of Cylinders

PISTONS

The piston acts as a seal for compressing the gases and for transmitting their energy to the crank shaft; it functions also as a guide for the piston pin. It should, therefore, fit the cylinder as closely as possible, and should be as long as possible.

Pistons are usually made of cast iron, and this type is the one in general use. When heated, cast-iron pistons expand, but not as much as aluminum-alloy pistons.

Aluminum-Alloy Pistons

Aluminum-alloy pistons are used in some engines. They expand more than cast-iron pistons, but since they cool more rapidly than cast iron, they permit a higher compression pressure. (Higher compression increases heat.) By reducing the weight of reciprocating parts, quicker acceleration is also made possible. They give longer life to the bearings by reducing the bearing pressure, especially at high speeds. The inertia of the reciprocating piston is reduced approximately 67 per cent. This cuts down side pressure, or thrust, on the walls of the cylinders and reduces friction and the consumption of lubricating oil. The great heat conductivity of aluminum alloy lessens the carbon deposit on the piston head, and the deposit is more easily removed. It is claimed that in cases of extreme heat the lynite piston will not "score" or cut the cylinder walls. It is a proved fact that the lighter the piston, the quicker it will operate. Therefore **greater speed and flexibility are the result.**

The main drawback, however, is the "slap" which often occurs, as explained on page 779. Unless the pistons fit or the clearance is exact (and it will be observed that if the aluminum-alloy piston expands twice as much as a cast-iron piston when heated, it would be necessary to give twice the clearance), the clearance of an aluminum piston when cold is considerably more than cast iron. Thus, until the engine is warmed up, there is more or less slapping noise. As the heat increases, however, the piston expands and the noise disappears. But during this expansion period raw gasoline is drawn into the cylinder, past the pistons, into the crank case, thinning the oil. Many methods have been devised to overcome this objection.

Gray-iron pistons or semi-steel pistons still are used by the majority of engine makers. With all their other advantages, aluminum-alloy pistons, as just explained, still have the disadvantage of having a rate of expansion different from that of cast iron, of which the cylinder is made. The rate of expansion is considerably greater, and therefore with alloy pistons it has been necessary to allow two or three times the piston clearance that is allowed with cast-iron pistons.

A long step in advance is the **constant-clearance** type of aluminum piston. Briefly, this is a piston which does not expand in the same way as we think of when speaking of piston expansion in an iron piston. Usually there is a cut in the piston, so that when the piston does expand it simply closes this cut and does not, therefore, change its diameter. Hence the clearance substantially remains the same in all cases. Where the constant-clearance type of piston is used, it is generally made with an opening extending circumferentially around the piston excepting for a small portion where the piston pin bosses are located. The object of this slot is to separate the upper portion of the piston, or heat portion, from the skirt.

A very good example of the constant-clearance type of piston is that used in the Cole Eight (Fig. 1). The pistons are cast of aluminum alloy in a metal mold and are slotted circumferentially below the lowest of the three piston rings.

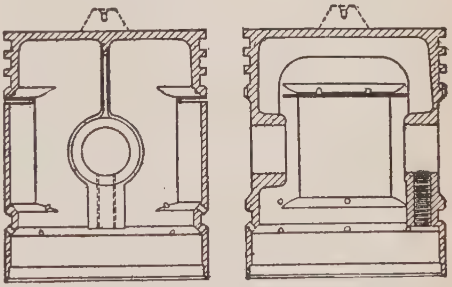

Fig. 1. Sectional view of the Cole aluminum-alloy piston.

The slot is cut by a 1/16" saw and extends over an arc of 83° on each of the two pressure sides of the piston. By means of central ribs the load resulting from the gas pressure is transferred directly from the piston head to the piston bosses. The pistons are a snug fit in the cylinder, even when cold. There is, therefore, no undue noise in the engine when first starting up. When heated, the sides expand circumferentially and along the diagonal slot without increasing the outside diameter.

A piston adopted by the Essex is also of the constant-clearance type. In order to use small clearances and still avoid any trouble due to expansion of the metal, the piston skirt is slotted and split and joined to the head only above the piston pin bosses. Interior ribbing makes for an exceptionally strong piston in which binding of the piston pin has been eliminated. Besides eliminating the effects of expansion of the piston, the slots act as oil drains. There are three rings above the piston pin and two oil grooves below. (*Motor Age.*)

The layout for the making of this piston (Fig. 2) has been arranged in the belief that piston wear, oil pumping, and failure of the piston rings to make proper contact with the cylinder walls are due largely to misalignment. This misalignment causes the piston to cock in the cylinder so that one side of it becomes a scraper, giving unequal lubrication around the walls, as shown in Fig. 76, page 803.

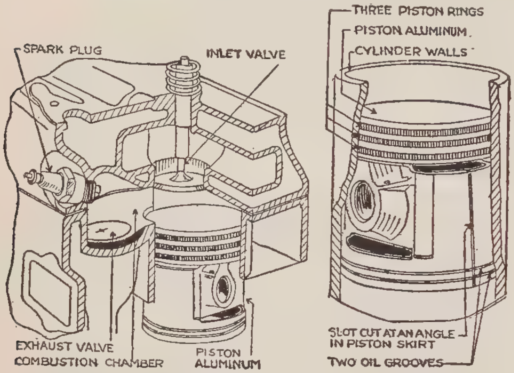

Fig. 2. **Essex aluminum-alloy piston and section of cylinder head.** The Essex engine is the type which has intake valves in the cylinder head and exhausts in the side. The gas passage is arranged so that the carburetor is placed above the inlet port and valve. Thus the flow of gas to the inlet valve is downward, the exhaust being at the side. The inlet valves are 1⅞″ in the clear, with a lift of .3125″. The exhaust valves are 1⅜″, with a lift of .325″. With this arrangement, and by the use of aluminum pistons which cool readily, the use of the large valves and high compression is permissible.

The spark plugs are located on the right side and the ends of the plugs fire in a depression in the head. There are four such depressions or cups. This design is used so that the plugs are constantly fanned by flame, with the result that oil is quickly burned away, if any should work its way up.

The skirt of the piston is split with a slot cut at an angle, so that it does not work vertically in the cylinder, but with a sliding motion. Part of the piston and rod assembly operation is such that a final check is made on the alignment of the piston and makes it certain that the latter will operate on a true axis.

Light Iron or Semi-Steel Pistons

Where iron or semi-steel pistons are used, there has been a tendency to get them very light. In fact, some of the semi-steel pistons weigh little more than aluminum-alloy pistons. Flexible pistons of this type have the advantage that they will shape themselves into the cylinder bores in which they are working. In other words, the pistons will conform much better to the shape of the cylinder, should the latter wear oval.

One of the things in favor of the semi-steel piston is that owing to the nature of the metal it can be machined to much closer limits than is the case with cast iron. There is, therefore, a reduction in weight—and a desirable feature in any of the reciprocating parts of an engine.

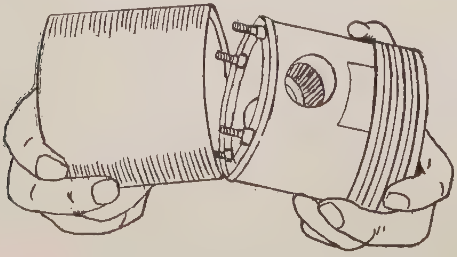

Fig. 3. The Marmon piston is a combination piston. The head and body are aluminum, and the skirt is cast iron.

Most makers of engines are now polishing the heads of the pistons. It is well known that carbon or soot will not so readily adhere to a polished surface, and while it is somewhat more expensive to finish pistons in this manner, it is worth it in the better appearance and in results.

The Deluxe Light-Weight Gray-Iron Piston

Attention is called to the design or construction of the Deluxe light-weight gray-iron piston, and to the system of ribs or webbing extending across the head and down the skirt of the piston. These ribs or braces give the piston extraordinary strength and permit of the walls between the ribs or braces being made very thin.

The strength of the piston depends almost entirely on the ribs or braces extending across the head and down the skirt, and very little on the walls between these ribs. Actual tests show Deluxe pistons to be three times as strong as necessary to hold up in the cylinders under all conditions, but they are in no case strong enough to withstand abuse or rough treatment, nor being handled in the way in which ordinary heavy cast-iron pistons are handled.

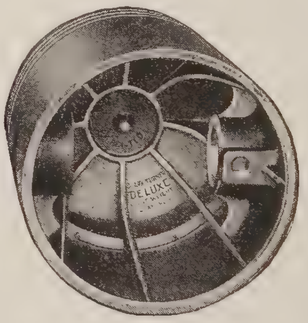

Fig. 4. The Deluxe light-weight gray-iron piston.

The manufacturers of the Deluxe piston (Clark-Turner Piston Co., Los Angeles, Cal.) claim that this piston expands and contracts equally and evenly; that it never warps, and that it is always round and true and can be fitted to a closer clearance than any other piston. Thus, with a close clearance, compression leaks and piston slap on starting are eliminated, and the other advantages of the aluminum-alloy piston are likewise obtained.

The **clearances** recommended by the manufacturers of this piston are as follows:

Diameter of Piston			Clearance	
2″	to 2 13/16″	allow	.0015″	on skirt
2⅞″	to 3 1/16″	allow	.002″	
3⅛″	to 3 11/16″	allow	.0025″	
3¾″	to 4¼″	allow	.003″	
4 5/16″	to 4 15/16″	allow	.0035″	
5″	to 5½″	allow	.004″	
5 9/16″	to 6″	allow	.0045″	
6⅛″	to 6⅞″	allow	.005″	
7″	to 7⅞″	allow	.006″	
8″	to 8⅞″	allow	.007″	
9″	to 10″	allow	.008″	

Exceptions: Allow .003″ on Essex engines and Ford engines.

Deluxe pistons are supplied "semi-finished," finished to "standard," finished "exact," and finished to any "oversize." The semi-finished pistons are from 1/16″ to 3/16″ oversize, according to diameter, and can be finished down to standard, or to any oversize up to within .010″ of the semi-finished size.

On orders for "standard" size pistons, clearance is allowed for. When ordering oversize pistons, allow for clearance. For instance, if you order a 3¼″ piston finished to .010″ oversize, the finished piston will be .010″ over 3¼″. If you have a regrind job ground to .010″ over 3¼″, then you should order the piston finished to .007″ or .0075″ oversize, allowing for "clearance." In other words, when ordering oversizes you receive exactly that size, whereas, when ordering finished to standard, a size equal to the diameter of bore, less proper clearance, is supplied.

When ordering pistons always state the name of the car or engine, the diameter, and the number of cylinders.

Cast-Iron Pistons

We shall now confine our attention to the piston in general use, which is the plain cast-iron piston.

The cast-iron piston expands under heat, as do all other types—some more or less than others—and the extent of this is, of course, governed by the amount of heat generated in the engine. On the Ford piston, the top is .010″ smaller than the skirt, because the piston is subjected to greater heat at the top; consequently there is greater expansion at this point. The clearance of a piston is measured at the skirt.

The piston proper is made with grooves for rings (**R**), which are placed as shown in illustration (Fig. 5), which is of the Ford piston. Note that there are two rings above the piston pin and one oil-ring below. Sometimes an oil groove takes the place of the oil-ring. (**B**) is the bushing for the piston pin.

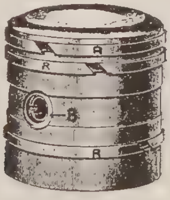

Fig. 5

The average automobile engine piston is fitted with three rings above the piston pin and one below. Pistons are usually ground to fit the cylinders, but not to a tight fit.

Questions and Answers on Pistons

Q. 1: What troubles result from too loose a piston?

Ans.: In addition to a "slap" and the wear of the cylinder wall, there is a third trouble resulting from the gasoline passing into the crank case and thinning the oil, thus injuring the bearings. The piston will also pump oil, causing carbon and smoke.

Q. 2: What is meant by "squaring" the piston?

Ans.: When fitting pistons in the cylinder, if the cylinder blocks are not lowered carefully, the connecting rods will be slightly bent; or, if in scraping a bearing, one side is higher than the other, the piston will set at an angle. It is very important that pistons be in perfect alignment. See Index under "Alignment of pistons."

Q. 3: What are pistons usually made of, and what is meant by "seasoning" and "heat-treating"?

Ans.: Pistons are usually made of cast iron, and are not machined for a long time, to allow them to set so that they will not change their shape. The result of this is that they do not contract so greatly when cold or expand so much when heated, thus permitting maximum clearance, and reducing "slapping" when cold. Heat-treating is supposed to have the same effect as long seasoning.

Q. 4: How are pistons machined?

Ans.: They are turned down to within .005″ of size, then ground to exact size on a special grinding machine. On high-grade engines the pistons are seasoned or heat-treated, then turned and ground to fit each cylinder individually. On some of the cheaper grades of engines they are not always heat-treated or seasoned, and are made in quantities, and the assembler fits the pistons to the cylinders as they come, termed a selective fit.

Piston Clearance

A piston does not fit the cylinder wall tightly. If it did, it would seize and stick when it was heated, as it expands with heat.

The piston rings fit tight, however, but, being split and of spring tension, they fit the cylinder at all points—or at least they should. For this reason clearance must be allowed between the wall of the cylinder and the piston.

Cast-iron pistons require about one-half the clearance that those made of aluminum alloy require, because they do not expand so much under the same degree of heat.

More clearance is required at the top of a piston, because here the heat is greatest, and there is therefore greater expansion at the top.

If pistons are fitted very close to the cylinder they will run very quietly but may heat and stick and cause the engine to slow down or stop if it is driven at a high speed. In fact, all **new engines should be driven at moderate speed** for the first 1,000 miles in order to work or run-in the pistons, bearings, etc., without cutting.

If pistons are fitted moderately loose, they may "slap" until heated up. The practice is to give greater clearance for higher speed.

If pistons fit too loose, a "piston slap" and oil leakage will result.

The amount of clearance depends upon the speed of the engine, the efficiency of the cooling system, the type of water circulation, and the length of the water jacket. If the engine is "hot-running" or heats quickly, clearance is increased proportionately. If it is "cool-running," give less clearance. The clearance needed will vary, depending on the conditions mentioned. Air-cooled cylinders usually expand outwards, which equalizes with the expansion of the piston. Therefore the same ratio applies.

How to Determine Piston Clearance[1]

The clearance of cast-iron pistons is usually graduated. For example, refer to Fig. 6. The piston is ground straight, or one size from the bottom of the skirt up to the lower part of the piston-pin hole. From the lower ring groove to the head of the piston, the piston is slightly tapered, so that it is from .006″ to .010″, or more, smaller at the top than at the skirt.

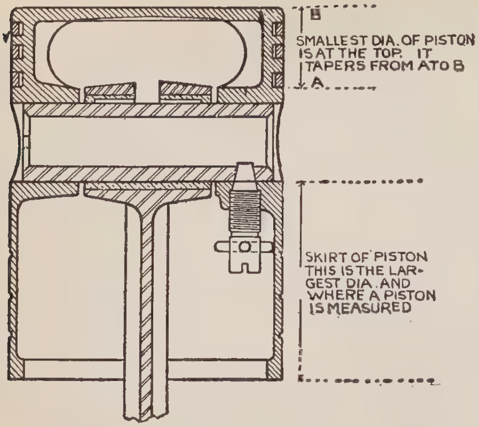
The clearance of a piston is allowed at the skirt, and, **as a rule,** this part is ground so as to allow approximately **.001″ clearance for each inch in the diameter of the piston.**[2]

For example: If a piston is to be fitted to a cylinder of 3″ bore, the skirt of the piston should be

---

[1] **The S. A. E. has never adopted any standards for piston clearance** because the difference in materials, in cooling, and in design both of pistons and cylinders, affects the amount of clearance necessary.

[2] **A clearance of .00075″** (three-quarters of one-thousandth) of an inch for each inch diameter of piston is now more generally used.



B
SMALLEST DIA. OF PISTON IS AT THE TOP. IT TAPERS FROM A TO B
A
SKIRT OF PISTON THIS IS THE LARGEST DIA. AND WHERE A PISTON IS MEASURED

Fig. 6

measured as .003″ less in diameter than the bore. Thus, in the case supposed, when the cylinder bore is 3″ in diameter the piston should be .003″ less, or 3″ − .003″=2.997″ (two inches and nine hundred and ninety-seven one-thousandths), measured at the skirt.

This rule is not always adhered to. One manufacturer states that they give .002″ to .003″ clearance to passenger-car engines and on racing cars; .003″ to .004″ to truck engines, and .004″ to fire-apparatus engines, **regardless of diameter.** Where engines run for long periods under full power they require more clearance than others, and, of course, the heating of the engine, the cooling surface, etc., as previously stated, are factors governing the clearance to a certain extent. For example, in fire-apparatus engines, where they are run at times for long periods, pumping water at full power, it is clear that greater heat will be generated; there will consequently be greater expansion. Thus in such cases it is necessary to allow more clearance.

It is also clear that a close-fitting piston is desirable—and the idea is not to give any more clearance than necessary.

No hard-and-fast rule can be given as to the amount of clearance which should be allowed between the pistons and cylinder walls. There are many conditions to be taken into consideration, including the construction and speed of the engine, the style and material of the pistons, the service given the engine, after grinding, and even the characteristics of the driver himself.

Even the manufacturers themselves are divided on this point, each having his own pet theory as to what the clearance should be. Some idea of how manufacturers vary can be gathered from the table showing the clearances allowed by a few of the makers of cars, shown on this page.

As a general rule, it is safe to allow .00075″ to .001″ to each inch diameter of the bore on cast-iron pistons. The majority of the regrinding concerns—and, as can be seen from the table above—**the manufacturers themselves, shade this a little.** This can be done, provided that the fitting of the piston rings and pins is an A-1 job, and provided that, when assembling the engine, every precaution is taken in regard to squaring up the pistons and rods, to giving the engine plenty of oil. In addition, the driver **should operate the car at moderate speed the first few hundred miles.**

Manufacturers' Clearance of Pistons in Cylinders when Regrinding Cylinders[1]

Maker	Finish	Diameter	Clearance	Piston Material
Chalmers	Grind	3¼″	0.005″	Lynite
Chevrolet	Ream	3.686″	0.003″	C.I.
Continental	Grind	3¼″	0.001″	C.I.
Continental	Grind	3½″	0.002″	C.I.
Continental	Grind	3¾″	0.002″	C.I.
Continental	Grind	4⅛″	0.002″	C.I.
Continental	Grind	4½″		C.I.
Dodge	Ream	3⅞″	0.003″	C.I.
Franklin	Grind	3¼″	Taper from 0.003″-0.001″	Magnalite
Hudson	Grind	3½″	0.0035″	C.I.
Hupmobile	Grind	3.248″	0.001″	C.I.
Kelly-Springfield	Grind	3.7460″ 4.4970″	0.003″ 0.003″	C.I. C.I.
Locomobile	Grind	4½″	0.015″ 0.003″	C.I.
Lycoming	Grind	3½″	0.004″ 0.0065″	C.I.
Maxwell	Grind	3.622″ plus	0.013″	C.I.
Mitchell	Grind	3¼″	0.0025″	C.I.
Oakland	Ream	2 13/16″	0.005″	Alum.
Oldsmobile	Ream	2⅞″	0.004″	Lynite
Packard	Grind	2.998″	0.002″	C.I.
Pierce	Grind	4½″	0.002″ 0.003″	C.I.

"Lynite" is aluminum alloy; C.I., cast iron.

In many cases, piston manufacturers themselves can tell best what clearance should be left for their particular style of piston, especially on patented construction, or on alloy material.

A prominent piston manufacturer gives the following clearances for different cylinders of different diameters, between the finished piston and cylinder:

Diameter of Piston		Clearance
2 13/16″ or under	allow	.0015″
2⅞″ to 3″	allow	.002 ″
3⅛″ to 3¾″	allow	.0025″
3⅞″ to 4¼″	allow	.003 ″
4 5/16″ to 4⅞″	allow	.0035″
5″ to 5½″	allow	.004 ″
5¾″ to 6″	allow	.0045″
6¼″ to 6¾″	allow	.005 ″
7″ to 8″	allow	.006 ″
Ford	allow	.003 ″

Piston Clearance; How Measured

Method of measuring piston clearance: Place the inside micrometer caliper (**IM**) in the cylinder, as indicated in Fig. 7, and determine **the inside diameter of the cylinder** (see also page 703).

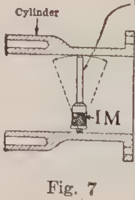


Fig. 7

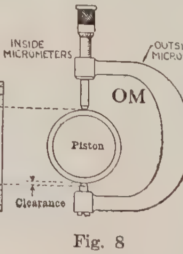

Fig. 8

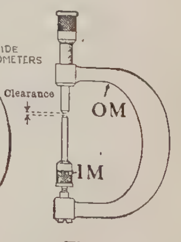

Fig. 9

Then place an **outside micrometer (OM)** over the piston, as shown in Fig. 8, to determine **the outside diameter of the piston.**

Then place the inside micrometer (**IM**) (Fig. 9), as shown, in **between** the outside micrometer, and note the clearance.

---

[1] This table is given through the courtesy of the Heald Machine Co., Worcester, Mass., manufacturers of cylinder regrinding machines. (*Copyrighted.*)

In the absence of suitable micrometers, and if the pistons are to be ordered, cut a 3/16″ bar of steel, filing both ends smooth so as to fit the cylinder at its **smallest** point, and number each bar for each cylinder. Send these bars to the piston manufacturer and state the clearance desired.

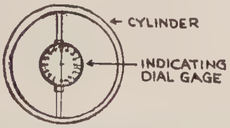

Fig. 10. A device, termed a **dial cylinder gauge,** for comparing the diameter of cylinders, to see if they vary, is called an Indicator Dial Gauge. Manufactured by B. C. Ames Co., Waltham, Mass.

Note. **If a piston is fitted to a worn cylinder,** it will be found that the **wear is where the rings travel** (Fig. 24, page 822), and not at the bottom or top of the cylinder. Thus, if the piston is fitted with proper clearance at these points, it may have considerably **more clearance when up into the cylinder,** and this is one reason why worn cylinders should be enlarged and oversize pistons fitted, if worn more than .003″. When worn, cylinders are usually out of round.

Free-Fit and Tight-Fit Piston Clearance

Frequently instructions advise fitting a piston, say .003″ **"free"** or **"loose-fit,"** and .004″ **"tight-fit."**

This means that the piston is placed in the cylinder and a thickness gauge (also called a "feeler") is placed alongside the piston, between it and the cylinder wall (Fig. 11).

The piston should fit free, or loose, or fairly snug with a .003″ gauge, and tight with a .004″ gauge.

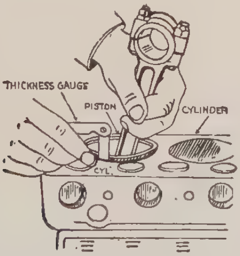

Fig. 11. **Method of testing piston clearance** between piston and cylinder wall. The **"feeler," or thickness gauge,** should be tried at several points between the piston and cylinder bore. The piston should then be turned a quarter turn and checked again. If the piston shows out of round, tap it with a rawhide mallet on the greatest diameter of the skirt to true it up.

Note. A 1″ strip of heavy tough wrapping paper can be **"miked,"** that is, its thickness can be measured with a micrometer and then the paper can be used to test the clearance when fitting pistons, by laying it in the cylinder between the piston and cylinder wall.

How Pistons Are Marked

Pistons are usually stamped on the head, and this stamp indicates the diameter at the skirt. For example, a **standard size** piston for, say, a 4½″ bore cylinder with a .003″ clearance may be stamped 4.497″, meaning that 4½″ in decimals is expressed as 4.500″ and 4.500″−.003″=4.497″. This method of marking, however, does not hold true in all instances, as manufacturers have different methods.

When an **oversize piston** is ordered from the manufacturer of a car, the probabilities are that it will be stamped for the oversize only. For example, suppose the cylinder diameter was 4″, and the standard clearance was .003″, the **standard piston** would then measure 4″−.003″=3.997″.

Suppose the cylinder was worn and the piston was loose, and you ordered a piston .002″ oversize. This would mean that the piston would measure at the skirt .002″ more than the standard size. It may be marked simply .002″ OS ("O.S." stands for oversize), or it may be marked the actual measurement, as 3.999″. The 3.999″ is arrived at by adding .002″ to the standard size of 3.997″.

Standard and Oversize Pistons

Pistons can be purchased in **"standard"** and **"oversize"** diameters.

A standard size piston is the original diameter of the engine cylinder, less the standard clearance.

The oversize piston is fitted to a cylinder when the cylinder is worn, or is enlarged, by re-boring, re-grinding, or reaming, as explained farther on. In many instances, when a cylinder is worn and the piston is loose, an oversize piston of .002″ or .002½″ is ordered, and it is then "lapped" in.

Oversize pistons can be secured in sizes .005″, .010″, .015″, .020″, .031″, .046″, .062″, larger than the original or standard size of the piston. Cylinders are seldom ground less than .010″ oversize.

A concern that makes a specialty of oversize pistons, rings and wrist pins and that specializes on grinding cylinders is the H. & H. Machine Co., St. Louis, Mo.

Finished pistons are furnished complete, minus rings and pins.

The Continental Motors Corporation, manufacturer of the Continental Red Seal engine, and its parts-distribution depots, carry in stock replacement or **oversize pistons** from .002″ to .045″ oversize. These figures represent the actual oversize of the piston, as, for instance, if the **standard piston** is 3.248″ diameter, then a **.002″ oversize piston** would be .002″ larger than the standard, or 3.248″+.002″=3.250″.

Miscellaneous Oversize Engine Parts

Oversize piston pins, are cheaper to use than it is to re-bush a piston. Simply ream the bushing when a piston pin is loose, and fit an oversize pin. (These can be secured of the H. & H. Machine Co., St. Louis, Mo.)

Oversize valve stems, such as are used on the Ford, where there is no provision made to put in cast-iron bushings, are necessary when valves become noisy and air leaks into the cylinder through the inlet valve, causing missing at low speeds. The guide is reamed 1/64″ oversize, and a 1/64″ oversize valve stem is fitted with .002″ or .003″ clearance.

Oversize piston rings can be obtained of any supply house or piston-ring manufacturer. See page 834.

Oversize valve tappets and also **oversize cylinder head bolts** can be secured of the Stevens Co., 375 Broadway, New York.

Questions and Answers on the Standard Bore of Cylinder, Standard Size of Piston, Standard Clearance of Piston, Oversize Pistons, and How a Piston is Measured

The Ford Piston as an Example

Q. 1: **What is meant by a "standard bore" of a cylinder?**

Ans.: The bore or diameter of the inside of a cylinder as it comes from the factory. On the Ford it is 3¾″ or 3.750″, expressed in decimals (three inches and seven hundred and fifty one-thousandths of an inch).[1]

---

[1] On all engines the bore may vary even as much as .002″. We shall assume that it varies one one-thousandth on the Ford; thus the cylinder bore may be 3.750″ or 3.751″. Therefore in working out the answers to these questions, we shall assume that the bore is 3.750″, which is what it is intended to be, although, as stated, almost all cylinders vary at least .002″.

Q. 2: What is meant by a "standard size" piston?

Ans.: The diameter of a piston to fit this standard size bore, less the clearance. The actual diameter of a Ford "standard" piston is supposed to be approximately 3.748″ (it may vary .001″).

Q. 3: What is meant by a "standard clearance" of a piston?

Ans.: The clearance adopted by the manufacturers. On the Ford, the standard clearance of the piston in the cylinder is as follows: On a repair job, a Ford piston should fit to the bore of the cylinder so that a .004″ thickness gauge, placed between the piston and the cylinder wall is tight, and at .003″ is loose. On commercial jobs pistons may be fitted so that at a .006″ gauge they will be tight, but in such a case the pistons are liable to slap and be noisy until warmed up. Therefore if the cylinder is 3.750″ in diameter and the clearance is to be .003″, the piston should measure at skirt, 3.750″=.003″=3.747″.

Q. 4: Where is a piston measured?

Ans.: At the skirt.

Q. 5: How much smaller is a piston at the top than at the skirt, and why?

Ans.: On a Ford, the piston is .010″ smaller across the head, and .005″ smaller at the second ring. The reason for the piston being smaller at the top is the fact that cast iron expands when heated, and the heat is greater at the top where the combustion takes place.

Q. 6: What is meant by an "oversize piston" and when is it used?

Ans.: A piston which is larger than the "standard size" is called an oversize piston. It is used when the cylinder is worn, by lapping the piston to a fit, and also when a cylinder is enlarged, by re-boring, grinding, or reaming.

Q. 7: Do some of the manufacturers adopt a "standard oversize piston"?

Ans.: Yes. The Ford has adopted three: a .0025″ (two and one-half one-thousandths); a .03125″ (thirty-one and one-quarter one-thousandths), and a .033″ (thirty-three one-thousandths of an inch).

Q. 8: When is the ".0025″ oversize piston" used?

Ans.: When the cylinder block becomes slightly worn, the .0025″ oversize can be lapped into the cylinder without enlarging the cylinder. After running a new car 4,000 miles with standard-size pistons, the cylinders usually wear enough to be able to fit this .0025″ oversize-piston without much trouble, and it is "run-in."

Q. 9: What is the diameter of a ".0025″ oversize piston"?

Ans.: The standard size plus .0025″.

Q. 10: What is the standard size of a Ford piston expressed in "decimals"?

Ans.: If the bore of the Ford cylinder is 3¾″, or 3.750″ (expressed in decimals), and the standard clearance is .003″, the piston should have a diameter of 3.750″−.003″=3.747″, which would be standard size. Owing to the fact, however, that the cylinders vary slightly, the standard diameter will vary accordingly. Therefore the fit of the piston to the cylinder should be a selective fit.

Q. 11: Would a .0025″ (two and one-half one-thousandths) oversize piston fit this cylinder?

Ans.: If the cylinder was exactly 3.750″ in diameter and the standard piston was 3.747″, a .0025″ oversize piston would mesaure 3.747″+.0025″=3.7495″ (3″ and 749½ one-thousandths); therefore, if the oversize piston measuring 3.7495″ was put into the cylinder measuring 3.750″, there would be .0005″, or only one-half of one one-thousandth of an inch clearance, and the piston would seize when heated.

Q. 12: Then if the .0025″ piston is only one-half of one one-thousandth of an inch (.0005″) smaller than the cylinder bore, this would be too tight, would it not?

Ans.: Yes, but it is assumed that the cylinder is worn somewhat, and the piston can be lapped to a proper clearance, if not worn sufficiently.

Q. 13: Would .002″ clearance answer?

Ans.: Yes. In fact, many Ford mechanics take out the standard-clearance pistons (.003″ size), even in new engines, and lap in the .0025″ oversize pistons with a .002″ clearance. An experienced Ford mechanic states that this is his remedy for a piston pumping oil. He states that he fits the piston until he can easily push it through the cylinders without binding anywhere, and then runs the engine idle for an hour or so, slowly, and with plenty of oil. A .002″ or .0025″ clearance is plenty, as Ford pistons are not polished.

Q. 14: When is the ".03125″ oversize piston" used, and how is it marked?

Ans.: The cylinder must be enlarged 1/32″ or .03125″, by boring, reaming, or grinding, to take this piston. The piston can then be lapped in enough to polish it. It is marked ".03125″−O.S." (O.S. means oversize.)

Q. 15: What is the diameter of an ".03125″ oversize piston"?

Ans.: The standard size plus .03125″, or 3.747″+.03125″=3.77825″.

Q. 16: How much would the cylinder be enlarged to take this ".03125″ oversize piston"?

Ans.: If the standard bore of the cylinder is 3.750″, then, if we take a .03125″ oversize piston, it would be enlarged 3.750″+.03125″=3.78125″.

Q. 17. Would this leave ".003″ clearance"?

Ans.: Yes. If the cylinder was enlarged to 3.78125″ and the diameter of an .03125″ oversize piston was 3.77825″, this would leave .003″ clearance.

Q. 18: Would you advise enlarging a cylinder to to 3.78125″?

Ans.: Enlarge to give a .002″ free-fit clearance after measuring the exact diameter of your piston, providing the engine is not used for long periods of time at full power, otherwise give .003″ free fit.

Q. 19: When is the ".033″ oversize piston" used?

Ans.: When the cylinder becomes worn after it has been enlarged for the .03125″ oversize piston, the .033″ oversize piston is used by lapping it in.

Q. 20: What is the diameter of an ".033″ oversize piston"?

Ans.: The standard size plus .033″, or 3.747″+.033″=3.780″.

Q. 21: What clearance would this ".033″ oversize" require to fit the cylinder?

Ans.: If the cylinder had been enlarged to 3.78125″, then it is assumed that there is wear; hence the reason for fitting the .033″ oversize piston. It is thus lapped in for a .002″ clearance.

Q. 22: Is it advisable to fit pistons of the same size to all cylinders?

Ans.: Yes, otherwise the engine will be out of balance.

Q. 23: What is meant by a "balanced engine"?

Ans.: This is a broad subject, but if all pistons are the same size, and all cylinder bores are uniform, then the cylinders will come nearer getting a uniform charge of gas; and this is still more true if all connecting rods weigh the same, and the crank shaft and flywheel are perfectly balanced. All reciprocating parts should be as light as possible.

Q. 24: What about "oversize piston rings" when fitting oversize pistons?

Ans.: Oversize piston rings should also be fitted. For instance, if a .0025″ oversize piston is fitted, fit .0025″ oversize piston rings; in like manner the fitting of rings should be correspondingly the same for .031″ and .033″ oversize pistons.

Q. 25. How much "clearance" should be allowed at the "gap of the ring"?

Ans.: The top ring should be given not less than .004″ nor more than .008″; the center ring may go as high as .012″, while the bottom or oil ring may have as high as .016″, since it is necessary that a small amount of oil work up between the piston and the cylinder walls.

Q. 26: How is the clearance measured at the gap of a ring?

Ans.: Place the ring in the cylinder and measure the gap with a thickness gauge. If the gap is too small, file.

Q. 27: How are the rings installed?

Ans.: Ford rings are cut .002″ taper, and should be installed with a file or punch mark-up.

Q. 28: Should a ring have equal pressure or tension at all points of its circumference?

Ans.: By all means. See the discussion on the subject of "Piston Rings."

Q. 29: Is "lapping" by hand advisable?

Ans.: No. The compound is liable to get into the bearings unless thoroughly cleaned out. After running a new Ford engine for 4,000 miles, it will be found that the cylinder will be worn sufficiently to take the .0025″ oversize piston, and the process would be to fit it so that the piston can be pushed through the cylinder without binding anywhere, and then to run-in with plenty of oil, slowly, for about two hours. This will take the place of lapping. If pistons are out of round, they will require reboring.

Q. 30: How would you "fit" a piston if you did not lap it?

Ans.: Place the piston in the cylinder and work it around. Take it out, and you will notice bright spots at different points where it binds. This is usually around the piston-pin hole. Then dress these high places down with a mill file and fine emery cloth, being careful to wipe off well with gasoline. Then follow the process of running-in.

Q. 31: What is meant by "running-in"?

Ans.: When pistons are fitted so that they can be pushed through the cylinder without binding, then connect up the engine and run it slowly for two hours, using plenty of oil. Then run the car for the first 200 miles not to exceed 15 m.p.h., using plenty of oil.

Q. 32: Suppose the piston fits too loose?

Ans.: Then try others, as Ford pistons vary. If these are still too loose, and the .031″ oversize will not go in, then you must enlarge the cylinder. When enlarging, however, do not make the clearance over .002″, and "run-in" the piston in oil. Pistons are not all exactly the same size, and are not polished. The high spots are dressed down with a mill file and fine emery cloth held around the piston in the hand while rotating it. The piston is then thoroughly cleaned with gasoline to remove all particles of emery and filings which would cut the cylinder if left on, and is then fitted to the cylinder and is run in.

Measurements of Ford Pistons

The diameter of pistons and the diameter of the bore of a cylinder may vary as much as .002″ from the following measurements:

Length: 3.808″ to 3.817″.
Diameter at skirt: 3.748″ to 3.749″.
Diameter at second ring: 3.743″ to 3.745″.
Diameter at top: 3.738″ to 3.740″.
Ring groove: ¼″ x 13/64″ deep.
Diameter of piston-pin bushing: .740″ to .741″ (15/16″ dia. x 1 7/32″ long), phosphor bronze in pairs.
Diameter of piston pin: .740″ to .741″ (47/64″).
Length of piston pin: 3½″.

Piston Replacement

The three following conditions make it necessary to replace a piston: (1) scored pistons; (2) leaky pistons; (3) undersize pistons.

The scored piston, if it is not too badly scored, may be dressed off with a mill file. However, this practice is not recommended unless the mechanic is skilled in the use of a file. Again, a scored piston usually means a scored cylinder, which requires enlarging the cylinder, and fitting an oversize piston.

Leaky pistons are found by setting the piston bottom side up in a pan of gasoline, or by pouring about 1″ of gasoline into the interior of the piston. The gasoline will seep through any leak.

Undersize pistons cause excessive wear on the walls of the cylinder and cause the engine to knock. A cylinder may be made to hold compression by fitting new rings on a badly undersize piston, but because of the wear on the block, such practice is false economy.

On the Ford car the piston is fitted to the cylinder bore so that it is tight on .004″ and loose on .003″. Commercial repair jobs may be fitted tight on .006″, but this high limit may result in a piston slap.

Owing to the jar and rough handling in shipping, and the various methods used in storing the pistons, they become out of round. In fitting a piston it is therefore necessary to watch for this condition.

Where speed is desired, the lower part of the piston is frequently drilled with holes, and the piston is made of aluminum alloy, or of light construction, to lighten it as much as possible (see Index under "Tuning engine for speed").

Note. When replacing a piston, always replace it on the same cylinder from which it was removed, as each cylinder usually varies in bore to a slight extent.

CYLINDER REPAIRING

When an engine runs without oil, the cylinder wall may become scratched or "scored." In fact, cases have been known where the cylinder was getting plenty of oil, yet, if the rings were loose, the flame from the combustion would work past the loose ring and prevent it from receiving proper lubrication, causing it to heat and cut the cylinder.

The cause of a scored cylinder is lack of oil, and is frequently the result of a loose piston pin, which scores or cuts the cylinder wall, thereby permitting a leak between the wall of the cylinder and the ring.

A scored cylinder can be repaired only by re-boring, reaming, or grinding. This is a job that ought to be done where a special re-boring or re-grinding machine is installed. When a cylinder is enlarged, **oversize pistons and rings** must be fitted.

If the cylinders are not scored too deep, they can be lapped in with an old piston covered with oil and emery, as stated on page 816, or scores can be **filled,** if the cylinders are not out of round.

Repairing scored cylinders: One method is by fusing silver nickel alloy into the scores and regrinding the bores. This is called the Lawrence process, and is controlled by the L. Lawrence Co., 292 Halsey St., Newark, N.J.

Another method is known as the Eagle process, controlled by the Eagle Machine Co., Indianapolis, Ind. Copper alloy is inlaid and rolled into the scores which have been dovetailed, thereby making the alloy a part of the cylinder.

The third process is known as the Bull-Dog process, controlled by the Metal Repair & Supply Co., Washington, D.C. In a way, it is a combination of the two methods mentioned above, since the score is dovetailed and a metallic filler of high melting point is fused into it.

Seized pistons also cut the cylinder walls and the piston itself.

A "seized" piston is where the piston is stuck to the cylinder wall, and this, in turn, is caused by excessive heat which can be due to lack of water or lubricating oil, or running a new engine at too high a speed.

Remedy for a seized piston: Occasionally the repairman receives a call to start an engine that has the symptoms of a seized piston, and that has resisted the best efforts of owner of the car to start it. At such times the repairman must exercise the utmost ingenuity, for the owner has generally tried all the easy methods before he arrived.

In such cases, the first thing to do is to make sure that it is the engine and not some other part of the transmission or the rear axle that is at fault. The rear wheels should be jacked up, the emergency brake released, and the gear-shift lever placed in neutral. The wheels should turn freely, and there should be no binding in the rear axle system.

The spark plugs should be removed, or the compression cocks opened, to relieve the compression. Then if the crank cannot be turned over by hand or by means of the starter, or by the two working together, the car may be towed with the gears in high and the clutch disengaged. As soon as the car has attained some momentum, the clutch may be allowed to engage gently, care being taken not to allow a sudden motion which might strip the gears in the rear axle, or even break a shaft.

If this does not free the engine, kerosene can be poured into the cylinders and allowed to remain for a couple of hours. This will have a tendency to dissolve any old oil which may have gummed the pistons to the cylinder walls. Then the car may be towed again, and an attempt made to turn over the engine by engaging high gear. The engine can be turned over more easily in high than in low gear because it does not have to revolve so rapidly.

After one has succeeded in turning over the engine, one should open the drain cock in the bottom of the crank case and drain out the mixture of kerosene and old oil thoroughly. Then the new oil should be added, the radiator should be filled with hot water in order to expand the cylinders, and the spark plugs should be replaced. After starting, the engine should be run slowly under its own power for some little time, in order that the new oil may work to all parts.

The first troubles caused by worn or scored cylinders are fouled spark plugs and excessive carbon deposits resulting from oil leaking past the piston and rings. Compression also escapes by the worn parts, causing loss of power and wasting gas and oil. A very annoying knock or clatter, known as "piston slap," soon develops. The longer the engine runs, the worse this condition becomes. An engine in this condition is not only wasteful, but also very noisy.

When a cylinder is cut or scored, but not worn, and is not out of round, then the score or cut can be "filled," as stated on this page. In this instance the original or **standard-size piston can be refitted,** if of the correct clearance.

If the cylinder is worn out of round (and it is usually out of round when worn), then it will be necessary to enlarge the cylinder bore and fit oversize pistons and oversize piston rings.

Usually, when a cylinder wears, it wears where the rings travel, which is the upper part of the cylinder. The lower part of the cylinder may measure true, but when measuring the upper part, where the rings travel, it will more than likely be found to be out of true. If, on observing the rings, a black spot is found on the ring and it is not smooth, either the ring has lost its tension at this point or the cylinder is out of round. The result is that the cylinder leaks compression, pumps oil, fouls the spark plugs with oil, and consumes oil and gasoline all out of proportion to the power delivered.

When a piston is too loose or the cylinder is worn, then a "piston slap" develops, which not only causes a knock, as explained on page 779; but in all probability the cylinder will be worn at the upper point, on one side, owing to the explosion pressure forcing the piston, at an angle, constantly against the wall of the cylinder. This permits gasoline to pass into the crank case and to thin the oil, and also permits oil to pass into the combustion chamber. A bent connecting rod will also cause a piston slap. See also page 802.

To test a cylinder to see if it is out of round, an inside micrometer caliper (page 810) is necessary. The cylinder should be tested from top to bottom carefully and thoroughly. If out of round .003″ or more at any one point, then the only safe remedy is to have it re-ground and new pistons ground to fit. After an engine is run 20,000 to 30,000 miles, it most likely needs re-grinding.

To test a piston, an outside micrometer is used. The piston, of course, will measure less at the top than at the skirt, but it should be true. If it is not true, or if the clearance between piston and cylinder wall is greater than normal, then a new piston should be ground to fit the cylinder. Pistons out of round cause oil pockets, which results in an excess of oil entering the combustion chamber.

When and How Much to Enlarge a Cylinder

The following will determine the necessity of enlarging a cylinder: (1) the cylinder condition; (2) the piston condition.

To determine how much to enlarge a cylinder, depends upon how much out of round, how badly worn, or how deep the cut is. Usually, one of the dimensions stated, or the S. A. E. standard oversize for pistons (below), will meet all conditions. One must be careful, in enlarging a cylinder, to see that the wall of the cylinder is thick enough to stand the enlargement.

No uniform practice has hitherto existed as to the amount of metal to be removed in re-grinding worn cylinders, with the result that difficulty is experienced in securing new pistons of correct size from the manufacturers.

Oversize Cylinders (S.A.E. Standard)

With a view to eliminating all unnecessary expense and delay, **the following standards have been adopted by the Society of Automotive Engineers,** and pistons to correspond can be obtained from most engine manufacturers.

10 one-thousandths of an inch (.010″) large for 1st
20 " " " " " (.020″) large for 2d
30 " " " " " (.030″) large for 3d
40 " " " " " (.040″) large for 4th

The meaning of 1st, 2d, 3d, and 4th is this: If the cylinder is scored or cut, say, .009″ deep, then bore it to fit a .010″ oversize piston. (Or enlarge the bore to the original diameter, + .010″.) If cut .011″, then bore it for a piston .020″ oversize—but not between the two. In other words, a number of automobile manufacturers furnish pistons larger than their standard product by increments of .010″, thus making it possible to re-grind scored or worn cylinders to these S. A. E. standards and to procure pistons from stock.

Cylinder and Piston Information

What constitutes a perfect cylinder? A cylinder block, before it is machined ready for use, has holes in it which represent the cylinders, but are considerably smaller than the size required. For instance, if the cylinder is to be 4″ in diameter, when machined and ready for use, the original hole will be about ¼″ smaller. This is because it is impossible to cast a perfectly smooth and true surface, and the holes, or cylinders, must be bored out by machinery to arrive at this result. A cylinder-boring machine is used for this, and generally two cuts are made in the cylinder, a cut which removes all the material except just enough to be taken off in the finishing cut, which is a very fine cut. Sometimes a third cut is necessary to obtain the exact size, and when this is completed the cylinder walls are perfectly straight from top to bottom. **The cylinder is perfectly round and the surface of the wall is nearly as smooth as polished glass. A cylinder in this condition is said to be in perfect condition.**

Examine the condition of the cylinders in a job. First, see if the cylinder walls are perfectly smooth and free from scores or scratches. Second, **see if the diameter of the cylinder is the same throughout,** that is, beginning at the top and measuring the diameter about every inch of the depth of the cylinder. Having done this, determine whether the cylinders need repairing. If the scores or scratches are very slight, they may be remedied by lapping, but if they are too prominent they must be re-bored. The lapping process may be done without any special equipment, but the re-boring requires a boring machine, or at least a special boring tool which can be operated by the lathe by hand.

When a cylinder requires lapping or re-boring, it is understood immediately that the old pistons are useless, so far as this particular job is concerned. Lapping or re-boring increases the size of the cylinder, and the pistons which undoubtedly are worn considerably will be too small.

There are several methods of lapping cylinders. Since the old piston will be of no further use, it probably will be the handiest to use. Remove the connecting rod and attach the piston to a shop-made lapping bar. Apply a moderate quantity of fine valve-grinding compound, thinned with engine oil, to the outside wall of the piston and insert it in the cylinder. Work the piston up and down in the cylinder with the same motion as that described for valve grinding. Keep this operation up for a few minutes and withdraw the piston. Wash the cylinder thoroughly with gasoline, and wipe it dry with a soft cloth. Examine it now to see how nearly it presents a fine, smooth surface. When sufficient lapping has been done to restore the prefect condition of the cylinder, it is ready to be measured for diameter. This measurement is noted, and when making or ordering a new piston, it is made about 0.003″ smaller than the new bore. About 0.003″ is the proper clearance between the piston and cylinder wall of 4″ bore.

There are cases when the scoring of a cylinder is so bad that lapping would be useless, and the cylinder must be re-bored or reground. In this case the most satisfactory results are obtained by turning this part of the job over to a machine shop that is specially equipped for this class of work.

Remarks on Piston and Rings

Next in order are the pistons and rings. Very much the same can be said of the pistons as has been said of the cylinders. Their wearing surfaces should be perfectly smooth, the same as the cylinder wall, but if their surface is badly scored or scratched there is no repair for them.

When a piston is perfect except for a small amount of even wear, for instance, 0.002″ or 0.003″ too small, the trouble can be remedied by heating and expanding the old piston. The heating is done in charcoal, and should be done very slowly and carefully. After the piston reaches a red heat, permit the charcoal fire to die out slowly so that the piston is cooled in its charcoal bed. Pistons can be expanded to as much as 0.004″ in this manner, if the work is done properly.

Piston rings loose their tension after long use, and cease to have enough strength to press against the cylinder wall all around. As a result oil is permitted to pass by them and to enter the combustion chamber. Besides, compression sometimes is lost because the gas is permitted to escape past the rings. Excessive oil coming up into the combustion chamber is one of the first indications of poorly fitting rings. If plain rings are to be fitted, care must be taken to fit them properly. The gap between the ends should not be less than 1/64″ nor more than 0.020″. In the case of fitting patented rings, the manufacturer has a specially machined ring for each type of engine, and it would be well to specify the make and model of engine when ordering. If the engine has been rebored, the amount of oversize should be stated. (*Motor Age.*)

Lapping Piston and Rings to a Cylinder

Lapping piston and rings: When a new set of pistons and rings is installed in a cylinder which has been worn slightly out of round, the practice is to "wear in" or "lap in" each piston asembly for a few moments by moving the piston assembly slowly up and down in its proper cylinder after carefully coating the cylinder wall and the piston assembly with a fine "lapping compound."

When this practice is employed, **care must be used to remove all particles of grit from the cylinder wall or the piston assembly** by a liberal washing in kerosene of all parts to which the "lapping compound" has been applied. Thorough workmanship also demands that the rings be removed from the pistons before washing, in order that no particles may find lodging behind the piston rings. These particles of grit might later find their way out and perhaps severely score the cylinder wall or ruin the bearings in the engine. Replace each ring in the groove from which it was removed.

Lapping Slightly Scored Cylinders

If the cylinders are slightly scored, they can be lapped with an old piston. It is not desirable to use a new piston, because it will be worn away. For the same reason new rings should not be used in the piston during the lapping process.

If the cylinders are badly scored, an old piston with old rings should be used, and after all marks are removed the new rings should be lapped in place, using an old piston.

When the cylinders are badly scored, an expanding lapper may be used instead of the old pistons.

Aluminum pistons cannot be treated in the same way as cast-iron pistons, because they are too soft. High spots on the pistons may be removed by means of a semi-cylindrical brass lap into which the piston fits.

Lapping Rings to Cylinder

If the cylinder surfaces are in good condition, only the rings need be lapped. The purpose in lapping the rings is to make them fit tightly against the cylinder surfaces at all points.

The lapping process consists in moving the rings back and forth in the cylinders in connection with a mixture of ground glass and cylinder oil, or carborundum and cylinder oil. The abrasives should be the finest obtainable.

When the rings bear all around, the work is finished. This can be seen with the naked eye. See also paragraphs above, under "Lapping Piston and Rings."

Another lapping compound for piston, rings, etc., is engine oil or coal oil and flour of emery. For a very fine finish use valve-grinding compound secured at supply stores. It is often made of crocus, which is finer than emery and is usually used on razor strops. A compound for this purpose is the Clover Lapping Compound. Write for a free pamphlet on this to the Clover Mfg. Co., Norwalk, Conn. This concern supplies compound for grinding or lapping pistons, rings, and crank shaft bearings, and for grinding valves, etc.

Note. It is advisable not to use any compound in which there is emery, as it tends to imbed itself in the parts and is difficult to clean out. A mixture of rotten stone ground to a paste with oil and applied to the rings serves very well for lapping and can be cleaned off more readily.

Lapping Methods and Devices

Lapping new pistons into cylinder for clearance is done when the new piston will go into the cylinder but with not quite enough clearance.

Lapping the cylinder for a new piston is done when the piston is slightly too large to go into the cylinder. An **old piston** is split so that it will expand and the cylinder walls are lapped down with it so the new piston will fit with proper clearance.

Lapping the cylinder for a slight score is done with an **old piston** split, and **oversize piston** must then be used.

Lapping rings into the cylinder can be done with new or old piston.

The following illustrations give an idea as to the different devices used for lapping a cylinder.

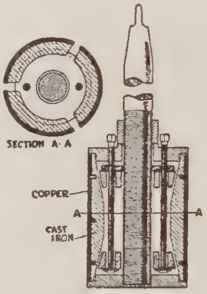

Fig. 12

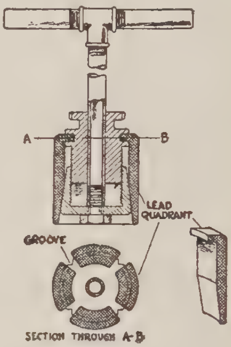

Fig. 13

Fig. 12. A simple design of an expanding lapper. Such a tool as this may be used in the drill press, an up-and-down and rotary motion being supplied at the same time.

Fig. 13 shows another tool of this type. Its construction will be readily understood.

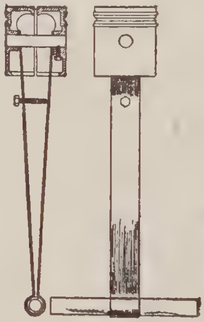

Fig. 14

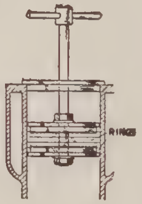

Fig. 15

Fig. 14. An expanding piston lapper which may be used for lapping rings or cylinders. The two operations should not be simultaneous, however. When the cylinders are slightly scored, the marks should be removed first, and then the new rings should be lapped in.

Fig. 15. When no piston is available the rings may be lapped between two blocks of wood as shown.

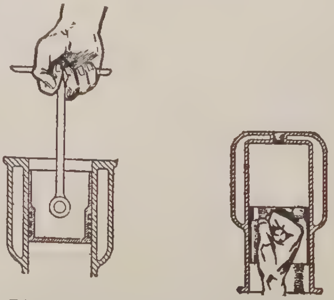

Fig. 16. Rings may be placed in an old piston. A new piston should not be used because it will wear away to some extent, and this is objectionable. The illustration shows two methods of accomplishing this.

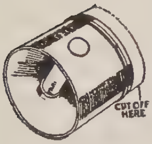

Fig. 17

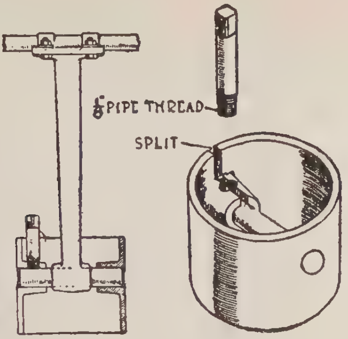

Fig. 18

Fig. 17. **Another method** is to cut off the head of the piston and to use the wristpin for a handle, as shown in Fig. 16.

Fig. 18. **An expanding cylinder lap,** made from a worn-out piston. The head of the piston is removed. One wristpin bearing is tapped; the piston is then split, as shown in the right-hand cut, so that a plug screwed into the tap hole will cause the piston to expand. An old connecting rod and handle is then provided as shown in the left-hand cut. Ground glass and oil are used for a lapping compound. (*Motor World.*)

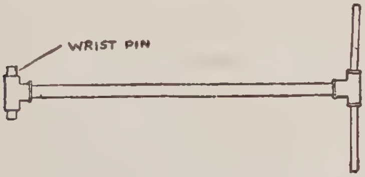

Fig. 19. **Piston lapping handle.** When it is desirable to lap a piston of a detachable-head engine without removing the cylinder casting, the tool shown is a time-saver. It is made of ordinary ½″ pipe, a T at the lower end slipping over the wristpin of the piston. The wristpin used in lapping should be made of fiber, as a metal one is likely to score the cylinders. Ground glass and crocus mixed in equal parts are used at the finish, and ordinary valve-grinding compound at the start.

Questions and Answers on Enlarging Cylinders

Q. 1: When should a cylinder be enlarged?

Ans.: When it is badly scored, worn, or out of round more than .003″. See pages 811, 814, 818.

Q. 2: How can you tell if it is out of round?

Ans.: By measuring with an "inside micrometer," as described on page 810.

Q. 3: Suppose it is not out of round but cut, should it then be enlarged?

Ans.: No; it can then be "filled," as described on page 814.

Q. 4: How much should it be enlarged if out of round?

Ans.: Enough to have it perfectly true.

Q. 5: How is a cylinder enlarged?

Ans.: By grinding, boring, reaming, or lapping.

Q. 6: Which is the best?

Ans.: Grinding. Boring, on a special boring machine is next best. Reaming is third best. Lapping would come fourth. See pages 821, 815 relative to lapping.

Q. 7: How is a grinding machine operated?

Ans.: Grinding is done on a special grinding machine, employing a wheel made of abrasive material revolving at a high rate of speed on the end of a rigid spindle. The spindle at the same time moves in a circular path, so that the revolving wheel travels around the hole. The path of the spindle is adjustable to the diameter of the hole. The cylinder is held stationary, and a multiple cylinder block can be ground without moving it, thus insuring all cylinders being perfectly round, smooth, straight, and square with the base of the cylinder casting. Grinding gives a true, smooth surface and no matter how hard or soft the material, the grinding wheel will grind it just the same. A lathe tool cannot leave a cylinder as smooth as a grinding wheel.

Q. 8: How are cylinders bored?

Ans.: By placing them in a lathe; by placing them in a drill press; by placing them in a special boring machine.

When placing a cylinder on the face plate of a lathe, a long boring bar is used. The cylinder, unless clamped securely, will move and ruin the job. Other disadvantages are that the long boring bar is likely to vibrate or jump and slide over a hard spot without cutting. Furthermore, the cylinder must be moved and reset on the face plate, if a multiple cylinder block, thus requiring skill to bore each cylinder straight with its base. A lathe tool cannot leave a cylinder as smooth as a grinding wheel. When placed in a drill press, this is better than on a lathe, as the cylinder does not revolve, and can be held more securely, but otherwise there are the same disadvantages. When placed in a special boring machine, the work can be done better than on a lathe or drill press, as the cylinder is held securely in place and the boring-bar spindle is heavy and rigid.

Q. 9: How are cylinders reamed?

Ans.: Cylinders can be reamed on a drill press (see page 694), or by a reaming outfit which can be attached to cylinder block (page 714). The disadvantage of reaming, to enlarge a cylinder, is the tendency of the reamer to follow the course of the old hole, thus preventing it from making a new and perfect hole. It is also necessary to take a deeper cut than would be necessary if grinding. Reaming can be done without removing engine, and thus costs less.

Q. 10: Is it necessary to fit larger pistons when a cylinder is enlarged?

Ans.: Yes; oversize pistons must be fitted as directed on pages 811, 824, and oversize rings must also be fitted to piston (page 828).

Q. 11: Would you advise sending a cylinder to a specialist to regrind, and do you advise having the entire block reground?

Ans.: Yes. If you wish a perfectly balanced engine it is best to have the block reground, especially if the engine has been run 20,000 to 30,000 miles. Also have oversize pistons ground to fit each individual cylinder. Read also answers to questions 4, 3, and 2, page 824.

The best plan is to have cylinders reground and have new pistons ground to fit each individual cylinder, with new rings, and in this way you will obtain a job that will give full power to the engine. After having cylinders reground and pistons and rings fitted, it is necessary to run the engine the first 500 miles at not over 15 m.p.h. and to use a lot of oil.

Q. 12: What are the symptoms of a worn or cut cylinder?

Ans.: Lack of power, heavy fuel and oil consumption, smoke, fouled spark plugs, and a piston slap. See answer to question 1, page 809, 817.

Q. 13: Where do cylinders usually wear?

Ans.: In the space where the rings travel. If the piston is loose, then the constant pressure from explosion force will wear the cylinder on one side, near the top, owing to the piston striking the cylinder wall at an angle.

Q. 14: Isn't it possible to fit oversize rings to a worn cylinder?

Ans.: Yes, but it is not altogether satisfactory, because the wear is usually where the rings travel, and in order to fit the rings, they must go in at the open end which is not worn. In this instance the rings are filed at the gap, so that they will pass the lower part; then they open up at the point where the cylinder is worn. If the cylinder is oval, then no round ring can fit it true (this also applies to pistons).

Q. 15: Is it advisable to lap oversize pistons to a worn cylinder?

Ans.: The piston or lapping tool is sure to follow the old hole. Thus, while lapping may improve conditions, it is impossible to make the cylinder perfectly round, if it is out of round. If the cylinders are perfectly round and the pistons are too small, then oversize pistons can be fitted. See also, Ans. 14.

Q. 16: Are all high-grade engine cylinders ground?

Ans.: Yes, and heat-treated, or seasoned castings are used and ground pistons are fitted to each individual cylinder. Almost all cylinders, when new, are first bored to within about .005″ of size, and then ground. Read the answer to question 4, page 809.

CYLINDER, PISTON, AND CRANK-SHAFT GRINDING AS A BUSINESS

The following material is taken by permission from the copyrighted 116-page booklet (price 50c.) issued by the Heald Machine Co., Worcester, Mass., manufacturer of cylinder-grinding machines. This book discusses the following subjects:

> "The Field and Profits; Equipment and Component Parts; Reasons, Advantages, and Methods of Refinishing Cylinder Bores; Kinks and Time-Savers; Operation of the Heald Machine; Advertising and How to Get Business; Facts Worth Considering."

Reground cylinders fitted with new pistons and rings will give the engine as much, if not more, power and pep than when it was new. It cuts the oil and gas consumption in two, and stops all excessive smoking.

It has been shown that quite a virgin field presents itself in the smaller shops, because on a small investment they can often place themselves in the class with the larger shops. Many of the small shops are fully equipped with the exception of a grinder.

There is no business today that has the possibilities and which fits so nicely into a small machine shop, automobile repair shop, or a concern doing welding as the regrinding of worn or scored cylinders.

The field for regrinding: There were over 9,000,000 commercial and pleasure cars registered during last year. Truck and tractor cylinders require attention once a year. Passenger cars should be looked over at least once every two or three years. Figure out for yourself what your chances are with only approximately 350 concerns properly equipped for such work. Consider also the fact that 3 four-cylinder blocks a day will bring profitable returns.

No one knows so little about cylinder regrinding as the average repairman. The car manufacturers as, for instance, Brewster, Cadillac, Cunningham, Dorris, Franklin, Hudson, Lafayette, Lincoln, Locomobile, Marmon, Mercer, Packard, Peerless, Pierce-Arrow, Stevens-Duryea, Stutz, and Winton, have their cylinder bores ground, and Heald machines are used for the purpose. Many engine manufacturers, such as Continental, Beaver, Buda, Herschell-Spellman, Lycoming, Duesenberg, Teetor, Erd, Fales, Hercules, Waukesha, Midwest, Rutenberg, have long since recognized this as the best method of finishing cylinders. Many of the repairmen advocate it; but to the owner it still means an unnecessary operation—only another way to add a few more dollars to his already overtopped garage bill.

It is, however, so vitally important in helping the engine to function properly that careful thought and study should be given it by every driver.

Prices Charged for Regrinding

As for prices that are charged for regrinding, they vary in different sections of the country, as well as in the localities in the same sections. It is best to get several price lists from the nearest concerns doing business, and to charge according to the conditions in your particular city. Never cut prices under a competitor, as regrinding is a quality proposition and it will cheapen your work and eventually be a losing proposition.

On the other hand, remember you cannot make a fortune overnight. Excessive prices will simply be an incentive for your customers to buy new blocks or to refinish by the boring method.

Average Prices in Different Parts of the Country for Regrinding Cylinders

Size	Cyl.	East	South	High Middle West	Low Middle West	Far West
Under 3″	2	$22.50	$24.00	$23.00	$17.00	$28.00
	4	43.00	41.50	45.00	34.00	42.00
	6	58.00	60.00	64.00	51.00	60.00
	8	74.00	77.00	83.00	66.00	76.00
	12	109.00	100.00	120.00	101.00	107.00
From 3″ to 3½″ dia.	2	22.50	27.00	24.00	18.00	32.00
	4	46.00	45.00	48.00	36.00	50.00
	6	59.00	64.00	68.00	53.00	71.00
	8	75.00	79.00	87.00	68.00	90.00
	12	114.00		131.00	106.00	128.00
From 3⅝″ to 4″ dia.	2	24.50	29.00	28.00	23.00	36.00
	4	44.00	49.00	54.00	42.00	58.00
	6	66.00	70.00	76.00	63.00	81.00
	8	82.00		104.00	85.00	104.00
From 4⅛″ to 4½″ dia.	2	25.00	35.00	32.00	24.00	43.00
	4	50.00	55.00	60.00	46.00	69.00
	6	68.50	77.00	84.00	68.00	97.00
From 4⅝″ to 5″ dia.	2	28.00	37.00	35.00	26.00	49.00
	4	53.00	62.00	67.00	50.00	79.00
	6	72.50	82.00	93.00	73.00	111.00
From 5⅛″ to 6″ dia.	2	28.00	40.00	42.00	26.00	60.00
	4	55.00	66.00	78.00	50.00	93.00
	6	72.50		130.00	73.00	136.00
		Prices without pins				Prices with Pins

Parts to Carry in Stock

For small concerns starting in the re-grinding business, it is by all odds more desirable at first to buy pistons, rings and wrist pins in various sizes from the manufacturers of these parts, confining all the efforts to re-grinding and fitting up the component parts. In this way a large volume of business can be done with a very small organization, and thus a very tidy profit can be made.

A certain amount of stock of all these parts should be carried, depending on the class of trade, the distance from the source of supply, and the size of the shop.

Pistons can be carried in three different stages of completion: rough, semi-finished, and finished, depending on whether the equipment of the shop will take care of the rest of the finishing operations.

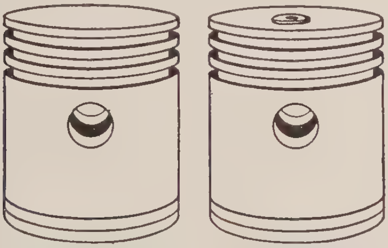

Fig. 20

Finished pistons are furnished finished complete, minus rings and pins; but these in many cases will be included, if so ordered. They usually come in oversizes of standard, .003″, .005″, .010″, .015″, 020″, .025″, .030″, and .040″.

Semi-finished pistons are finished with the exception of the outside diameter, which is left large to be ground down to the required diameter, and the wristpin holes which are rough-reamed and must be finished-reamed.

Finishing Semi-Finished Pistons

There is one operation on pistons that can be nicely taken care of by practically all re-grinding concerns, and that is the finishing of the outside diameter.

Most piston manufacturers will furnish them finished or semi-finished. By using a semi-finished piston, which usually comes 1/16″ oversize, and grinding it down to fit the bore, not only will it increase production, but it will allow the carrying of a larger supply on the same investment.

Finished pistons will change, even when bought from the best of manufacturers, and will frequently be found out of round. (A slight tap with a wooden hammer when fitting out-of-round pistons to holes will usually bring them back.)

In finishing the outside of the pistons a suitable external grinding machine must be obtained, as the cylinder grinder is of no value for such work. In securing such a machine, it is well to keep in mind two facts: that the length of a piston seldom exceeds 6″ or 8″, and the diameter, even on the larger sizes, does not ordinarily run over 5″. Therefore a small-size external grinder that will swing 6″ or 8″ with sufficient length between the centers is very satisfactory.

The pin holes on semi-finished pistons come rough-reamed with .002″ or .003″ left for finish-reaming. Any good adjustable hand-reamer will take care of this.

Remember, that in finishing the outside diameter, the lands should be relieved and made smaller than the skirt by at least .008″ or .010″. The excess heat and solid metal cause greater expansion at this point.

Always measure a piston below the wristpin hole, and not above it on the head.

Crank-Shaft Grinding

An allied line which fits in very nicely with cylinder grinding is that of crank-shaft grinding. Too much cannot be said about the importance of keeping a crank shaft in perfect condition. The crank shaft, virtually the backbone of the motor, when sprung out of alignment or when its journals are worn out of round, will soon wear the main bearings and connecting-rod bearings which bear directly on the shaft; consequently it will cause the motor to knock.

It is impossible properly to fit a set of bearings to a shaft which is out of round or out of alignment, and the extra time consumed in obtaining even a fair job would more than pay for re-grinding of shaft.

There has, however, been a great deal of misunderstanding regarding actual crank-shaft grinding.

By the old method of filing, lapping, and polishing a shaft—a slow and expensive operation, which is often misconstrued as grinding—it is impossible to obtain accurate results. This work should be done on machines built especially for crank-shaft grinding.

Equipment Required[1]

To do re-grinding, or to fit pistons, rings, and pins successfully, one must have the proper equipment. We have listed below the machines and accessories that make up such a shop. Prices for these will vary, especially if second-hand tools are used. Therefore it is hard to state any given value. All local machine-tool dealers will be glad to fill these in, and the amount of capital required can be determined at that time.

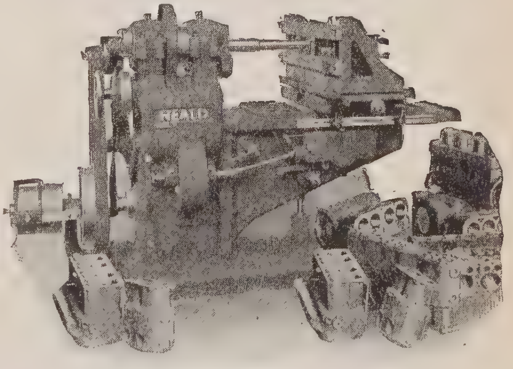

Fig. 21. A Heald cylinder grinder.

Machines Needed for the Average Shop

One style No. 55 or 65 Heald cylinder grinder fully equipped.
One small external grinder.
One 12″ lathe.
One 16″ lathe.
One sensitive drill press.
One back-geared drill press.
One 15 h.p. motor.
One emery stand.
Expanding reamers, sizes ⅝″ to 1½″.
Shafting hangers and belts.
Benches and tools.
Supply of pistons, rings, and pins.
Office equipment.

---

[1] From copyrighted booklet of Heald Machine Co., Worcester, Mass.

This comprises a fully equipped shop planning to use semi-finished pistons. For anyone just starting in, it is possible to do away with part of this equipment. By using finished pistons, it will not be necessary to have an external grinder; and while two lathes are much more convenient, the 12″ one will handle the work very nicely, and for the work which you would ordinarily use the back-geared drill press for, such as drilling wristpin holes, a lathe will answer the purpose.

When to Grind

Passenger cars: Cars that do not run tight, that use an excessive amount of gas or oil, lack power or pep, or smoke, need overhauling. A disagreeable piston slap is a sure sign of worn cylinders. This is usually heard on hills, or when the engine is laboring hard.

After it is taken down, it can best be determined whether it needs to be re-ground or not. If found scored, out of round, or with excessive clearance between the piston rings and cylinders, the cylinders certainly need regrinding.

All cars that have been run two or three years should be pulled down, re-ground, and fitted with new pistons and rings.

If the cylinders have been welded for any purpose, such as a score or a crack, they must be re-ground. Welding distorts and changes the shape, in addition to leaving excess metal. Only by being re-ground can it be brought back to a true, round, smooth hole.

With commercial cars or tractors, the same reasons for re-grinding hold true as with passenger cars. They are usually worked constantly to their full capacity, and are required to perform tasks which require every ounce of power.

Tractors, in particular, are subject to excessive wear, owing to the conditions under which they must work, and to the dust and dirt working into the engine. Re-grinding should be done at least once a year.

Why Engine Cylinders Should Be Re-Ground

It is essential, in order to have an engine run properly, that the cylinders be re-ground so that they do not vary more than a .001″ as to roundness. The hole must be straight and absolutely square with the base of the cylinders, otherwise there will be a noticeable loss of power and pep, excessive use of gas and oil, piston slap, continual fouling of the spark plugs, and general troubles of all kinds.

Compression

It is necessary that a cylinder bore be straight and round to obtain the proper compression. You cannot fit a ring and have it tightly seal a cylinder with an unround hole or one which has been enlarged in the top, either by error or inaccurate machining. Compression means a live engine, and rings must fit the hole. See also page 765.

Waste of Oil and Gas

When an engine has lost its compression, and knocks on the hills, etc., the owner usually makes the mistake of trying to cure the trouble by enriching his mixture. While this will temporarily cure the trouble, an excess of raw gasoline in the cylinder, on the compression stroke, is forced past the rings, thinning the oil and destroying its lubricating qualities, and possibly resulting in scored cylinders.

This gasoline eventually reaches the crank case, where it thins the oil to such a degree that it is useless as a lubricant. Old and worn cylinders are not the only places where this happens, as it also occurs in many motors where the holes were not originally ground, but were inaccurately bored or reamed.

Thus not only is excess gas being used in proportion to the power secured, but a large share of oil is going off in smoke, or is being rendered useless, thus requiring constant renewal.

Missing

Ill-fitting rings not only allow leaking of gas, but on the suction stroke air is sucked up from the crankcase, thinning the mixture and causing the engine to skip. This is particularly noticeable when traveling at idling speeds or starting on cold mornings.

Carbon

When the oil gets by the piston rings into the combustion chamber and is burned by ignition, it gives off a bluish smoke, leaving carbon formed on the head of the piston and in compression chamber.

Carbon holds heat, and if the compression is high, it will often explode the mixture earlier than it should. This is called pre-ignition, and it very often results in a broken piston pin, bent connecting rods, or a scored cylinder. Of course, burned oil soots the spark plugs and requires constant cleaning to keep a hot spark.

Engine Knocks

There is nothing more aggravating to the driver than to have his engine knock. Some engines have such a thick carbon deposit that the slightest pull will result in this annoying sound. This condition is all caused by oil leaking past the rings into the combustion chamber, where it is burnt by ignition.

Are Re-Ground Cylinders, with Pistons Ground to Fit, Better than New?

When the statement is made that a re-ground engine which has been fitted with new pistons and rings is better than it was originally, few people can understand why. It is a well-known fact among those connected with the metal industry that castings change shape after they are cast. This is caused by strains and stresses resulting from the heavier walls of metal cooling last and shrinking from the already cooled lighter walls.

These strains can be relieved if the castings are seasoned for a long time, or by heat-treating processes.

Castings that are immediately machined and put to work in a car change more or less, owing to the heating and cooling of the engine, which acts as a heat-treating operation. Therefore, an engine which has been run several hundred miles is thoroughly seasoned and is in ideal condition to be re-ground and fitted up.

Once having been relieved of all the strains and stresses, the castings will retain their shape continuously after grinding, if properly machined and fitted up.

Actually, of course, an engine does not have any more power after re-grinding than that for which it was originally designed.

The fact, however, that the casting is seasoned, and that each hole has had individual attention, often gives better results than a general-assembly proposition. (*Motor Age.*)

DIFFERENT METHODS OF FINISHING BORES OF CYLINDERS

Methods of Finishing Bores

There are four methods of enlarging cylinders: (1) by boring; (2) by reaming; (3) by lapping; (4) by grinding.

The prime object of either operation is to **finish** the cylinder, so that it is absolutely round and straight, and then to fit the cylinders with new oversize pistons and rings.

The following discussion of the advantages and disadvantages of each method is taken from the instruction book of the Heald Machine Co.

Reboring Cylinder

Boring is done by a steel-cutting tool in the same manner as that in which a lathe cuts. It produces a porous-like surface which is subject to rapid wear.

When a cylinder is re-bored, the tool must get under the hard surface skin of the worn and polished cylinder wall, and as a result a heavy cut, as compared with grinding, must be taken. Therefore, the cylinder bore is enlarged 5 to 10 times more than is necessary and the walls are often reduced in thickness to a dangerous degree.

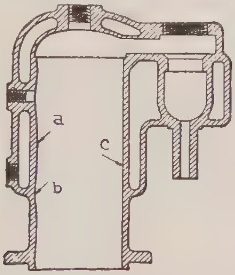

Fig. 22. Cross-section of a gas-engine cylinder.

With the re-boring method, a considerable amount of pressure will be exerted on the walls of the cylinder. Since these walls are comparatively thin and are reinforced only by the water jacket in certain places, it will be found that the walls where they are not reinforced will spring away from the cutting tool, when it springs back after the tool passes on, leaving an elevation, shown at (a). Where the walls are reinforced, the tool will take a slightly heavier cut, as at (b) (Fig. 22).

There are also hard and soft spots in the iron, and the cutting tool will bite into the soft spots and spring away from the hard ones.

It is not, therefore, practical to produce a true, straight bore within exceedingly close limits of accuracy by the re-boring method; and, furthermore, if a bore is out of square with the flange, reboring will not correct this error, since the tool will follow the bore.

Reaming Cylinder

Reaming is similar to boring, except that a number of tools set in one head are used instead of a single tool. What has been said about the disadvantages of boring applies equally well to reaming.

When the pistons and rings are assembled in the cylinder, **after reaming,** as shown in Fig. 23, they will rest on minute hills of metal. About half the bearing surface is thus lost, owing to the depression of metal between each hill. A full bearing surface is not realized until from .002″ to .005″ of metal has been removed by the pistons and rings. This causes a very rapid wearing of the cylinder walls until they are worn to solid metal. This extra amount worn off permits a large percentage of gas and oil to leak by the ring.

Fig. 23. Showing uneven surfaces left on walls of cylinder after reaming (exaggerated).

Lapping Cylinder

Lapping the holes of worn cylinders will not make them round or straight, because the lapping process is good only for polishing surfaces, and even after hours of work, but little material is cut away, leaving much of the lapping compound imbedded in the walls. It is an expensive operation, and the degree of accuracy and success to be achieved depends entirely on the skill and experience of the workman.

A worn cylinder is always larger at the top than at the crank end, owing to the friction of the rings and also to greater heat and poorer lubrication. Therefore, the grinding machine must be used to cut away the material necessary to get a round and straight hole for the entire length.

When lapping is done, two metallic surfaces are rubbed together with oil and abrasive material between them. This will charge the surfaces with grit.

Grinding in a machine with a hard, vitrified grinding wheel running at a high speed to cut the metal away is an entirely different proposition, and is the only way to secure right results.

Finishing by Grinding

In finishing a cylinder by grinding, an abrasive wheel held by a very rigid arm moving at high speed cuts away the metal freely without putting undue pressure on the cylinder walls. The feed of the wheel into the work can be adjusted so that it will remove the metal rapidly if a large amount is to be taken off, or so lightly that it is practically immeasurable.

The grinding wheel revolves in a perfectly true circle and cuts away the iron until a round and straight hole is produced, without either high or low spots, and having a beautiful, smooth, and mirror-like surface throughout.

The work is held on an angle-plate attached to the cross-slide of the machine; the main table, traveling lengthwise, moves automatically. When a hole is finished, movement of the cross-slide gives the proper position for the next hole.

The block remains set during the entire operation, insuring the bores being absolutely parallel to each other and at right angles to the base.

By this method all the disadvantages of boring or reaming are absolutely overcome. The high-grade cylinder-grinding machine produces a true, straight, accurate bore, the usual limits of accuracy being within one one-thousandth of an inch. The bore is absolutely square with the flange, the surface produced is hard and glass-like, and the amount of stock taken out is only a fraction of what would be necessary in re-boring.

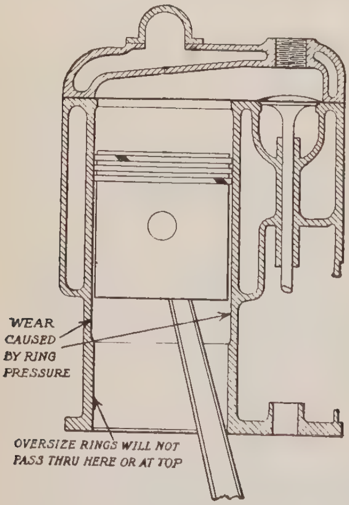
New Rings No Help

A large share of repair shops are still advising new rings when an owner is confronted with motor troubles. He believes it is a cure, but it is only temporary, since in most cases the carbon has been cleaned out, valves have been ground, and the motor has been generally tuned up. It therefore seems to have overcome the ailment. It is not lasting, however, for no matter how expensive or complicated the rings may be that are used, with or without compression guaranteed, a round ring will not fit an egg-shaped hole; and if the motor has been run at all, that is what you will have.

Thousands of strokes of the rings up and down the cylinder, while aided by road dust and other abrasives which are sucked into the cylinders with the mixture, will gradually wear down the cylinder wall.

This wear is greater on the two sides at right angles with the crank shaft. It is the result of the pressure of the piston against one side of the cylinder wall on the compression stroke, and on the opposite side of the cylinder wall on the power stroke.

No ring will fit such a shaped hole, so there is bound to be a chance for gas to escape and a long time needed for the rings to wear in, if they ever do so.



WEAR CAUSED BY RING PRESSURE
OVERSIZE RINGS WILL NOT PASS THRU HERE OR AT TOP

Fig. 24. Showing the points where rings usually wear cylinder walls.

Therefore, as the **cylinders are worn only the length of the ring travel, it leaves the lower and upper ends smaller.** To put a ring of the proper oversize in the worn part through the smaller hole is impossible.

The only cure for a worn cylinder—and it takes but a few thousandths of an inch to show appreciative loss of power—**is to have the cylinders reground and fitted with new pistons and rings.**

Fig. 24, which has been somewhat exaggerated, shows the wear in a cylinder which may have been made by various causes. Note how the gaps in the rings are spread, allowing gas to pass up through or around the rings.

New rings in such a worn cylinder would do no good, unless they were of the correct size to fill this hole. This is impossible, since rings of the proper size would not pass through the space either at the top or bottom of the cylinder. It will require grinding to take out sufficient stock to allow proper oversize pistons and rings to be inserted.

At Right Angles to the Flange

What is meant by "square with the flange," is indicated in Fig. 25.

It does not matter so much if the holes are not at right angles with the flange from side to side, but end to end they must be parallel, and perpendicular to the base.

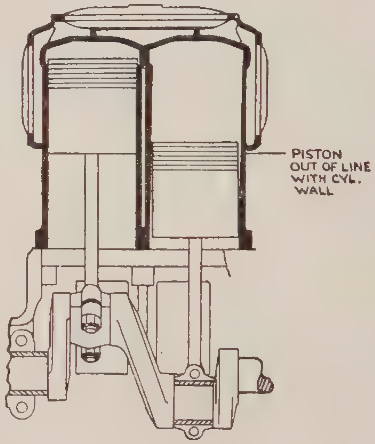


Fig. 25. Cylinder bore that is at right angles with the flange.

The right-hand side of the cut shows how the piston is often cramped in the cylinder by being out of square.

This may be caused in several ways. First, the bore in the cylinder may not be square with the crank case. Second, the piston-pin hole may not be drilled square with the sides of the piston. Third, the holes in the ends of the connecting rod may not be parallel with each other. Any one or more of these may result in excessive wear on the cylinder walls, or in a frozen motor.

Thin Cylinder Walls

Occasionally the shifting of the cores, when molding the cylinders, leaves a thin wall. In re-grinding such cases, if the wheel should break through, of course the man doing the work cannot be held for this misfortune. Furthermore, should there be a deep score and the owner wished it ground out and not filled, he must assume all the responsibility if he has trouble later.

It would be better business for all re-grinding concerns to refuse to touch such jobs, if, in their opinion, there is a doubt as to the strength of the wall after grinding.

New Pistons and Rings Necessary

If the cylinder is re-ground, new pistons and rings must be installed. The amount of stock to be removed in order to bring a bore back to a true round hole is usually at least .010″ and, if the cylinder is scored or badly worn, will go from .030″ to even .040″. Such clearance would never allow the use of the old pistons.

Many a perfect re-grinding job has been spoiled when the engine is being assembled. If you are in a position to take down and reassemble, then you are more fortunate than many who must trust this final and very important part of the job to someone else.

Great care should be taken first to wash the cylinders and pistons, rings, etc., carefully with gasoline. Be sure that every particle of abrasive material and foreign matter is removed.

Make certain that the **wristpin fits both the rod and the piston,** and see that it is securely fastened on. Better go over this an extra time and make sure, for a loose pin or screw will ruin the entire job the first time the engine is run.

Measure the pistons for roundness after assembling with the connecting rods, to see that they have not gone out of shape. A slight tap with a wooden hammer will correct any change.

After reassembling the pistons on the crank shaft, test them to see if they are absolutely square. Do not take it for granted, because the connecting rods were straight before it was pulled down, that they will be so when you reassemble them. There are many chances and reasons for their having become twisted or out of square. This could happen in taking off the block with the pistons still connected to the crank shaft, when it is an easy matter to bend or twist the rods. Again, in scraping in the connecting-rod bearing or in tightening the caps, a slight variation at this end will increase many times at the piston end.

That the **pistons should be square** (see Fig. 25) is highly important; if they are not, the cylinders might just as well not have been ground, for the pistons hitting on the sides will give all the troubles of an out-of-round hole.

Put plenty of oil on all the pistons before assembling in the cylinder.

The rest of the assembling is purely a repairshop job, but every detail should be thoroughly gone into as if it were a brand new car. In fact, the vital parts are new and with limits usually closer than those allowed by the manufacturer; therefore, they should receive careful attention.

Be sure that the crankcase is well filled with a good light or medium oil, and that the system is working perfectly. Run the engine slowly for one half-day, giving it time to cool naturally.

RE-BORING OF CYLINDERS TO FIT THE PISTONS

The preceding pages are devoted to matter taken from the booklets of a prominent cylinder grinding machine manufacturer.

The following is taken from the printed matter of K. R. Wilson, Buffalo, N.Y., who specializes on repair-shop tools for Ford motors.

The proper method is to bore cylinders to fit the pistons, thus giving same clearance in every cylinder.

The old method of boring the cylinders "all one size," and hoping to find pistons to fit them (selective fit), has been abandoned as obsolete, and expensive, because Ford pistons vary so much from the size with which they are marked that hand-fitting, filing, turning, or lapping in is necessary to turn out even a fair job. All of this extra work contributes toward the cost of the finished product.

Measuring and Marking Pistons

The pistons are first marked 1-2-3-4. They are then measured with a 4″ micrometer ("miking" is the trade name for measuring with a micrometer), first for roundness, by measuring them across the skirt in the direction of the wristpin; then at right angles to it. The piston is then laid on a block of wood, with the high side up, another block is laid on top, and a few sharp taps with a hammer will suffice to drive it back into its original roundness.

Measuring the piston with a micrometer, to check the size as stamped on it, and thus to obtain its actual measurement, is the first operation, because pistons do not always measure as marked. Suppose a piston was stamped .031″ oversize, meaning that it should be .031″ larger than the standard size (3.750″), or a total of 3.781″. By means of the micrometer (**E**) (Fig. 26), measure the piston. Suppose this measurement shows that the piston is actually 3.784″, it would thus be 3.784″−3.781″= .003″ **larger** than stamped. This piston would then be chalk-marked 3.784″. Suppose that the next piston is also stamped .031″ oversize, but the micrometer measurement proves it to be 3.777″, this piston would be 3.781″−3.777″=.004″ **smaller** than stamped. This piston would be chalk-marked 3.777″.

Setting the cutter to bore the cylinder is the next operation. A clearance of .003″ must be allowed between piston and cylinder. Take the piston which was chalk-marked 3.777″. By adding the specified amount for clearance, we obtain 3.777″+ .003″=3.800″. Therefore the single-bladed cutter (**C**) (Fig. 27) must be set to bore the cylinder to 3.800″. Take another piston, as the one chalk-marked 3.784″. Allowing .003″ for clearance, we obtain 3.784+.003″=3.787″. Therefore the cutter must be set to bore the cylinder to 3.787″ for this piston.

Boring Operation

The boring bar is now placed in the cylinder, and is instantly located by means of two (two-piece) tapered locating plugs (**L**), as shown in Fig. 27. One of the plugs at each end of the cylinder on the boring bar insures perfect centers.

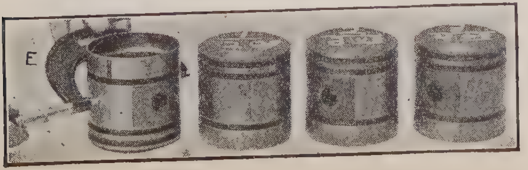

Fig. 26. "Miking" and chalk-marking pistons.

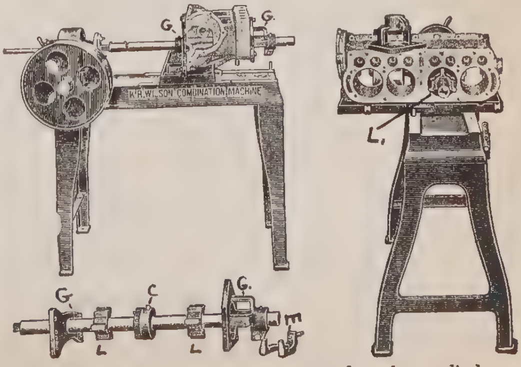

Fig. 27. K. R. Wilson machine being used to rebore cylinders.

The permanent guides (G) are then positioned and fastened to the block on both cylinder-head and crank-case ends. The tapered locating plugs (L) are then removed through the openings provided, leaving the boring bar all set up. We now place an 8″-wrench on the square end of the boring bar, and with another "speed-type" wrench, we tighten the adjusting screws of the split bearings on each of the permanent guides until it requires considerable pull on the 8″-wrench to turn it. Note that it is impossible to bore a tapered or uneven hole unless you purposely allow these bearings to become loose and a sloppy fit for the boring bar. The bearings on the two permanent guides are adjustable, and will take up any possible wear, and will thus prevent "chatter." Now place the universal joint in position, and throw in the feed lever. In 9 minutes the cylinder will be rebored, during which time no other attention except setting up is required.

The table holding the cylinder block contains four sets of two No. 5 taper-pin holes and one 7/16″ cap-screw hole opposite the center line of each cylinder. Corresponding holes are drilled into the bed of the machine by moving the table with the cylinder block attached on the bed. Any cylinder can be brought into exact location wherever the pins will fit into place.

The time required is about 1¾ minutes to set up for each hole, and 9 minutes to bore it, making a total time of 43 minutes; but on account of the automatic feature, not more than 10 minutes labor cost can be charged to boring the four cylinders, for the reason that the operator can be grinding valves, fitting pistons, connecting rods, or overhauling the transmission or doing many other jobs while the machine is taking care of itself.

Cutters are interchangeable (cost 50c. each), and it is not necessary to tie up the cylinder re-boring machine while the cutters are returned to the factory to be re-sharpened and fixed up. The cutter is adjustable to take up any wear, and on account of the narrow cutting edge will not dub over when it hits a hard spot or a scored cylinder. A narrow cutting edge could not be used with any equipment other than a cylinder boring bar, having a fixed guide on each end that will prevent chatter and keep cutter from digging in or following the old hole.

Because the "cylinders are bored to fit the pistons," eliminating nearly all hand operations, such as filing, turning, lapping-in, etc., only a slight amount of hand filing to remove the high spots and niches is required. Pistons fitted by this process to .002″ clearance are absolutely free in the cylinder and, without rings or oil on them, will "fall through" without friction.

Mr. Wilson states that lapping-in will cut off some of the high spots in the cylinders and pistons, but it will not fill up the low spots.

Filing pistons in a lathe will make them smaller, but will throw them out of round more than ever, for the reason that when the file hits the relieved portion of the piston near the piston pin boss, it will jump and "dig-in" again about one inch from the edge of this relieved portion.

Lathe turning is unsatisfactory because the average service station is not equipped with proper tools for this work. Even if it were, it is a difficult proposition to "chuck up" a Ford piston accurately to remove only a few thousandths of an inch. These facts show why it is necessary to bore the cylinder accurately in the first place, if you want a first-class job at a minimum cost.

Questions and Answers on Enlarging Cylinders; Continental Engines

The following questions and answers pertain to the Continental engine (see Index), but are applicable to many other engines:

Q. 1: Are cylinders ground, reamed, or bored?

Ans.: All Continental cylinders are bored and reamed with special fixtures and tools which insure perfect alignment. After these operations they are ground accurately to a glassy smooth finish.

Q. 2: Are pistons fitted to each individual cylinder, and what is the standard clearance?

Ans.: Not only the piston, but the piston rings as well, are individually hand-fitted to each cylinder bore. The clearances allowed in each case depend upon the size of the engine and the service for which it was designed.

Q. 3: How are engines marked to show the original diameter of the cylinder bores?

Ans.: The diameter of each cylinder is stamped on the lower machined face of the cylinder block where the valve-chamber cover is attached. These marks are in decimals.

Q. 4: What factor determines the amount of clearance to be allowed when fitting pistons in the cylinders?

Ans.: The amount of expansion. This depends upon the materials used in the pistons and cylinders, the general design, and the operating temperature of the engine. The temperature of an engine in operation is affected by the amount of fuel consumed, the resistance offered the power impulses, and the timing of the ignition.

Q. 5: What is meant by .003″ loose-fit and .004″ tight-fit of piston clearance?

Ans.: The piston would be free in the cylinder with a .003″ thickness gauge (also called "feeler") between it and the cylinder walls, and the same piston would be tight in the cylinder with a .004″ feeler.

INSTRUCTION No. 71

PISTON RINGS: Types, Construction, and Fitting; Piston-Ring Gap Clearance; Piston-Ring Groove Clearance; Measurements of Piston Rings; Standard and Oversize Piston Rings; Testing and Fitting Piston Rings

PISTON RINGS

The piston ring is used to fill the gap between the piston and cylinder walls, preventing the gases escaping into the crank case and an excess of oil working into the combustion chamber.

A piston must be fitted with piston rings. The piston is slightly smaller than the bore of the cylinder, in order that it will not stick to the cylinder wall (termed "seizing"), when it becomes hot and expands.

Since the rings are softer than the cylinder walls against which they are tightly pressed, and also present small wearing surfaces, they become undersize in time. To insure maximum power, together with minimum oil and gas consumption and the best all-round satisfaction, the rings should be renewed about once every 10,000 miles.

Ring grooves are provided on pistons for the rings. The grooves are slightly wider than the ring. For instance, the Ford ring is ¼″ wide and the width of the groove is one and a half one-thousandth of an inch wider (clearance). On the Dodge, the ring is 3/16″ wide, and the groove has a clearance of one and a half one-thousandth of an inch.

If a ring groove becomes worn and is over .005″ clearance, the piston can be put in the lathe and the groove can be widened to take a 1/32″ oversize-width ring.

The depth of the grooves averages about 3/16″. The average **thickness of a ring** is 5/32″; thus the groove is 1/32″ deeper than the ring is thick. On some of the V-type engines the grooves are shallow. The rings are about ⅛″ thick, and the depth of the groove is about 1/32″ or 1/64″ more.

If the groove is too large, there will be a compression leak between the groove and the ring. If **too narrow,** the ring will stick in the groove and will not exert its tension against the cylinder wall.

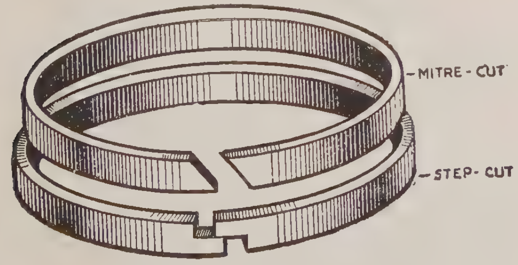

Fig. 1 (upper); Fig. 2 (lower).

Fig. 1. Piston ring with a beveled joint, cut slantwise, Easier to make than the other type, but not quite so effective in preventing possible leakage. Termed a "mitre cut" or "diagonal" joint or "bevel joint."

Fig. 2. Piston ring with stepped or lapped joint which prevents leakage of pressure at the joint. Termed a "step-cut" or "lap-joint" ring.

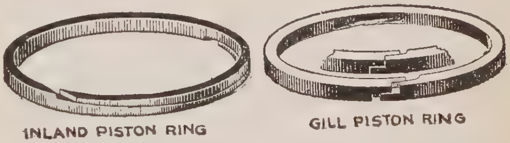
The ring gap is provided on all rings in order that it can be fitted to the piston groove and so that it can expand and exert tension equally against the cylinder walls at all points of its circumference.

The two types of ring joints which are generally known and used are shown in Figs. 1 and 2, and are known respectively as the **"step-joint"** and **"mitre-joint"** ring. There are many other kinds of joints or gaps used on the various patented rings. The step-joint is used most.

Patented Piston Rings

Patented rings are made in many different constructions, some of which are shown in Figs. 3 and 4.

The two principal advantages claimed by the patented ring manufacturers for their rings over the ordinary type are: (1) that the joints are gas tight at all times, and (2) that they exert equal tension or pressure on the cylinder wall at all points of their circumference. Usually the manufacturers make two types of rings: a "high-compression ring" and an "oil ring."

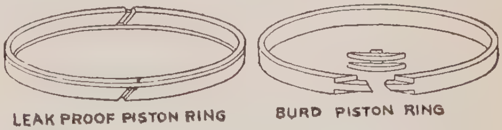


INLAND PISTON RING
GILL PISTON RING

Fig. 3. A few of the popular patented type of piston rings. Note the different joints and methods employed to obtain equal tension at all points of the ring circumference.

The Inland, or Star-K-Inland, as it is known, is a one-piece ring with a long lap (made by Star-K-Inland Machine Works, St. Louis, Mo.).

The Gill is also a one-piece piston ring of the concentric type made from a single-piece casting of special gray iron and machined to accuracy. This ring has an interlocking joint and is termed the "Gill joint," or, technically, "a double-step interlocking-joint" ring (made by Gill Mfg. Co., Chicago, Ill.).



LEAK PROOF PISTON RING
BURD PISTON RING

Fig. 4. The Leak-Proof piston ring is a two-piece ring, manufactured by the McQuay Norris Co., St. Louis, Mo.

The Burd ring will best be understood by referring to the illustration above (made by Burd Ring Co., Rockford, Ill.).

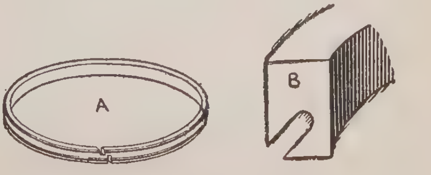


Fig. 5. **The oil ring** made by two different manufacturers. **(A)** is the Star-K oilless quick-seating piston ring, designed to

overcome oil pumping. It has two oil grooves: one in the middle for lubrication; one on the lower shoulder to scrape down all excess oil. (B) is an end view of the "Superoyl" piston ring.

A small oil groove, or reservoir, is cut around the lower edge of this concentric ring, providing a scraping edge. One "Superoyl" ring is placed in the top groove of the piston and the two Leak-Proof piston rings below, in cases where an excess of oil reaches the combustion chamber (manufactured by the same concern that make the Leak-Proof ring).

When the ring is in the cylinder, the gap clearance is very slight. If it were too great, there would likely be a leakage of compression through the gap, or if all of the gaps were in line when in the cylinder, it is likely that there would be a leakage of compression from the combustion chamber to the crank case through the gaps. Inasmuch as the rings are free to work in their grooves, the common belief is that the rings move, or work around in the grooves, until they are all in line at one time. However, this is improbable, as well as probable; for if the rings thus work around, they are likely to continue working, and if originally placed on the piston an equal distance apart, there is not much chance for all of them to get in line at the same time.

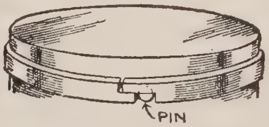

Fig. 6. A pinned piston ring.

Before the advent of the patented ring, the rings were usually pinned, that is, the gaps were first placed 120° apart on the piston, and then the ends of the rings were notched with a fine round file, so that the semicircular notches just closed over the pins (see Fig. 6). The pins were a source of trouble in high-speed engines, and unless great care was exercised in screwing or fitting the pins tight into the piston, they would loosen and project and cut the cylinder wall. Thus this practice was abandoned to a certain extent. Pins are still used on many large, slow-speed engines and on two-cycle engines. There is no doubt that the pins had the advantage of insuring against their getting in line. But they also had disadvantages. The growth of the popularity of all kinds of patented rings with gas-type joints has thrived on this claim as well as on the claim that the patented ring exerts equal pressure at all points of its circumference. For instance, note the long lap of the Inland ring and the construction of the Leak-Proof and the Gill ring.

Concentric and Eccentric Piston Rings

It is important that a piston ring exert equal pressure or tension against the cylinder wall at all points of its circumference. Right here is one of the most important duties of a piston ring. If it fails to do this, then the part of the ring which does not press against the cylinder wall is bound to permit the compressed gas to pass into the crank case.

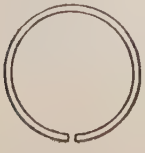

Fig. 7

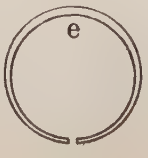

Fig. 8

The concentric ring (Fig. 7) is one of equal thickness throughout its entire circumference.

The eccentric ring (Fig. 8) is made eccentric (thicker) at one point, as shown at (e).

Some manufacturers claim that the concentric ring will maintain equal tension under heat, if made of the right material, and others claim that the eccentric ring is the best—see Q. 6 and answer, page 834.

A very popular step-cut concentric ring is the "hammered ring," made by the American Hammered Ring Co., Baltimore, Md. This ring is shown in Fig. 9. Note that the inside of the ring has been hammered, or peened, with hammer marks.

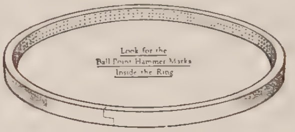

Fig. 9

The makers claim that this operation causes the ring to have **equal tension** at all points of its circumference. This make of ring is used on the Buick, Dodge, Pierce-Arrow, Locomobile, and Stutz engines. Another peened, or hammered, ring is made by the Wasson Piston Ring Co., Plainfield, N.J. and also by the Victory Piston Ring Co., Newark, N.J.

Number of Piston Rings to Piston

There are usually two or three piston rings above the piston pin, and quite often an oil groove is in the skirt of the piston. On many engines, there are three piston rings above the piston pin and one oil ring below the piston pin. On the Ford, there are two piston rings above the piston pin and one below. See Fig. 10, and note how the Ford rings are tapered in order to prevent an excess of oil getting to the combustion chamber.

Racing engines often use one or two piston rings, so as to facilitate more perfect lubrication, perfectly tight compression not being so necessary for high-speed motors as for low-speed ones. Moreover, good compression is more necessary for good carburetion at low speeds, while it is not so imperative at the higher speeds.

The ring below the piston pin serves two purposes: (1) to prevent piston slap; (2) to keep oil down, and is often called the **oil ring.**

Therefore, we might term the rings above the piston pin, the "compression rings," and below, the "oil ring." The oil ring is usually given slightly less clearance at the gap (see Ford ring-gap clearance, Fig. 10).

If the piston pumps oil and the spark plugs are constantly oil-soaked, the oil ring should have holes drilled in the groove behind the lower ring, as directed on page 169 (see also Index under "Piston pumping oil").

On this page, it will be noted that the oil holes are in the ring groove above the piston pin, as well as below. The practice is first to drill holes in the ring groove below the piston pin, and if this does not relieve the excess oil reaching the combustion chamber, then do the same with the first ring above the piston pin.

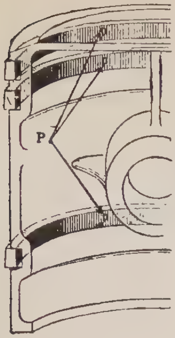

Fig. 10

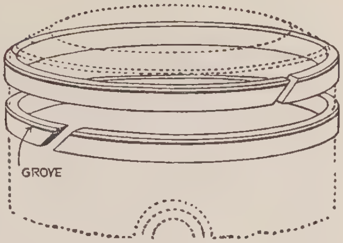

Fig. 11

Fig. 10. **The Ford rings are cut .002″ taper.** This insures the ring wearing so as to conform to the cylinder walls in the shortest possible time, and, when assembled with the file or punch mark up, as shown, the ring presents a sharp edge to the cylinder wall on the down-stroke and an incline on the up-stroke. The incline rides over the oil, while the sharp edge pushes the oil before it, thus preventing the oil from working into the combustion chamber.

On some of the earlier rings, there was a file mark in the upper edge, to show which side to place up. If the ring is upside down, it will have a tendency to pump oil.

Ford piston rings are also machined with a **groove** near the edge, which **should be toward the top** when installed on the piston. See Fig. 11. On later models, the word "Ford" is stamped on the upper side of the ring.

Ford ring-gap clearance: First and second rings, .008″ to .015″; bottom, or oil ring, .004″ to .005″, since it is necessary that a small amount of oil work up between the piston and the cylinder wall.

Measurements of Piston Rings

Manufacturers differ as to the measurements of a piston ring. A gauge is generally used for this purpose.

One type of gauge[1] consists of hollow tubes in which the piston ring is fitted. For instance, this tube would represent, say, a 4″ ring, and when the ring fits into this tube with a certain opening of the ring gap it would be a 4″ ring. Thus it will be observed that a ring is not measured by closing it tightly and measuring its outside diameter, but, in other words, the gap opening of the ring must be considered.

For example, the average clearance of a piston ring is approximately .002″ **diametrical clearance,** so as to allow for an oil film between the piston ring and the cylinder wall.

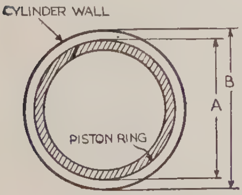

Fig. 12

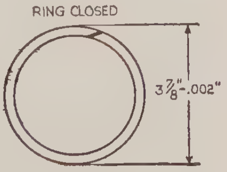

Fig. 13

The term "diametrical clearance" means the difference between the diameter of the cylinder wall (the bore) and the outside diameter of the piston ring (gap closed). In Fig. 12 the diametrical clearance is the distance (**B**) minus the distance (**A**).

The term "radial clearance" means the radius of the cylinder minus the radius of the piston ring. In Fig. 15 it is represented by (**B**-**A**). It should be 001″.

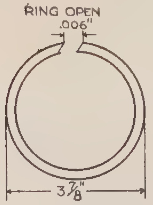

Fig. 14

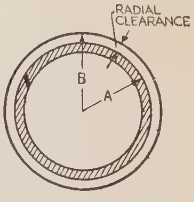

Fig. 15

Therefore a ring that was rated as of a 3⅞″ diameter would, when **closed** (Fig. 13) measure 3⅞″ less .002″ in diameter, or, in other words, if the ring were allowed to **open** .006″ in its gap, it would measure 3⅞″ (Fig. 14), because a **difference** of .002″ in **diameter** equals a **difference** of .006″ in **circumference** (.002″ x 3.1416″=.0062832″).

Piston-Ring-Gap Clearance

If the **ring is out of the cylinder,** it would approximately measure on its outside diameter, with a .006″ open gap, 3⅞″, as shown in Fig. 14. **If in a cylinder** of 3⅞″ bore, the gap would be approximately .006″ when stationary.

When the **engine is in operation,** the piston-ring gap would almost close, and in that position should have approximately .002″ diametrical clearance from the cylinder wall for an oil film, which would force its way between the ring and the cylinder wall.

The **oil film** would occupy a radial clearance or space of .001″ all around the piston ring, consequently the **diameter** of the piston ring would be reduced .002″. And, if the diameter is reduced by .002″, the **circumference** is reduced by 3.14″ x .002″ =.006″. This reduction must be taken up by the gap, and consequently the gap of .006″ is reduced. However, in actual practice, the gap is not closed entirely, but should be almost closed when in operation, so as to prevent oil from being pumped through the gap. This clearance is allowed so that the ring can expand and contract and yet fit firmly to the cylinder wall, allowing for the oil film. Thus if the gap is too great, the diametrical clearance will be greater, and consequently a greater oil film will result in that part, and the oil will pass to the combustion chamber. Hence the importance of the exact gap clearance which should be ascertained from the piston-ring manufacturer when ordering piston rings.

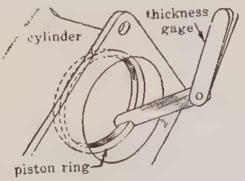

Fig. 16

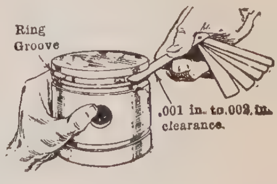

Fig. 17

Method of finding the ring-gap clearance in the opening of the ring (see Fig. 16): Place the piston without rings into the cylinder. Then slip the ring into the cylinder behind the piston, as shown in Fig. 16. Pull the piston up against the ring in order to square the ring up in the cylinder. If the cylinder is worn, it is usually so at the upper end. A thickness gauge is then applied, as shown in Fig. 16.

---

[1] Another make of piston-ring gauge, made by D. F. Dunham, Oxnard, Cal. The piston ring is measured across the extreme outside diameter when the piston ring is tightly closed.

The average ring-gap clearance, or the distance between the end of a gap-cut ring, should be .0015″ (1½″) to .002″, for each inch in diameter of the cylinder. Some manufacturers, the Gill Co., for instance, advise .003″ clearance for each inch in diameter of the cylinder.

In the absence of explicit instructions from the piston-ring manufacturer, the following gap clearances could be followed:

2″ to 3″ ring: gap clearance .006″
3″ to 3½″ ring; gap clearance .007″
3½″ to 4″ ring; gap clearance .008″
4″ to 4½″ ring: gap clearance .009″

The usual method of ordering piston rings is to measure the diameter of the piston and the width of the groove, and to state the make of engine. The manufacturer has a list which he refers to, and can then give the proper ring. The best plan is to measure the cylinder, as it may be worn. To do this, cut and file a wire which will fit **exactly** to the bore of the cylinder, and measure the width of the piston groove, and send this to the manufacturer.

Note that the test of the cylinder for size should be made in that part of the cylinder where the rings travel, as more wear usually takes place at this point.

Standard and Oversize Piston Rings

On new cylinders, where they are perfectly round, the piston ring is the standard size.

On old cylinders which have been worn out of round, as a result of piston slap, or in cases where the rings "travel," it is necessary to fit **oversize** piston rings.

Therefore, **in ordering oversize piston rings,** it is necessary to measure the cylinder where the rings travel. However, it will be found that the fact that the cylinder is out of round will necessitate a slightly larger ring which should be lapped in and the gap dressed down as the fit is being made, the idea being to **seat** the ring to the out-of-round position of the cylinder. Usually, when this work is done, the rings are very stiff, and the engine is run at idling speeds with water running through the radiator and with plenty of oil. The rings are fitted tight, so that they will work or seat to the cylinder, and many hours of running in this manner may be necessary to make a good fit.

Piston-Ring-Groove Clearance

The ring should be rolled around the ring groove in the piston, as shown in Fig. 26, page 831. The proper fit of a piston **ring in a groove** is that which permits the ring to **fit snugly without binding** or sticking at any point. When it is loose or sloppy in its ring groove, there is danger of lubricating oil getting behind the ring and traveling to the combustion chamber, resulting in the formation of carbon and in gumming the ring.

Likewise, extreme care should be taken to see that the groove is clean, and that the wall thickness of the ring is not greater than the depth of the ring groove. Therefore the inner edge of the ring should not extend above the edge of the piston at any point when placed in the groove.

S.A.E. Depth and Width of Ring-Groove

Size of Piston	Depth of Groove	Width of Groove
2½″	.113″	.126″
3 ″	.127″	.188″
3½″	.142″	. 188″
4 ″	.158″	.188″
4½″	.174″	.251″
5 ″	.190″	.251″
5½″	.207″	.314″
6 ″	.224″	.314″
6½″	.240″	.377″

Owing to slight variations in the width of ring grooves, it will occasionally be found that the ring is slightly tight or wide for the groove for which it is intended. This difficulty can be overcome by the use of a piece of fine emery cloth tacked to a flat surface (Fig. 30, page 832). The ring should be gently rubbed with a circular motion on this emery cloth until it will fit the groove without sticking.

To measure ring-groove clearance (see Fig. 17): Remove all grit and see if the groove walls are straight and not worn. The rings should fit freely into the grooves, and should be from .001″ to .002″ narrower than the groove.

PISTON-RING TROUBLES, TESTS AND REPAIRS

If the rings do not fit the cylinder wall with equal tension at all points, there will be a loss of compression and a smoky exhaust.

If the rings are exerting equal tension, they will be smooth and shiny, as will also the cylinder walls.

If the rings are dull, and there are spots in streaks on them, it will indicate that the flame from the combustion passes between the piston rings and the cylinder wall, leaving a sooty deposit, and the compression will also pass, reducing the power of the engine.

Causes of Leaky Piston Rings

1. **Rings sticking in their grooves** because of gummy deposit from lubricating oil; rings that are stuck in their grooves will usually not press against the cylinder walls.
2. **Rings may have become broken.**
3. **The joints of the rings may be in line,** allowing the compression to escape.
4. **Rings may be worn or cut** from lack of oil.
5. **Rings may not be wide enough** for the grooves.
6. **The oil pressure may be too great,** and oil of too thin a body may be used.

Testing Rings and Cylinder for Leaks

In order to find out if the rings leak, try the piston and see if the gas is escaping through the rings into the crank case. This can best be accomplished by removing the lower part of the crank case, after which turn the crank so that the piston makes its compression stroke, and listen for a bubbling sort of hiss in the crank case. Test each cylinder separately by opening the relief cocks in the cylinders that are not being tested. First determine which cylinder it is that is leaking. There is no mistaking this sound, since the crank chamber acts as a resonator, and even the slightest leakage is distinctly audible.

If the sound of gas escaping past the piston rings continues for an appreciable time (upward of a minute or so), the chances are that the use of an oil of slightly heavier "body," for cylinder lubrication, might cure the fault.

However, if the escape is of short duration, the matter is more serious, involving as it may a cracked piston, scored cylinder walls, or broken, warped, or gummed rings.

If this is suspected, flush out the cylinder combustion chamber with an oil-gunful of gasoline, making no attempt fully to remove the liquid. Again put the piston on lower dead center, and with the aid of an electric lamp and a small mirror, observe the bubbles caused by the escape of the gas about the lower edge of the piston. There will naturally be no bubbles at this point if the piston head is fractured, but it may be possible to see the crack through which the leakage occurs. At any rate, if enough gasoline has been left in the cylinder, one will be able to see it trickling down the connecting rod or inner piston walls, should such a crack exist.

If the cylinder walls are scored, one will see the liquid at but few points about the lower edge of the piston, and, as the gasoline washes the oil away, possibly the score marks will also be seen.

In case the trouble is with the rings, the bubbles will be more evenly distributed about the periphery of the piston, and will be all of about the same size. Should this latter be the condition, use the kerosene treatment for gummed rings; this may eliminate the leak if the rings are only gummed. If this latter is not effective, the job is one of replacing rings.

If the gas is escaping through the rings, it will be necessary to take out the pistons and to look at the rings. If there are **black spots on the rings,** it is evident the gas has been escaping at this point.

To test a piston for a leak: Set the piston bottom side up in a pan of gasoline and pour about 1″ of gasoline into the interior of the piston. If there is a hole in the piston, the gasoline will seep through it.

Remedying Piston-Ring Troubles

Gummed rings: After long periods of running, a deposit of charred, or partially charred, lubricating oil is liable to form behind the ring and to interfere with its free movement; it is a good plan, therefore, when overhauling the engine, to slip the rings from the piston and thoroughly to clean out the grooves.

A kerosene oil treatment to loosen rings: Engines have been known to lack power merely from the rings becoming gummed up. This trouble can be remedied by first running the engine until it is warm; then stop it, take out the spark plugs, and pour some kerosene into each cylinder, by pouring the kerosene through the spark-plug holes. Plug up the holes with old spark plugs, and then crank the engine several times by hand, so that the oil will work its way down around the rings; leave this oil in over night, and next morning crank the engine a number of times until you think the oil has passed into the crank case. Drain the crank case. After thoroughly draining, and putting in fresh lubricating oil, start the engine. The engine will smoke considerably to begin with, but this will soon pass away. This will not only loosen up the rings, but will also clean any carbon that may have become deposited in the combustion chamber. This treatment often saves the trouble of fitting new rings, and in some cases will make a marked difference in the running of the engine. Be sure, however, to clean out all kerosene, otherwise the lubricating oil will be thinned.

If the ring is broken or if it is dull and dirty in spots and streaks, a new ring or rings must be fitted.

If a ring is cut or scratched, a new ring is necessary.

If the walls of the cylinder are cut or scratched, then rebore, grind, ream or lap, as directed on page 815, and fit oversize rings.

If the ring has lost its tension and does not spring freely against the walls of the cylinder, it can be peened, as shown in Fig. 18.

Remedying Excessive Smoke

As previously stated, if the rings are leaking, an excess of smoke will pass out of the exhaust, as a result of the oil passing the rings and entering the combustion chamber. See pages 168, 768.

Peening Piston Rings

This operation is for a ring which has lost its tension. A peening hammer should be used instead of the various flat-headed types that are used at times for peening a piston ring. The metal may be more readily distributed by the blows from a peening hammer, which can be directed better, since the head is so designed that a large part of the surface is not covered at one time nor struck by any single blow.

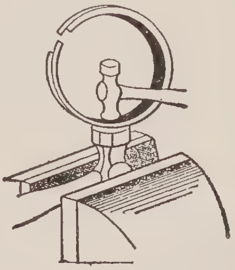

Fig. 18. Peening a piston ring.

In this manner slight changes in the shape of the metal may be made without distorting the metal in any way. It is very important in any peening operation that the surface upon which the hammering is done be as flat and hard as possible, for any irregularities in the shape of the surface plate will be just as effective in causing distortions as a blow from a badly shaped hammer. A good method of providing such a surface plate is shown in Fig. 18.

Note. This work should be avoided if possible, by selecting a new ring.

Removal of Rings

The removal of rings from piston grooves is not difficult if a little forethought is taken. To open them, it is best to use a pair of very thin-jawed pliers, the jaws opening outward (see Fig. 19). A substitute for pliers can be made from iron wire.

When the ring is slightly expanded by the use of special pliers, similar to those shown in Fig. 20, a

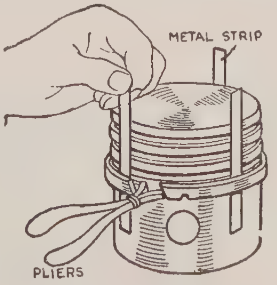

Fig. 19

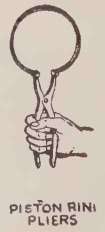

Fig. 20

Fig. 19. One method of removing piston rings from piston grooves. The ring is expanded slightly by special pliers. Strips of metal are then inserted under the rings at equidistant points, when the ring can be safely slid off. In replacing the rings, the lower one is first fitted on over the strips, and then the other two.

Fig. 20. Piston-ring pliers.

narrow strip of very thin metal (tin or brass will do) should be pushed through the opening and worked to the opposite side of the slot; then if the ring is opened a trifle more, an additional strip of metal can be placed near the ends of the ring, when it can be worked off quite easily and without any risk of breaking it, such as would result from an attempt to expand it larger than the piston diameter.

It is a good plan to mark each ring for its own groove, and also, when they are not pinned, to mark just where the slots should come on the piston.

Marking Piston Rings when Removing

The amateur or junior repairman who removes the piston rings from a piston for the first time, either for examining the piston-ring slots for sandholes or wear, or for cleaning the rings and slots, generally neglects to see that the rings are marked so that they may be replaced in their proper grooves. The result is that considerable difficulty often is experienced in getting the rings back into the piston in good order. To avoid this, mark the piston rings as indicated.

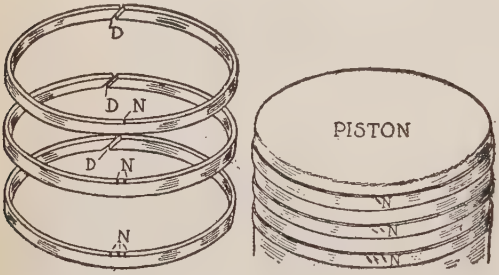

Fig. 21. Mark piston and rings when removing the rings.

The ring in the top groove of a piston has one notch (N) in the upper, inner edge, opposite the diagonal (D) where the ring is thickest. This notch is made with a file and is very small, so as to be just visible, but at the same time not deep enough to weaken the ring. In a similar manner, the next ring below it is marked with two notches, and the third ring, with three notches. If more rings are used, a corresponding number of notches are employed to mark them. With rings thus marked there should be no difficulty in getting them replaced in their proper grooves. Care should be taken, however, when the rings from more than one piston are removed at the same time. In fact, it is advisable to remove, clean, and replace the rings of one piston before removing them from others.

Fitting and Testing a Ring to Cylinder

After having selected a set of rings, the first operation is to fit them into the cylinder to see if they have the proper ring-gap clearance. Taking one of the rings, try very carefully to shove it straight in, concentric with the cylinder walls; if the ring is of the diagonal slot or miter-cut type (Fig. 1, page 825) and its diameter is a little large, the ends will run upon each other, throwing the edges out of line; while if a ring with step-cut overlapping ends (Fig. 2, page 825) is used, it will not go in at all. In such case, the ring ends must be filed (see also page 827, for testing piston-ring gap clearance).

Filing Ring Gap for More Clearance

A very simple and effective means of **holding a ring for filing** is shown in Fig. 22. The ring is placed on a block of wood and a few small nails are driven into the block both inside and outside of the ring in such a manner that the ring is held securely in place for filing.

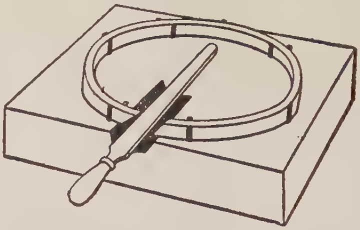

Fig. 22. Filing a ring joint.

The heads of the nails are then cut off, the ring is removed, and the nails are filed down so that they will extend just below the top surface of the ring when it is replaced on the block. With the nails well placed, there will be no danger whatever of breaking the ring when filing. A thin, smooth, flat file is best for this. The ring can also be placed in a vise, between vise clamps, and filed.

The ends must be trimmed off so that when the ring is well up into the cylinder there will be a clearance space of at least .006″ between ends (Fig. 16, page 827), to allow for expansion caused by heat of the explosions. The groove on the block shown in Fig. 22 is used when reducing the diameter of diagonally slotted rings.

Try each ring in the cylinder to which it is to be fitted, being sure to have it placed fully up into the cylinder where the ring travels. Then measure the opening in the ring as described on page 827 (Fig. 16). If too great an opening is allowed to exist, compression can easily escape. See page 827 for "Gap clearances."

The ring should be repeatedly tried in the cylinder in order that the space may not be filed to exceed the dimensions stated. The inside portions of the rings near the ends should rest against the nails (Fig. 22), in order that they may not be broken off when filing the slot. Having attained the proper space between the ends of the ring, now place a light in the cylinder behind it and see how its face conforms to the wall of the cylinder.

If one part of the circumference of the ring fits and another part does not, the high spot shows up when the ring is dipped in gasoline and then rubbed with cloth. The high spot will be more shiny than the rest.

When the ring fits well all around, the overlap of the ends should be absorbed; if they are not, file them until the edges have at least .006″ clearance when the ring is in the cylinder.

If the ends of the rings are hard butted against one another when in place in the cylinder, they may be buckled by expansion when hot, and make starting the engine a two-man job.

If there is a contact all around, when testing rings in the cylinder, the ring is then ready to be fitted to the piston; but if the contact is poor, either the ring or the cylinder is out of round, leaving space between cylinder wall and the ring, as at (C) and (P) in Figs. 23 and 24.

If the fault lies in the ring, the face can probably be dressed down to fit, or another can be selected; but if the cylinder is badly out of round, it will have to be rebored or reground, or both, as the case may be.

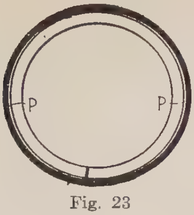

Fig. 23

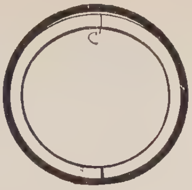

Fig. 24

Fig. 23. Cylinder out of round or ring is not exerting equal tension at all points. Note open space at (P).

Fig. 24. Note space at (C). The same conditions may have existed, or the ring was sprung when it was removed or was originally placed on the piston.

A ring which does not fit or seat the cylinder wall all around permits oil to pass to the combustion chamber and gasoline to pass to the crank case, thus thinning the lubricating oil.

Lapping a Ring to the Cylinder

To work or lap a ring to fit the cylinder: Make a plug of yellow pine (Fig. 25) to fit easily into the cylinder and square one end. Lay the ring on this end with a small batten across, secured by a screw through the center, but not holding the ring tightly.

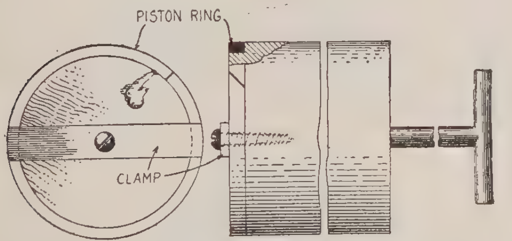

Fig. 25. **A handy device for testing and fitting the piston rings in a cylinder.** This device consists of a round block of wood with a handle on one end. The piston ring is placed on the other end and is held by a block and screw. It is placed in the cylinder and worked back and forth. (*Automobile Dealer and Repairer.*)

Smear the bore as evenly as possible with a little vermilion and lubricating oil mixed to a paste, and move the ring to and fro in the cylinder while it is held square by the plug. Generally, it will be found to bear hardest at each side of the slot. File such places carefully with a smooth file. See also page 816, for directions for lapping rings, pistons, etc. An old piston can be used for this purpose, but it is best not to use the regular piston. Rotten stone mixed with oil to form a paste can be used, and is preferable to emery (see page 816).

Testing Rings to Fit Piston Grooves[1]

When the rings have been fitted to the cylinder, the next operation is to test them for a fit in their respective grooves on the piston. As regards the fit of the rings in the grooves, they should be just a free fit, neither tight enough to jam, nor slack enough to rock.

If the piston ring is loose or sloppy in the groove, do one of two things: (1) turn the grooves out 1/32″ larger on the lathe and get rings to fit, or (2) buy and install new pistons. Remember, no piston ring will function properly if loose or sloppy in the ring groove.

If the pistons have too much play in the cylinders, replace them with new pistons. Don't expect the impossible of any piston rings.

If the bore of the cylinder is found to be worn extremely out of round, we recommend that the cylinder block be sent to some reliable concern for regrinding or reboring. Such a degree of efficiency in that art has been reached that a worn cylinder can often be made as good as, if not better than, new, and particularly when the repairman or mechanic specifies and insists on the installation of good piston rings. Have the same concern fit oversize pistons or rings individually to each cylinder at the time the cylinders are ground, as this is necessary if the cylinders are enlarged. Where this is not possible, secure oversize piston rings and lap to fit the cylinder, as explained on page 816.

Try each ring in its groove by rolling it around the groove in the piston, as shown in Fig. 26, and make certain it fits properly. This is extremely important as no piston ring will function properly if it is loose or sloppy in the ring groove, or if it is too tight.

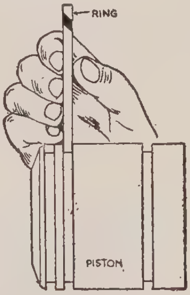

Fig. 26. **Testing a piston ring in the piston groove.** The ring should fit in the groove with about .002″ play, and should move freely all around.

It is very important that the groove be thoroughly cleaned of carbon and gum, which can be done with a small screwdriver, some kerosene, or gasoline, and a cloth.

Also be sure that the piston is perfectly round. If the piston is slightly oval, squeeze it in a vise, the jaws of which are covered with copper or lead, or tap the piston gently with a rawhide or wooden mallet.

The piston ring should fit snugly, as at (A) (Fig. 27), but should still be free to slide in and out easily; if it binds in any place, dress the sides down as in Fig. 30.

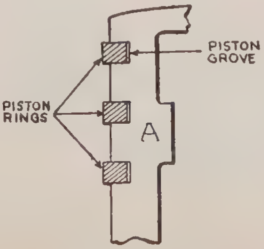

Fig. 27

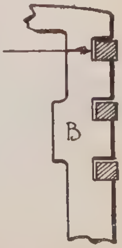

Fig. 28

---

[1] **When fitting patented rings,** remember, if the rings are absolutely tight at the joints and the wall of the cylinder, they might prevent lubrication altogether, and the cylinder would run dry. Therefore many place merely one patented ring in the top groove, and the regular rings in the other grooves.

The patented type of ring requires very little lapping by hand. When the rings, fitted to the pistons, are put in, the engine is allowed to run at low speeds until rings are worked in. You will find that that is all the lapping that is necessary, unless, of course, the cylinder is scored or badly out of round. In such cases, the proper remedy is to have the cylinder rebored and new oversize pistons made, and piston rings made to fit the new diameter of the cylinder.

An example of an ill-fitting piston ring is shown at (B) (Fig. 28) and also in Fig. 24, page 831, where (C) (Fig. 24) shows the space left open between the ring and cylinder wall by the ring being sprung when it was put on the piston.

Occasionally small ridges or shoulders are found at the back or bottom of the ring groove, which may prevent the ring fitting into the groove. These can be removed with a lathe, but where no lathe is available, this trouble can be overcome by making a slight change in the piston ring as follows: Take a file and rub it slowly around the inner edges of the ring—the edges which come in contact with the ridges at the back of the groove—and remove enough material in this manner to permit the ring to fit into the groove without touching these ridges.

It sometimes happens that a ring does not seat all the way round. Such a ring allows the oil and gas to pass, and should be replaced.

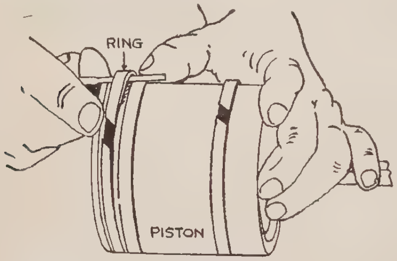

Fig. 29. **To remove a ring,** insert the handle end of a file or some similar object under the ring near the gap, and raise the end of the ring out of the groove. While pressing the ring out of the groove, run the file around the piston until the ring has been completely lifted out. It may then be slipped off the end of the piston. Before replacing a ring, the groove should be cleaned of the carbon.

Most manufacturers now cut the grooves in the piston, and grind the face and edges of the rings to a gauge, making very little hand-fitting necessary. But there are cases (and these are the ones that generally come into the repair shop), where the cut was just a trifle larger, or the ring a little smaller, than the gauge, making it essential that each ring be individually fitted to the groove in which it shall subsequently rest.

Lapping Sides of Ring to Fit Groove of Piston

Tight rings in grooves may be eased by grinding or lapping the sides on a sheet of fine emery or crocus cloth, fastened to a piece of board planed quite flat and true. The ring is gently rubbed back and forth with a downward pressure, as shown in Fig. 30.

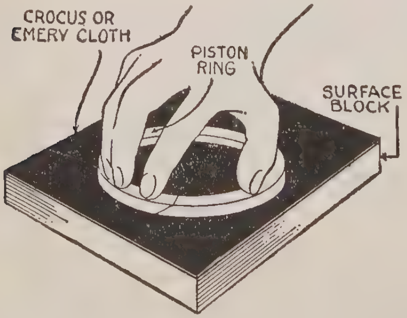

Fig. 30. Method of dressing or lapping the sides of a piston ring on a surface plate to fit the groove in the piston.

Lapping should not continue for a long period on one side. The ring should be turned over occasionally. After lapping, the ring should be immersed in clean gasoline and fitted to the groove—not to any groove, but to the groove which it nearly fitted before. If every part of the circumference of the ring fits every part of the groove, the lapping is complete and the ring may be tagged or marked to designate its location.

To dress down a ring properly requires some skill, and a good mechanic will select a ring which will demand the least amount of trimming, for it is a delicate operation.

Fitting Rings to Grooves of Pistons

When fitting rings in the grooves, begin with the ring selected for the bottom groove, so that that ring will be the first to be slipped on to the piston.

Select the best fitting ring for the top, so that oil below it cannot be consumed by the high temperature of the exploding gas. If fire, or flame from the combustion chamber flows past the rings, oil will be burned off the piston and the cylinder wall, causing it to become scored, even though the oiling system might be working perfectly with the best grade of oil.

When placing the rings on the piston ready to replace the cylinders, they should be set with the joints (if it is a piston with three rings) about one-third way from each other, so that the openings will not come in a straight line or be close together.

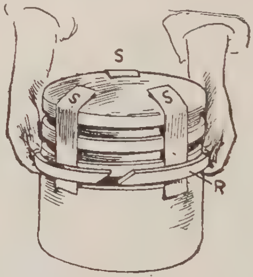

Fig. 31. One method of slipping a ring on a piston and into the groove.

A quick and safe method of slipping rings into the grooves is shown in Fig. 31. Take three strips of sheet metal, brass or tin (S), for instance, about 1/32″ thick, ½″ wide, and 5″ long; bend these at right angles and hang them on the edge of the piston at equal distances apart. The ring (**R**) may then be slipped over these skids till it is opposite its groove, when the strips may be removed and the ring allowed to slide into place. Install the ring in the lower groove first and work to the top groove last. The same strips may also be successfully used in removing the rings.

Replace the same piston rings in the same cylinders if removed and replaced again. The use of boards with numbered pegs is recommended, to avoid mixing the rings.

A ring should never be sprung over a piston to the second or third groove. Use strips (S) (Fig. 31), which will permit easy replacement without distorting the ring.

Piston-Ring Travel in Cylinder

Note (Fig. 32) the ring travel on a cylinder wall and how the cylinder wall is in time worn lower in this space, with the result that a projection is left at the top and bottom of the cylinder wall.

Overlap of Piston Ring

On some of the modern types of engines the ring is permitted slightly to overlap the cylinder wall, at top and bottom, as shown in Fig. 33.

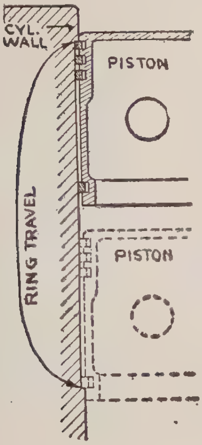

Fig. 32

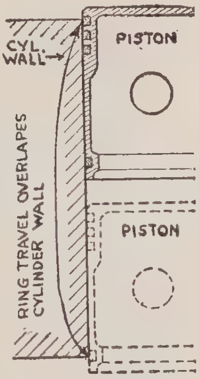

Fig. 33

Hudson and Essex Piston Ring

On the Hudson and Essex engines the piston-ring groove is burnished at top and bottom to prevent oil working up past the piston into the combustion chamber. Note also (Fig. 34), the oil duct to the piston pin.

See also page 808 for illustration and description of Essex piston.

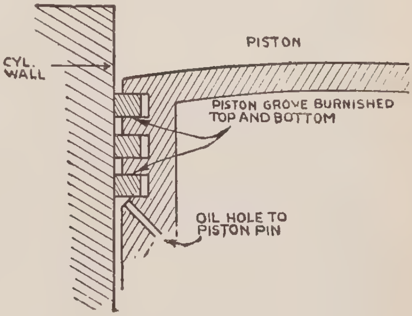

Fig. 34

REPLACING A PISTON IN THE CYLINDER

Before putting pistons into cylinders, oil the inside of the cylinder and the inside of the piston with cylinder oil, as oil will not have a chance to reach the upper portion when first starting. Also see that the piston pin is properly set, and that the set screws are tight, and that the piston and connecting rod are in alignment.

When replacing the piston in cylinder, some device must be provided for holding each ring in its groove, so that it will easily enter the cylinder. By no means force or drive the piston and rings into the cylinder. A string may be used as shown in Fig. 35. A better method is shown in Fig. 36.

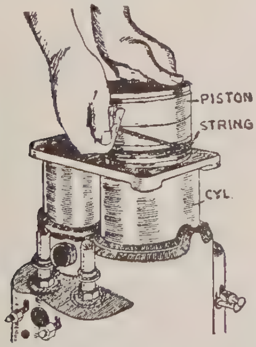

Fig. 35

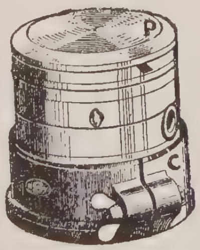

Fig. 36

Fig. 35. Method of **replacing a piston in the cylinder** with a string holding the ring in its groove.

Fig. 36. A serviceable **device (C) for compressing rings when fitting piston (P) to the cylinder.** Especially adapted for Ford pistons, which are not champfered. This tool is bored with a long gradual taper which allows the open rings to enter easily at the top. It is placed in position over the cylinder, and as the piston is forced downward into place, the rings are gradually compressed sufficiently to enter the cylinder.

Replacing cylinders over pistons: It is not difficult to put a single cylinder back on its piston after it has been necessary to take it out, but it is not so easy when the cylinders are cast in pairs, as it is difficult to guide the rings into the cylinder barrels simultaneously. The job is greatly simplified by taking the precaution to place the cranks up and down, so that one piston is at its highest point and the other is at its lowest. This means that the pair of cylinders can be dropped straight over the pistons, the rings of the upper piston being guided into the cylinder before those of the lower piston are replaced. When it comes to dropping one of the mono-block castings of four cylinders on to four pistons, it is still best to work this way, so that only one other pair of hands is required, and that the two upper pistons may be guided into their cylinders first.

Note. When **reinstalling a piston,** be careful not to push it up into the cylinder as far as it will go. The upper ring may jump over the valve opening, holding the piston until the ring is released, which is a difficult situation to remedy.

On many engines the piston and rings are fitted to the cylinder from the under side, and in many modern engines the lower ends of the cylinder bores are beveled to facilitate the insertion of the piston with the rings attached. In some cases there is a slight champfer at this point.

Running-in after Fitting

After completing the job, put plenty of oil in the crank case; enough so that not only the oil pan will be full, but that enough is above the oil pan so that the connecting rods will dip. Connect the radiator with the hose so that water will run through; run the engine slowly for about an hour or so. Do not race engine. Then run car at not over 15 or 20 m.p.h. for first 500 miles. Use plenty of oil. Thus rings will burnish to a nice fit to cylinder wall.

When fitting new rings to a piston, be sure that all the other cylinders have good compression, otherwise the cylinder with good compression will have a rich mixture and those with poor compression a lean mixture; result engine will not idle properly.

Piston Rings—Oversize

Oversize piston rings must be fitted to the pistons when oversize pistons are fitted to the cylinder. The oversizes of piston rings are: .005″, .010″, .015″, .020″, .031″, .046″, .062″, the same as in the case of the pistons. See also, page 828.

Questions on Pistons and Rings

Q. 1: How many rings are generally used?

Ans.: 3 or 4.

Q. 2: How many rings are generally used on racing car engines?

Ans.: 1 or 2. (See reason on page 826).

Q. 3: What clearance should cast-iron pistons have on an average?

Ans.: .001″ per inch of piston diameter. See page 809.

Q. 4: What clearance should aluminum-alloy pistons have on an average?

Ans.: .002″ per inch of piston diameter.

Q. 5: What is the difference between concentric and eccentric piston rings?

Ans.: A concentric ring is one of equal thickness throughout its entire circumference. An eccentric ring is not. At a point (e) (Fig. 8, page 826) opposite the split in the ring, it is made thicker.

Q. 6: What is the advantage of eccentric rings?

Ans.: Unless a piston ring bears with equal tension on the cylinder wall at all points of its circumference, the compressed gas would pass at the point where it did not bear, and thus leak compression. A ring is subjected to considerable heat, at which time it may loose its tension at some point of its circumference. Some claim that by making a ring eccentric, it will retain its tension under heat more than a concentric ring. Others claim that if a concentric ring is made of the proper material it will retain its tension. Most of the patented rings are concentric; in fact the majority of plain rings (page 826) are concentric. Sometimes two concentric rings (patented type) are fastened to each other, so as to have the splits diametrically opposite each other, as in the case of the Leak-Proof (page 825). The Inland (see page 825) is a one-piece concentric ring with a long lap. Some advantage is claimed for concentric rings over eccentric rings; for instance, the carbon that accumulates back of the ring will tend to lock an eccentric ring sooner than a concentric ring, thereby preventing the natural shifting of the ring around the piston groove.

PISTON RINGS OF ASSORTED SIZES

Regrinding and reboring shops have found that there is greater demand for their services when they **carry a stock of piston rings** and when they are able promptly to finish their jobs by installing rings.

The assortment below[1] includes popular sizes. Repairmen who specialize in overhauling particular make of car, truck, or tractors can make up stock assortments accordingly.

Suggested Sizes	For Following Cars	ASSORTMENTS 144	300	504	720	1008	1200
2 13/16 x 3/16	Oakland, Oldsmobile, Scripps-Booth	24	24	36	48	72	72
2⅞ x 3/16	Oldsmobile, Saxon, National, Singer		24	36	36	36	48
3 x 3/16	Packard, Cameron, Vim Truck, Avery Truck		24	24	24	36	48
3⅛ x 5/32	Paige, Roamer, Crow-Elkhart, Auburn		24	24	24	24	24
3⅛ x 3/16	Cadillac, Velie, Studebaker, Auburn		...	24	24	36	48

INSTRUCTION No. 72

ADJUSTING AND REPAIRING CLUTCHES, TRANSMISSIONS AND UNIVERSAL JOINTS

The fundamental principle and purpose of each of these parts, as well as their construction, are explained in the first section of this book. For instance, clutches[1] are explained on page 20, and transmissions on page 25.

We will now deal with adjustment and repairs, using as examples the parts of different makes of cars. Some of the older types of cars will be used, rather than taking all of our examples from the very latest types, owing to the fact that repairs and adjustments are more commonly required on the older types.

Types of Clutches

There are three types of clutches in general use: the cone, the plate, and the multiple-disk types.

The cone types of clutch are those using a **straight cone** or an **inverted cone.** The angle of the cone is usually 17°.

The **facing** of a cone clutch can be **leather** or **fabric.** The latter is being used now, more than formerly.

The plate clutch seems to be gaining steadily in favor.

Of the many different designs in present-day cars, the following are typical: (1) steel against asbestos fabric; (2) steel against molded asbestos; (3) steel against bronze; (4) steel against cork.

There is a strong tendency toward the dry-plate type of clutch, and this tendency seems to be largely due to the fact that the parts, frictional area, etc., of a dry-plate clutch can be made very much smaller than the parts and frictional area of a clutch running in oil. The oil film serves as a lubricant, which reduces the amount of friction and necessitates a very much stronger spring, or an elaborate system of multiple levers.

The introduction of the molded asbestos ring, which has now come into commercial prominence, has resulted in a great refinement in clutch design. These molded rings or disks can be made to closer limits and do not require any stapling at the joint. In some cases the ring is made flat, and in such cases no replacements need be made until these disks have worn practically all the way through. There are no rivet heads to consider.

The multiple-disk clutch, which has a greater number of disks than the plate clutch, each disk requiring multiplying levers to keep an engagement, is found operating both **dry** and **in oil.** Its greatly increased frictional surfaces over the plate clutch necessitate a strong spring, but the disk clutch running in oil is larger and has to have more frictional area than the dry disk type, for the same reasons as have been given in what is said of plate clutches above.

How to Use the Clutch Properly

The clutch on an automobile should be either **in** or out absolutely.

Many good drivers make it a plan to **keep their foot off the clutch pedal** while they are driving. The weight of the foot on the pedal and a little nervous tension in the driver's leg is sometimes just sufficient to hold the clutch out just far enough to "slip it" on a hard or sudden pull.

Another good way to spoil a clutch is to throw it out in traffic until the car comes almost to a standstill, and then to speed up the engine and to slip the clutch in with the gear-shift lever still in high speed.

When the car slows down with the clutch out, the gear lever should be slipped to second speed, and if the car comes to a full stop, it should be shifted to low speed.

Another important point in driving is to learn to **engage the clutch gradually,** and not to "bang" it in with the engine racing.

It is always better to **run on the engine as much as possible,** throttling it down instead of constantly throwing "out" the clutch.

A well-adjusted clutch **takes hold gradually,** does not slip after it has come to a seat, and releases instantly when the pedal is depressed.

CONE CLUTCHES; TROUBLES, ADJUSTMENT, AND REPAIRS

The parts of a cone clutch can be enumerated as follows:

1. **Leather or fabric facing** over the cone.
2. **Main clutch spring,** which holds the tension of the cone to the fly wheel.
3. **Pressure or plunger studs,** also called "clutch leather expanders," which are mounted under the clutch leather at various points and allow gradual engagement of the frictional surfaces. The "grabbing" feature is eliminated by the use of these plungers, of which there are usually six, inserted under the leather, as shown in Fig. **1.**
4. **Clutch rollers** on the shifter yoke.
5. **Ball-thrust bearings** on the clutch shaft.
6. **Clutch brake,** which prevents spinning of the clutch when released.

---

[1] See Index under "Specifications of leading cars" for types and make of clutch used on different makes of cars.

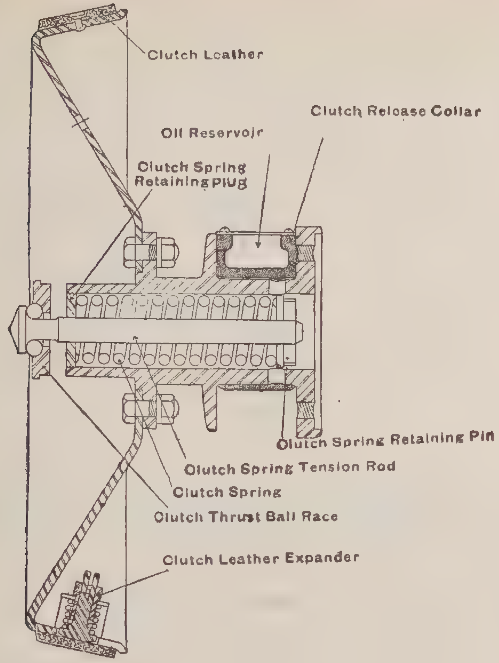

Fig. 1. Typical example of a **cone clutch,** the Chevrolet "490." Note that expanders are placed under the clutch leather so as to present slightly raised points of contact to eliminate "grabbing."

If the clutch takes hold too quickly and causes the car to start with a jerk, it is an indication that the clutch leather expanders need adjusting. To do this, turn each of the expander nuts to the right, until they lightly touch the clips, and then give them a half-turn to the left. This unscrewing allows the expander to act properly under the clutch leather.

The clutch leather will in time "dry" out, resulting in "grabbing," or slipping. Once a month rub a little neatsfoot or castor oil on the leather to soften it. Should the clutch leather become greasy, apply a little fuller's earth to it. Do not use sand or other gritty substances to make a slipping clutch hold.

Cone-Clutch Troubles

Cone-clutch troubles are either fierce engagement or grabbing, slipping, or spinning. The latter makes it difficult to shift the gears of the transmission.

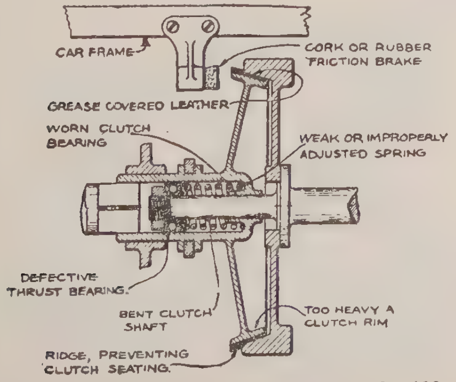

Fig. 2. Various cone-clutch troubles illustrated. (*Motor.*)

Cause of Clutch Grabbing

Clutch leather dry or hard: This can be remedied by applying neatsfoot or castor oil after first cleaning the leather with kerosene, using an oil gun to remove any mineral oil.

A prominent clutch manufacturer states: "We recommend keeping all oil off the clutch leather, and we do not use the common remedy, neatsfoot oil. Better results are accomplished by keeping the clutch face clean, and when an occasion arises where the clutch grabs, **clean it with kerosene, but not gasoline.** The kerosene leaves just enough oil to keep the leather in good condition.

Clutch rivets projecting, as a result of wear of the leather: Remedy by placing a center punch against the rivets and hammering until they are below the surface of the leather. A grating or grinding sound will indicate this trouble.

Clutch lever linkages out of adjustment: The amount of movement between the surfaces of the clutch is small, and it is important that no looseness exists in the pedal connections.

Excessive tension on clutch spring: If this is found to exist, weaken the spring tension. Excessive tension also causes undue strain on the ball-thrust bearings.

Plunger studs improperly adjusted: The six plunger studs, also termed the clutch leather expander studs (Fig. 1), should be properly adjusted.

Clutch release ring bearings may be worn, as a result of lack of lubrication. If run while dry, they are liable to seize and to prevent clutch releasing entirely, in which case new bearings must be fitted (see Fig. 9, page 841).

Cause of Clutch Slipping

Burned or worn clutch lining: Usually results from allowing the clutch to slip when starting, or speed changing, and from using the clutch too much, instead of the throttle, while running. Even though it be worn to a certain extent neatsfoot or castor oil will sometimes improve its operation. Otherwise a new clutch leather must be fitted.

Clutch leather oily and greasy: The cure for this is either to wash the oil off by spraying a pint or so of kerosene, with an oil gun, over the clutch leather, while holding the clutch out, or by wiping off with a cloth moistened with kerosene, and to dress the leather afterwards with neatsfoot oil, if necessary. The oil can also be absorbed by sprinkling powdered fuller's earth or talc over the surface and leaving it standing for a while. Don't use dirt or sand—it will cut the leather.

Leather worn down: If it cannot be raised enough by adjustment of the plungers (clutch leather expanders), a new leather must be fitted.

When the surface of the clutch and seat are new, the latter touch all over, but when worn, they touch on only the high places. If the surfaces touch in only a few places, they naturally cannot transmit the power that is possible with a good contact; they can be forced to transmit it by pressing them more firmly together, but it is better to reface the surfaces.

Clutch-spring tension weak: Tighten the adjustment (see page 841). If no adjustment nut is on spring, place a washer between the spring and its seat. **Also examine the pressure or plunger studs.**

Clutch shift out of line: Sometimes caused by too great a spring tension, causing the balls to break in the thrust bearing and cutting the ball race, lowering the clutch shaft out of line. It may also be due to a bent clutch shaft or the clutch shaft being out of alignment.

Ridge or shoulder worn on the clutch leather (see page 843 for remedy).

Clutch Spinning

When a clutch spins, when thrown out of engagement, it is difficult to shift gears.

The shift of gears by the gear-shifting lever ought to be made without a particle of noise if the clutch is thrown out when shifting. If there is noise, then it is usually due to the clutch not being fully thrown out, or to dragging or spinning, or to the transmission shaft being out of line, owing to worn bearings.

Clutch spinning is often due to excessive friction in the spring-thrust bearing (see Fig. 2), though sometimes faulty alignment of the flywheel and clutch cone prevents the engaging surfaces from entirely clearing each other. A bent clutch shaft might be the cause of this.

Sometimes the fault lies in the clutch. A heavy rim or cone will store up energy and continue to revolve when disengaged.

When a clutch spins from lack of alignment or adjustment, the remedy is obvious, but if the fault is in the design, a clutch brake (see Fig. 2) should either be fitted, or the clutch rim lightened by drilling or machining away metal at or near the outer circumference.

Clutch Brake

Unless the clutch-shaft speed is reduced approximately to the speed at which the main shaft of the gear shafting is revolving at the time, there will be a clash of gears at the time of engagement, with consequent damage to the face of the gears and annoyance to the driver. The clutch brake will overcome this to a considerable extent if it is properly fastened and proportioned.

The **purpose of the clutch brake** is therefore to keep the clutch from spinning when thrown out. See Figs. 2, 10 and 11. It consists of a small spring-mounted fiber pad attached to the left of the frame, against which the clutch cone strikes when disengaged. It should be so adjusted that when the pedal is pressed half-way down, the cone should just begin to come in contact with it, so that by the time the pedal is all the way down, the spring on the clutch brake will be fully compressed. For an example of a clutch-brake adjustment, see page 842.

If the car is not equipped with a clutch brake and it is desired to attach a clutch brake or dampener, to check the revolving of the cone when released, either cork or rubber can be fitted into a metal bracket which can be attached to the car frame.

The position of the brake should be just to the rear of the clutch rim, against which the clutch will draw when the disengaging pedal withdraws the cone.

Cone-Clutch Lubrication

Lubrication of a cone clutch is usually at the **rollers or clutch yoke and ball-thrust bearings;** otherwise oil should be kept from the clutch leather as much as possible, as a leather-faced cone is supposed to run dry, but yet be kept flexible. This can be done by the use of neatsfoot or castor oil, as explained.

If the Clutch Fails to Release

When a cone clutch fails to release, it is usually termed a "frozen clutch." This may be due to rusty or tight pedal connections or to loose pedal linkage connections; clutch yoke rollers run dry sometimes, from too tight a spring adjustment.

The amount of movement between the surfaces of a clutch is small, and it is important that no looseness in the pedal connections or bending of the levers should exist to prevent gradual engagement.

When cleaning or treating a clutch with neatsfoot oil, it can be held out of engagement by using a prop placed against the clutch pedal, as shown in Fig. 3.

The cone part of the clutch with the leather facing on it can then be turned by hand and neatsfoot oil applied, or the oil gun filled with gasoline can be used for cleaning, as shown in Fig. 4.

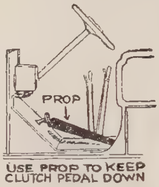

Fig. 3

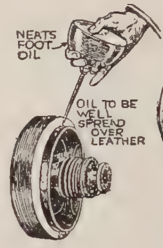

NEATS FOOT OIL
OIL TO BE WELL SPREAD OVER LEATHER

Fig. 4

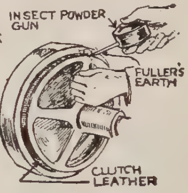

Fig. 5

An insect-powder gun, filled with talc or powdered fuller's earth can be used as a temporary remedy for an oily slipping clutch or brake, if necessary, as shown in Fig. 5.

Cone-Clutch Adjustments

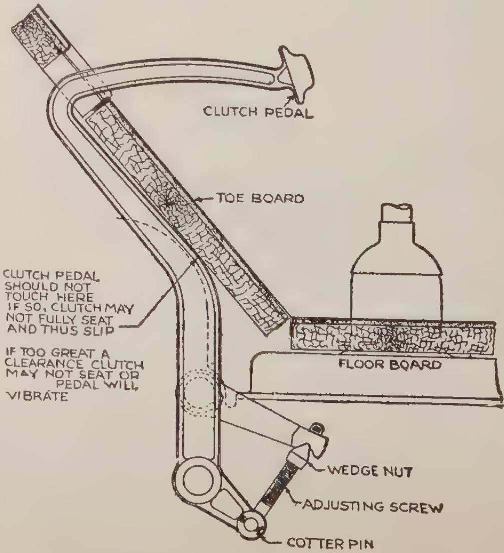
The adjustments on a cone clutch are:

1. Clutch pedal adjustment.
2. Main clutch-spring adjustment.
3. Clutch-leather expanding spring adjustment.
4. Throw-out adjustment.
5. Clutch-brake adjustment.

Clutch-Pedal Adjustment

There are two possible causes or reasons for the necessity of adjusting the clutch pedal:

1. The pedal, when in driving position, with the clutch in, may vibrate back and forth, owing to there being too much clearance between the pedal and toe board.
2. The clutch may be slipping, because of the pedal pressing against the toe board before the clutch is fully engaged.



CLUTCH PEDAL
TOE BOARD
CLUTCH PEDAL SHOULD NOT TOUCH HERE IF SO, CLUTCH MAY NOT FULLY SEAT AND THUS SLIP
IF TOO GREAT A CLEARANCE CLUTCH MAY NOT SEAT OR PEDAL WILL VIBRATE
FLOOR BOARD
WEDGE NUT
ADJUSTING SCREW
COTTER PIN

Fig. 6. Clutch-pedal arrangement of the Oakland "34-B."

Adjustment of clutch pedal: There are various methods used to adjust the foot-clutch pedal. The illustration (Fig. 6) is that of the Oakland model "34-B."

To remedy either condition mentioned above, remove the cotter pin and push the adjusting screw out of the hole in the pedal. Hold the wedge nut and turn the adjusting screw to the right or left until the proper adjustment is obtained, and replace it in the hole and put in the cotter pin.

The clearance between pedal and toe board should be approximately 1/16″.

The clutch-pedal adjustment on the **multiple disk type of clutch,** or, in fact, any type of clutch, is for the same purpose as mentioned above, although the construction may vary. For example, the clutch-pedal adjustment of the Cadillac type "57" is shown in Fig. 7.

Adjustment of clutch-pedal clearance of the Cadillac[1] (type "57"): After the car has been run for some time it may be found that the lacings on the clutch disks have become compressed or worn to some extent, and that consequently the clutch pedal strikes the stop screw before the clutch is fully engaged. When this condition exists, a readjustment may be made as follows:

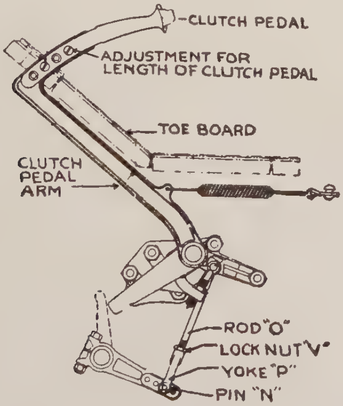


Fig. 7. Clutch-pedal arrangement of the Cadillac type "57." Note that the foot pedal is adjustable as to length.

Remove the pin (N) (Fig. 7), and unscrew the yoke (P) which is threaded on the rod (O), so that when the pin (N) is replaced, the clutch pedal has a movement back and forth of 1¼″ without starting to release the clutch. Secure the pin (N) with a cotter pin, and tighten the lock nut (V).

Adjustment of length of clutch and brake pedals: The clutch and brake pedals are each made in two parts, slidingly adjustable, to accommodate different drivers.

Main Clutch-Spring Adjustment

There are two or three methods of arranging the main clutch springs so that they will hold the clutch cone firmly to the inner surface of the flywheel.

One method is as shown in Fig. 8. Note that the main clutch spring (S) is placed over the clutch shaft between the clutch spider and a collar provided with an adjusting nut.

To adjust: With a screwdriver remove the cover plate, loosen the clamp screw on the clutch-adjusting nut, and turn up the clutch-spring adjusting nut (just below the clutch "throw-out" fork (F), until there is sufficient compression. Then tighten the screw. Also note the clutch leather engaging the spring, for the purpose of expanding the clutch leather (explained farther on).

Care: Keep the clutch-yoke grease tube filled, and be sure it does not clog. Keep the drain hole in the bottom of the clutch housing free, so that oil cannot accumulate on the clutch leather. Turn the grease cup down often, on the "clutch throw-out." The first 50,000 Dodge cars used the clutch as shown above. Later cars use disk clutches of the dry type, described farther on.

The first 50,000 Dodge cars used the "cone "clutch as described above. Later cars use the disk clutch, dry type, consisting of 4 driving and 3 driven members.

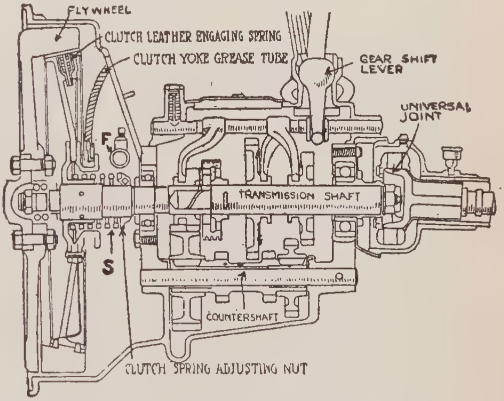

Fig. 8. Cone clutch and transmission used on the early model Dodge cars. Note the position of the main clutch spring (S).

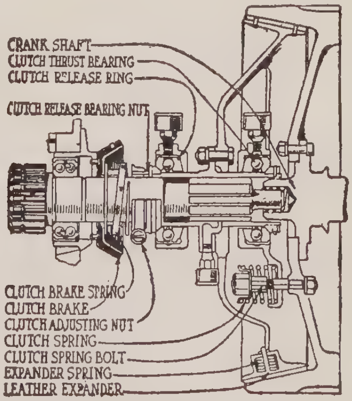

Fig. 9. Note the position of the clutch spring.

Another arrangement of the main clutch springs is shown in Fig. 9. Note the main clutch spring is within the clutch spider.

Here again, the regular remedies for a slipping clutch caused by a worn, oily, or burned leather, apply.

Adjustment: A worn leather may be made to hold by increasing the tension on the four large clutch springs within the clutch spider. In doing this, be careful to turn each nut to exactly the same extent.

---

[1] The Cadillac does not use a cone clutch (see page 22).

Clutch brake: When the lining of the clutch brake becomes worn, thus allowing the clutch to **spin** after disengagement and make the shifting of gears difficult, adjust by loosening the clamp bolt and turning the adjusting nut to the left, or counter-clockwise. This will compress the brake spring sooner, and consequently stop the clutch more quickly.

To grease the clutch, loosen the wing nuts and remove the cover of the clutch housing. Give the grease cup on the clutch release ring a turn or two. Press the clutch pedal, and turn the clutch cone around until that grease cup appears, and give it a turn or two. Turn the engine over until the grease cup on the clutch spider appears and turn that down the same amount. Apply a few drops of flowing oil to the clutch release-yoke trunnion bearings.

Note that the **leather expander and spring** for expanding the clutch leather are in this clutch also.

Clutch-Leather Expanding Adjustment

The clutch-leather expanding adjustment, called the "clutch-leather engaging spring" in Fig. 8, and the "expander spring" in Fig. 9, is for the purpose of preventing "grabbing." The expanders are so placed as to present a slightly raised point of contact of the clutch leather to the fly-wheel inner surface.

If the clutch takes hold too quickly and causes the car to start with a jerk, it is an indication that the clutch-leather expanders need adjustment.

The clutch-leather expanders usually consist of six small spring-mounted clutch plungers placed under the clutch leather, which raise it at various points and allow gradual engagement of the friction surfaces. Should these plungers become fast in their guides, or should anything prevent the leather over these plungers from first coming into contact with the seat in the flywheel before the entire surface engages, "grabbing" will result.

They should be **adjusted** so that with the clutch in complete engagement, approximately 1/16″ remains between the adjustment nut of the plunger stud and the guide to the cone, when the clutch is fully engaged.

The clutch leather will in time "dry" out, resulting in either **"grabbing," or slipping.** It is a good idea occasionally to rub a little neatsfoot or castor oil on the leather to soften it. Should the clutch leather become greasy, apply a little fuller's earth to it. Do not use sand or other gritty substances to make a slipping clutch hold. If you do, you are simply inviting a large repair bill.

Cone clutch with cork inserts: On the early models (1914, 1915, 1916) Moline-Knight cars, a cone clutch was used where the leather on the face of the cone had cork inserts regularly placed around the leather. They are backed up by an adjusting screw.

Clutch Throw-Out Adjustment

The throw-out adjustment, or the amount of leverage for the distance to which the clutch is thrown out, is adjusted on the clutch pedal, or, on some clutches, at the shifter yoke collar, also termed the releasing ring. See Figs. 9 and 11.

Clutch release ring bearings (Fig. 9), which, by pressure upon the clutch release ring, disengage the clutch from the flywheel, should be kept well greased or oiled, as the case may be.

Ball thrust bearings should be supplied with oil (see Fig. 2, page 839).

Clutch-Brake Adjustment

The clutch brake, as used on the Studebaker series "20" cars, is shown in Fig. 10. There are two arms, one on each side of the clutch, so arranged as to make the adjusting screws accessible after removing the floor board. The double construction equalizes the pressure on the clutch cone, and prevents any tendency for it to bind on the shaft.

The object of a clutch brake is to facilitate gear shifting and eliminate clashing of gears. Its action is to slow down the transmission counter-shaft gears so that the gears while being shifted, will have the same speed.

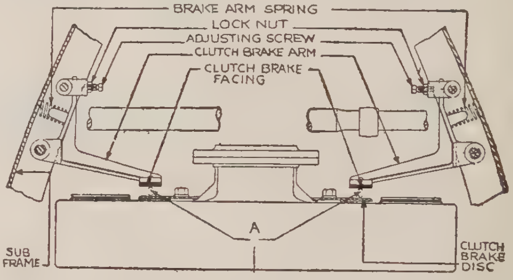

Fig. 10. Clutch brake as used on the Studebaker series "20" cars.

Cars when shipped are so adjusted as to give the best results. When a car has been driven 500 miles, the clutch-cone facing will become slightly compressed, allowing the cone to enter the flywheel farther, which, together with a slight wear of the clutch-brake facing, will increase the gap at (A) (Fig. 10). It will then be necessary to screw out on the adjusting screw, decreasing the gap (A) to 5/16″, taking care to adjust both sides alike.

Removing and Replacing a Cone Clutch

As an example, the Willys "six" is used, as shown in Fig. 11.

To remove the clutch, first remove the two cap screws which hold the spacer shaft (Fig. 11) to the clutch cone. Remove the three nuts on the motor side of the first member of the universal joint, and drive the studs back so that the spacer shaft, with the first member of the universal joint, can be removed.

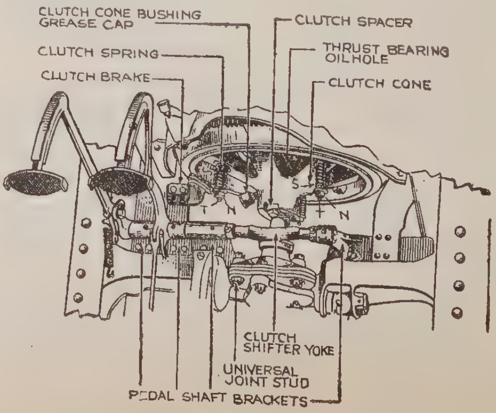

Fig. 11. Cone clutch and parts Willys "six."

Remove the clutch brake and the bolts holding the foot pedals and clutch shifter yoke, so that the shifter yoke and its shaft can be raised slightly. Next remove the nuts holding the three main clutch springs in place and take off the springs (Fig. 11), after which the clutch cone itself can be withdrawn.

In replacing the clutch, the springs (S) can be compressed sufficiently to start the retaining nuts (N), if a pry bar (P) is held back of the clutch spider (R) pressing the studs out (Fig. 12). Be careful to get an even tension on the main clutch springs, which will be reasonably assured if the retaining nuts are screwed on to their respective studs (T) approximately the same distance. Do not fail to fasten the cap screws holding the spacer and universal joint nuts with cotter pins.

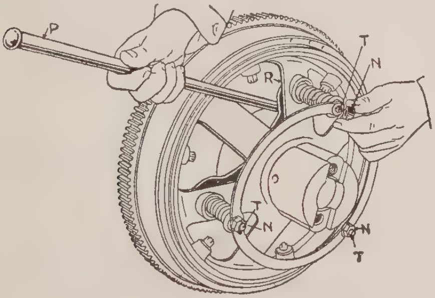

Fig. 12. Replacing clutch springs.

In replacing the clutch brake, it should be set so that when the clutch is thrown out to its limit the edge of the cone bears firmly on the clutch brake, but does not compress the spring solidly.

Fitting New Leather to Clutch Cone

First, be sure that replacement is necessary. See pages 839, 840, and note the causes of trouble.

If the leather is worn or the rivets project, then it will be necessary to remove the clutch in order either to replace the leather or to drive the rivets down below the surface of the leather.

If a shoulder of about 1/16″ or 1/32″ has worn on the leather, a careful trimming of it off with a file or rasp will permit the cone to go farther into the flywheel and may be all that is necessary—together with cleaning the whole surface of the leather and removing oil or glaze, and then applying neatsfoot or castor-oil dressing.

If however a new leather is necessary, then procure it of the dealer of the car if possible. It comes cemented ready to apply, and can be slipped over the cone and can be driven into position with a mallet or a piece of wood.

When the clutch must be relined in an emergency, and the old lining is not available to serve as a pattern, secure a piece of first-class, unstretchable belting, 3/16″ thick, 10″ wide, and 44″ long, as shown in Fig. 13.

If you must make the leather facing, then first remove the old leather by cutting the rivets with a chisel and hammer. Then procure first-class, unstretchable leather belting (or chrome-tanned leather) 3/16″ thick for the new leather. The leather should first be cut as shown in Fig. 13.

Then place the leather over the clutch cone in the correct position, and draw it as tight as possible. The leather, if cut as shown, will lap from 3″ to 4″. Mark on the inner side of the lapped leather the end of the first turn which lies against the cone. Next remove the leather and measure back or toward the long end of the leather ⅝″. Measure back from the unmarked end of the clutch leather 3″, and bevel the leather off, as shown in the illustration. Add 3″ to the corrected length of the leather, and bevel this end as shown.

The leather may now be cemented, and after it is thoroughly dried it may be installed. Always put the rough or flesh side on the outside. For the kind of cement to use, ask a harness maker.

Before a new clutch leather is installed, it should be thoroughly soaked in neatsfoot oil and stretched tightly over the clutch face. Before the leather is fastened to the clutch drum, the "clutch plungers" (or pressure studs) should be forced in below the surface of the clutch cone and held in this position by the clutch-plunger adjusting nuts, which may be screwed up on the stem of the plunger.

In riveting the leather on to the cone, extreme care should be exercised to see that the rivets are properly clinched or turned over on the inside of the clutch cone, and that the heads are driven into the leather of the clutch face until they are well below the surface. Unless this is carefully done, the clutch will "grab" or engage suddenly, with consequent disastrous results.

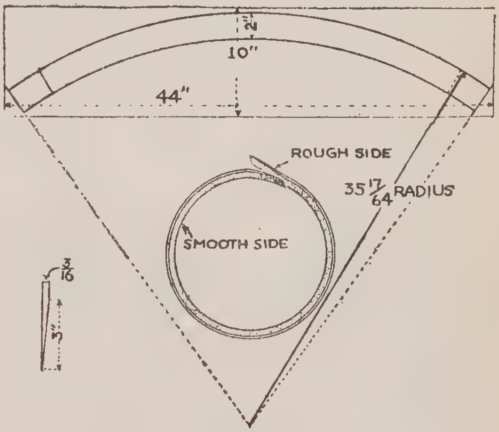

Fig. 13. **Pattern for cutting clutch facing for a Willys "six" cone clutch.** When the old lining is not available to serve as a pattern, secure a piece of first-class, unstretchable belting, 3/16″ thick, 10″ wide, and 44″ long.

To lay out the correct pattern of the facing, draw on a piece of heavy paper the arc of a circle, having a radius of 35 9/32″, and below it the arc of a circle with a radius of 33 9/32″, as shown. The exact length of the belt will be 44 3/16″, but it is well to make it somewhat longer, because it will be safer to be able to trim the ends later on. Put the rough or flesh side of the new clutch leather on the outside.

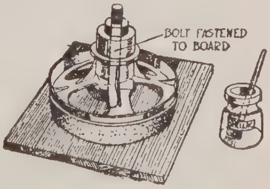

Fig. 14. **A suggested method of forcing a new clutch facing on a cone by drawing the cone into it by a bolt as shown.** A small amount of shellac is applied to the clutch and is allowed to set before the stud nut is loosened. After this, leather pegs are used to complete the bond between leather and clutch. (*Motor.*)

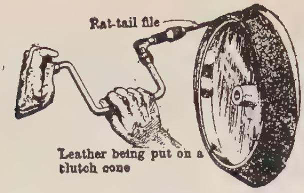

Rat-tail file
Leather being put on a clutch cone

Fig. 15. **Another method to force a one-piece clutch lining on a cone clutch.** Insert a rat-tail file in a bit brace. Force the lining on as far as it will go with the file, which should be a coarse one, and by turning the bit brace, the file will roll the lining into place.

An alternative sometimes used for older makes of various cars is "raybestos" strips, as used for brake lining. It is made in parallel lengths and riveted to the cone in six or eight sections, the edges being cut at a slight angle, according to the diameter of the cone.

Note. A very important point to observe in fitting a new clutch leather or fabric is to have the surfaces absolutely clean, otherwise the clutch facing will be raised if there is any substance under it, and will thus cause the clutch to grab.

If, after relining a cone clutch, the clutch grabs, or if it grabs even though not relined, this is usually due to high places on the facing, or the leather is dry.

If, after treating it with neatsfoot oil, it still grabs and the high spots cannot be determined by the general appearance of the leather, then try this method: Depress the clutch pedal and then insert a piece of white paper between the flywheel and the leather-faced portion of the clutch. Engage the clutch, and then depress the pedal again. When the paper is removed, the high spots will be plainly indicated on it. The leather should then be trimmed to the surface uniform in height.

THE MARMON CONE CLUTCH

The Marmon "34" cone clutch is simply an aluminum wheel having a conical rim engageable with the corresponding surface within the flywheel. Depressing the clutch pedal moves this cone back and disconnects the engine, while a spring action holds the clutch in contact when the clutch is let in.

Smooth application of power is assured by the **five steel disks set within the flywheel,** which give a slipping contact with gradually increasing force until the whole surface of the cone comes into full contact as the clutch is entirely engaged.

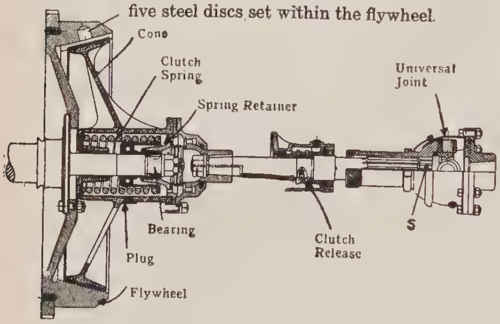

Fig. 16. The Marmon "34" cone clutch.

No adjustment for easy engagement is necessary. The metal and **asbestos fabric** with which the cone is lined usually require replacement after 10,000 to 20,000 miles of running, the life being largely dependent upon the class of service.

To disassemble the clutch, remove the circles of bolts at the universal joint and at the clutch flanges, and take out the drive shaft, thus released. Then remove the cotter and back off the main clutch nut. The spring retainer can then be pulled off its key after inserting ⅜" cap screws in its threaded holes. Then the cone will slide off the pilot shaft. In replacing, care must be taken in fitting the spring retainer on its key.

Relining clutch: The standard facing for these clutches is superior to leather, and to get the best service, renewals should be made with the same material.

To install, clean off all remains of the old facing, lubricate the cone with graphite, and slip the new facing in place. It may be necessary to force it gently, but do not hammer the edge. Soaking the facing in water will aid the facing to slide on easily. Then put rivets firmly in place, making sure the heads are below the surface. This is best done by placing the rivet head against a punch or small steel bar held vertically in a vise, and riveting with the round head of a machinist's hammer.

Replacing: See that the felt washer and hub bushing at the front of the cone are in good condition; then fill the hub with oil and replace, making sure to get all parts back just as they came out.

Clutch release: The shaft back of the clutch has two flanges about which is fitted a split collar, giving a marine type of bearing, which should be filled with oil. The backward thrust to release the clutch is applied to this collar by a yoke linked to the clutch-pedal shaft. The bushings of these shafts and links are self-lubricating. The clutch pedal stop is against the floor-board. Inspection should be made, from time to time, of the shifting collar, to be sure that, from lack of lubrication, this part does not revolve with the shaft when the clutch is released.

Note the play allowed in the splined shaft (S) for the movement of the clutch shaft when the clutch is thrown out.

CONE-CLUTCH REPAIR—THE CHEVROLET "490" AS AN EXAMPLE

Evidence of Trouble

1. **A heavy grinding noise when the clutch is released.** This is usually caused by worn or broken balls in the clutch-thrust bearing.
2. **Actual failure of the pedal to release or move the clutch or to come back into position when pushed out.** This indicates that the clutch-spring retaining plug has become unsoldered and has unscrewed from the clutch hub.
3. **Excessive slipping of the clutch,** that cannot be cured either by application of neatsfoot oil, if dry, or fuller's earth, if slippery.

The first necessitates a complete removal of the clutch, together with the flywheel and clutch-spring tension rod; the second a removal of the clutch hub, and the third the removal of the hub and clutch.

Disassembling the Clutch

1. Remove the floorboards.
2. Remove the wiring running from battery to starter.
3. Remove the three bolts holding the V-brace to the engine base and the gearbox support, and remove the V-brace.
4. Disconnect the brake rods from the pedals.

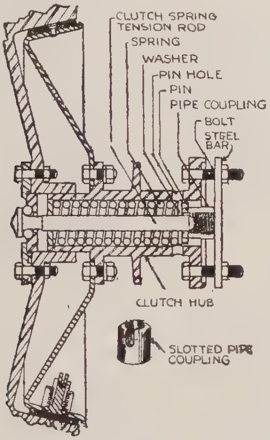

Fig. 17. Showing the **method of compressing the clutch spring.** The steel bar is 5/16″ x 1″ x 4″. The bolt holes are ⅜″ and 3″ between centers. The pipe coupling is ⅝″ inside diameter; the slots are about ¾″ deep.

5. Remove the bolts holding the clutch-release shaft to the gearbox support, and remove the clutch release cross-shaft, together with pedals.
6. Remove the bolts on the rear clutch-hub drive ring.
7. Remove the four bolts holding the gearbox to the gearbox side-arms. (Care should be taken in removing the shims under the gearbox, so that they may be replaced in the same position.)
8. Remove one bolt holding the left gearbox side-arm (on the pedal side) to the engine. (This permits the gearbox side-arm to spring to one side when removing the gearbox).
9. Lift the gearbox up and slide it forward. It may then be removed from the chassis. (A jack should be placed beneath the propeller shaft to hold it in place when the gearbox has been removed. In some cars it is necessary to spring the gearbox arms apart or to force the gearbox out with a jack.)

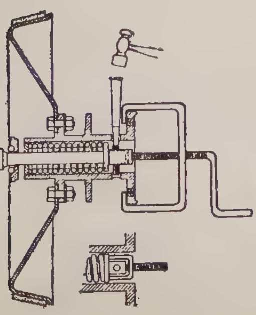

Fig. 18. Showing the method of compressing the clutch spring, **permitting the lock pin to be removed.**

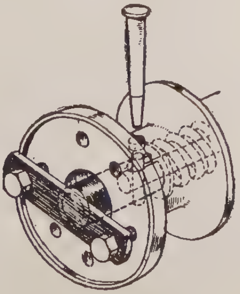

Fig. 19. Another form of clutch spring compressor, somewhat simpler than that shown in Fig. 18.

10. Turn the flywheel until the pinhole (Fig. 17) passing through the clutch hub is at the top, and the clutch-spring retaining pin is in line with the hole.
11. Using either the compressor shown in Figs. 17, 18, or 19, compress the clutch spring. The clutch-spring retaining pin will usually drop out when over the hole in the housing; but, if not, it may be driven out with a drift and hammer.
12. Draw out the clutch spring.
13. Remove the bolts holding the clutch hub to the clutch spider, and remove the clutch hub. (This is necessary, as the hub would otherwise interfere when removing the clutch.)
14. Pull out the clutch. (This will take some little effort, as the gearbox arms squeeze on to the clutch and must be sprung. But it can be pulled out.)
15. Remove the nuts holding the flywheel to the crank shaft flange and with a bar loosen the flywheel and remove it. (It is advisable to mark the position of the flywheel on the flange so that it may be replaced in the same relative position.)
16. Remove the flywheel together with the clutch-spring tension rod, and place it on two boards nailed to the bench.
17. Separate all parts and clean with gasoline and waste.

Clutch Troubles

Clutches of this type give but little trouble if properly used, and the necessity for relining is only occasional. **If slipping** has been experienced and the leather is damp, it is usually because it has been soaked with mineral oil. This may be removed by cleaning the leather with gasoline, after which neatsfoot oil should be applied to keep the leather flexible.

Grabbing: On model "490" there are six clutch leather expanders. These expanders are placed under the clutch leather and present a slightly raised point of contact. Their function is to prevent the clutch from grabbing. If the clutch grabs, the expander should be adjusted. To adjust the expanders, turn each of the expanding nuts in the same direction as the hands of a clock, or from right to left, until they lightly touch the clip, then give them a half-turn in the opposite direction. If this method fails, the chances are that the clutch is dry.

Though a dry clutch will occasionally cause slipping, it more often causes "grabbing." Unless the leather is burned, or worn out, it may be restored by roughing the surface slightly with emery paper, and then dressing it with neatsfoot oil.

Another cause of a sticking clutch is protruding rivets, and these should again be set beneath the surface of the leather. A small shoulder will also cause trouble, and this should be scraped or filed down.

A new leather should never be fitted unless it is absolutely certain that the old leather cannot be reclaimed.

If relining the clutch is imperative, it is best to obtain the new lining from the makers. If this is not expedient, the old lining should be carefully removed and used as a pattern for cutting the new lining. The new leather should be much thicker than the old lining, and of uniform thickness. The most essential point in fitting the new leather is to have it fit tight and true to the cone.

If the clutch has been relined it will not work perfectly until it has been worked in. This usually takes some time and during that period should receive frequent applications of neatsfoot oil.

To Fit a New Leather

1. Soak the leather in water.
2. Secure one end of the leather to the cone by one copper rivet (rough side out). (Never use anything but copper rivets; other metals will score the metal clutch facing.)
3. With only about three-quarters of the leather on the cone, pin the other end to the cone by a rivet. (See Fig. 21.)
4. Force the leather up into the cone. It should fit evenly and with uniform tension.
5. Drill and countersink the rivet holes.
6. Rivet the leather in place. Be certain that the rivet heads are 3/32″ below the leather and well headed on the inner side.
7. Allow the leather to dry slowly. It will otherwise shrink too much and expose the rivets. A coarse file may be used to remove the high spots.

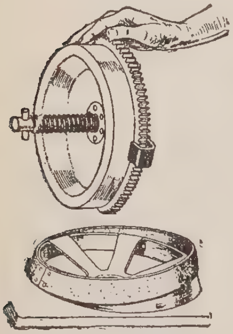

Fig. 20 (upper)
Fig. 21 (lower)

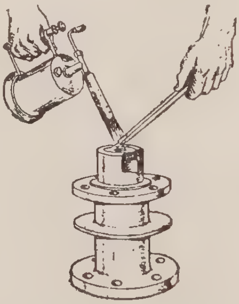

Fig. 22

Fig. 20. The **thrust-bearing assembly** is held together by three old valve springs, placed in the manner shown.

Fig. 21. The **new leather should be fastened at the ends,** and then forced over the face of the clutch.

Fig. 22. When loose, the **plug in the end of the clutch hub** should be sweated back in place.

Clutch-Hub Repair

If the solder holding the clutch-spring retaining plug has become loosened, permitting the plug to unscrew—

1. Clean and scrape both plug and hub end thoroughly.
2. Screw the plug into the hub until the upper surface is slightly below the hub.
3. Heat the end with a torch, as shown in Fig. 22, and run solder into the joint.

Thrust-Bearing Repair; Assembling

1. Examine the balls and races of this bearing, and if they are pitted or show the slightest indication of wear, the entire assembly must be replaced.
2. Place the flywheel on the bench, with gear side up.
3. Force a ball race into the flywheel casting. This must go in evenly and come to a seat evenly, otherwise the bearing will quickly destroy itself.
4. Assemble the balls and clutch-spring tension rod, packing the balls in grease.
5. Slip the clamp shown in Fig. 20 over the end of the stud. This holds it firmly in place and permits one man to put on the retaining springs.
6. Slip three old valve springs over the end of the stud and pin in place, as shown. The clamp may now be removed, and the stud, with the thrust bearing, cannot fall apart in reassembling the clutch.

   An alternative method, and one commonly used in assembling the tension rod and bearings is to place the ball race, balls and tension rod together before placing them in the flywheel. They may be held together by the three valve springs.
7. Lift the flywheel back into place on the engine. Bolt it back in the same position as before it was removed. Do not tighten any one bolt until all are drawn snug. This removes the possibility of having the flywheel out of true, which would ruin the thrust bearings.
8. Remove the pin and three old valve springs from the clutch-spring anchor stud.
9. Force the clutch back into position.
10. Bolt the clutch hub to the clutch spider. Draw all bolts up snug, before any one is tightened.
11. Put the clutch spring back in place and pack with grease.
12. Using the compressor shown in Figs. 18, 17, or 19, replace the clutch-spring retaining pin.
13. Lift the gearbox back into the frame. It will have to be sprung past the gearbox side-arm.
14. Replace the bolt holding the gearbox side-arm to the engine.
15. Replace the bolts on the rear clutch-hub drive ring. Bring all up snug together.
16. Replace the bolts holding the gearbox to the side-arms. (Make certain that the shims are replaced exactly in the same position from which they were removed.)
17. Replace the clutch release shaft with the clutch yoke and pedals.
18. Connect the brake rods.
19. Replace the V-brake, connecting gearbox support with engine.
20. Refill the oil reservoir on the clutch yoke and the grease cups on the clutch cross-shaft. Oil all working parts.
21. Replace the wiring. Start the engine and note whether everything seems to be working properly. If there is a rattle in the clutch drive ring it will indicate that the gearbox is out of line. The shims will have to be shifted, or possibly removed. When perfect alignment is reached the rattle will cease. (*Motor World.*)

PARTS OF THE BORG & BECK SINGLE-PLATE CLUTCH, SHOWING ASSEMBLY

This clutch is termed a "single-plate clutch" because a single dry disk (2) (Fig. 23) is locked to rotate with the flywheel by gradual pressure between two asbestos rings (1) and (3), thus driving the clutch shaft that carries power to the transmission.

The pressure is brought to bear on this disk (2) by the positive lever action of three arms, or bell cranks (L) (Fig. 25A), which act as wedges, these wedges being forced into place by the thrust of the clutch spring (7).

Action of the Various Parts

The friction disk (2) (Fig. 23), and the asbestos rings (1) and (3), and the clutch shaft and its shaft sleeve (8), the only parts not anchored to the flywheel **float in the drum at rest** until they are locked with it by the wedge action at (T) (Fig. 25) of the bell cranks (L) carried on the mounting ring (5).

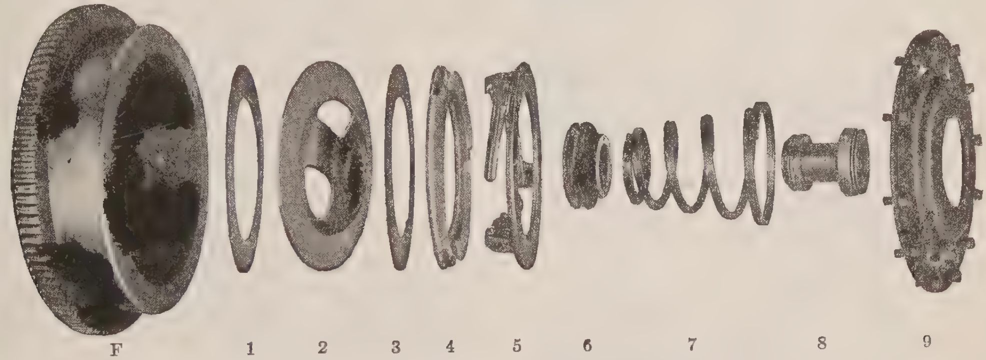

Fig. 23. **Parts of the Borg & Beck dry-plate clutch.** (F) represents the flywheel ready for the clutch parts, which are shown disassembled in the order in which they are to be assembled. Note that inside of the flywheel the dowel pins that carry the thrust ring (4) are shown projecting (see also **P**, Fig. 25).

(1) **Friction ring,** a duplicate of No. 3. These rings take all the clutch wear.
(2) **Friction disk,** or dry plate, keyed to the shaft by 10 splines.
(3) **Friction ring;** copper reinforced woven asbestos.
(4) **Thrust ring;** note the inclined face toward the center, and adjustment inclines.
(5) **Mounting ring;** fastens to the cover with adjustment bolts; it carries the bell-crank levers.
(6) **Retractor collar;** the ends of the bell cranks engage in slots.
(7) **Spring** is compressed between cover (9) and the retractor collar; it operates the bell-crank levers.
(8) **Sleeve** carries retractor collar; note the thrust bearings.
(9) **Clutch cover** bolts to the flywheel; note the adjustment bolts in the slots which are shown as (**A**) in Fig. 24.

Note. Parts 1, 2. 3, and 8 come to rest when the clutch is disengaged.

When the clutch pedal (Fig. 25) **is pressed,** the sleeve (8) and the collar (6) are pulled back, moving the bell cranks (L), and consequently releasing wedge pressure on the thrust ring (4). **When released,** the spring thrust moves the bell cranks forward, exerting the pressure that locks the drive disk (2).

It is to be noted that the thrust ring (4) is an inclined plane, thinner on the inner edge than on the outer. The thrust shoes on the bell cranks mount this inclined surface as the spring thrust is exerted, and gradually increase the pressure on the friction rings (1) and (3). This causes the friction disk to begin to move, at first slowly and then with increasing speed, until the pressure of the thrust ring (4) finally locks it to drive with the flywheel. Because it has finely polished surfaces, this slippage is even and smooth, and the car is not jerked or shaken by a too rapid engagement of the clutch.

An annular ball bearing, mounted on the sleeve (8) and inside of the retractor collar (6), allows the shaft and sleeve to come to rest with the friction disk when the clutch is thrown out. A similar ball-thrust bearing is mounted on the opposite end of the sleeve, and takes the thrust of the clutch spring as the sleeve is pulled backward under the pressure of the yoke of the clutch pedal.

Lubrication: Oil for the sleeve and bearings is provided from the transmission through the hollow clutch shaft and holes bored in the sleeve itself. Care should be taken to see that the oil level in the transmission is not too high; it should come approximately up to the center of the lower, or secondary, transmission shaft.

After about every thousand miles, remove the adjusting bolt and squirt a little cylinder oil into the clutch—just enough to moisten the asbestos rings. Too much oil will cause the clutch to slip until the oil is burned out.

The assembled clutch is shown in Fig. 24. Note that the parts are applied to the hollow flywheel (F) (Fig. 23), first by the friction ring 1, then by 2, 3, 4, and so on, until the cover (9) is bolted to the outer edge of the flywheel. It then appears as shown in Fig. 24. The drive shaft is not shown. It passes through the parts, beginning at 9, and ends in the splined disk (2).

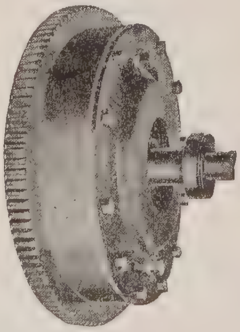

Fig. 24. Assembled clutch.

Note. The foregoing description covers the DX 10-inch and GX 12-inch types of clutches now used with unit power-plant assembly. All other types of Borg & Beck clutches are operated by the same principle of engaging and disengaging action, but have only the outer thrust bearing.

To adjust: Loosen both adjustment bolts (**A**) (Figs. 25, 25A). Hold clutch out by pressing clutch pedal. This permits bolts to slide easily in their slots. Sliding (**A**) bolts to the right tightens the clutch and at the same time increases the (**B**) distance, or the clutch-sleeve setting. Sliding (**A**) bolts to the left loosens the clutch and decreases the (**B**) distance. After obtaining the correct (**B**) distance, tighten the bolts. This completes the clutch adjustment.

When the adjustment bolts (**A**) reach the right end of the cover slots, as a result of repeated adjustment, remove them and replace them in the repeat holes which have been exposed at the opposite end of the slots.

Should it be difficult to slide the adjustment bolts far enough to obtain the specified adjustment position, it indicates that the pedal has been lowered from its original setting. This causes the clutch to be released insufficiently. Correct this condition by changing the pedal adjustment so as to raise it. This provides additional release, and will permit the bolts to slide easily.

Where a clutch brake is used, it is located at the (C) position—that is, ½" farther from the clutch cover than the engaged position, as shown. In this case the pedal should be adjusted to cause contact against the brake facing slightly before the pedal pad reaches the floor-board, as shown at (X). This setting will naturally allow proper clearance under the floor-board when the clutch is engaged.

Where no clutch brake is used, the pedal pad should make contact with the floor-board when the (C) position is reached. Care should be taken not to allow the pedal to release the clutch farther than the proper (C) position. Greater release will cause contact with the metal bearing cap on the forward end of the transmission.

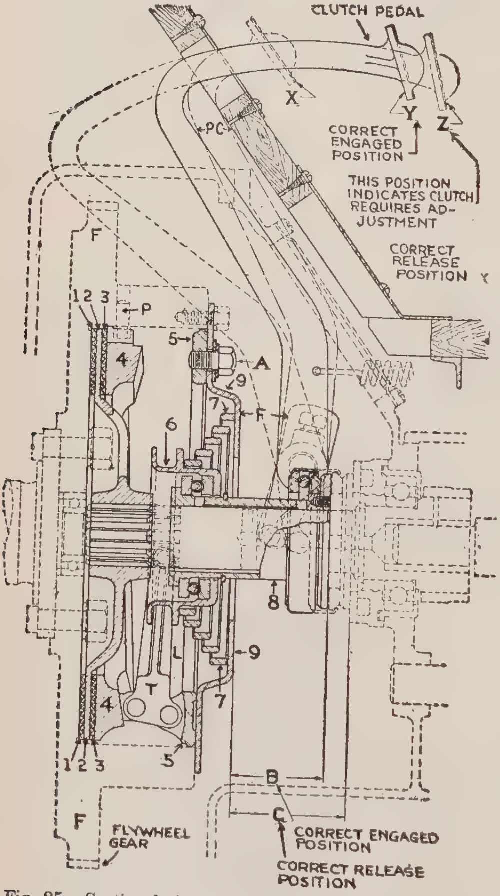

Fig. 25. Sectional view showing assembly of parts and how the clutch is adjusted by the "engaged and release method." Note (B) and (C).

Pedal positions: (X) correct release position; (Y) correct engaged position; (Z) this position indicates that the clutch requires adjustment.

Adjustment of the Borg & Beck Clutch: "Engage and Release" Method

The clutch should be properly adjusted when the car comes from the factory with ½" or more pedal clearance (PC) (Fig. 25) under the footboard and with the adjustment distance (B) (Fig. 25) set correctly for the type of clutch used.

A table showing the proper adjustment distance for all cars carrying the Borg & Beck clutch is given on this and the following page.

After a new car has run several hundred miles it is frequently desirable to make an adjustment to compensate for the "wear-in" of the asbestos friction rings (1) and (3). Thereafter adjustments are not necessary oftener than each 2,000 or 3,000 miles.

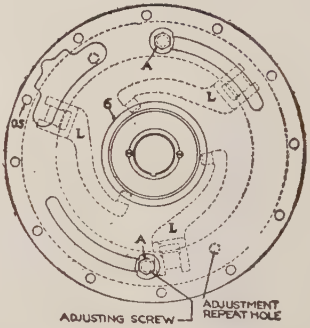

Fig. 25A. **Phantom view of clutch,** showing the bell-crank levers (L) and the adjusting bolts (A). Note the hole (OS); this is an odd-spaced hole in the cover. The mounting ring (5) (Fig. 23) must be assembled so that one lever comes directly under this hole when the adjusting screw (A) is in the left end of the slot.

To adjust the clutch, first release it by pressing the clutch pedal. Loosen both slot-bolts (A), and move either of them to the right or "clockwise," about ½". Let in the clutch, and if the adjustment distance (B), that is, the distance from the clutch-cover plate to the end of the sleeve, is more than it should be, throw out again and tap either slot-bolt back counter-clockwise far enough to get the correct adjustment distance.

The adjustment (A) **also adjusts the foot pedal.** When the clutch slips, it is usually due to the clutch pedal striking the under side of the floor-board. Moving the adjustment bolts to the right automatically lowers the clutch pedal, giving the necessary pedal clearance.

When the bolts (A) **reach the end of the cover** slots (Fig. 25A) as a result of repeated adjustments, screw them out of their mounting holes and set them back into the repeat holes exposed near the opposite end of the slots.

Adjustment Distance

Refer to Fig. 25. The adjustment distance is the distance from the flywheel clutch cover to the end of the throw-out sleeve: distance (B). A number of manufacturers listed below have used clutches of two or more different types. The Borg & Beck nameplate on each clutch indicates the type.

To Clean the Borg & Beck Clutch

It is sometimes desirable to clean the clutch by pouring about one-half pint of kerosene into it through the adjustment bolt hole, and allowing the engine to run for 15 minutes, engaging and disengaging the clutch as it runs. The surplus kerosene can be drained from the clutch by letting the car stand overnight with the front wheels higher than the rear.

Pointers on Operating Clutch

Do not slip the clutch excessively instead of shifting gears. Slipping it makes the clutch do all the work that the transmission was designed to do.

Do not drive with the foot on the clutch pedal. It puts a constant pressure on the throw-out bearing and shortens its life.

Keep the clutch properly adjusted. Many clutches run 30,000 or 40,000 miles without a single adjustment, and very few ever show enough wear to require replacement of parts.

It is, however, to be expected that a failure of lubrication or haste in assembly in the car may cause conditions that should be remedied, and the following suggestions are offered to assist in locating any malfunction in operation that may be encountered:

Clutch Troubles, Cause and Remedy (Borg & Beck)

Slipping is a bad condition that may ruin friction rings, drive disk, bearings, sleeve, in fact the whole clutch, if allowed to continue.

It is usually caused by a continual pedal pressure on the under side of the floor-board which holds the clutch partially "out," thus wearing the friction rings, or it may result from an excess of oil in the clutch.

To remedy: Adjust the clutch by moving the two adjustment bolts, as described on the preceding page. If slipping comes from too loose an adjustment of the clutch, the same remedy will correct it. If there is too much oil, drain the clutch housing and wash it out with kerosene. If this does not relieve the trouble, the clutch disks (1) and (3) are worn.

Slipping of the clutch, followed by chattering and grabbing: This indicates that the asbestos friction rings are glazed and should be replaced, and this necessitates the removal of the clutch.

Dragging, which makes gear-shifting difficult.

Cause: Failure of the clutch to release properly, and so to allow the drive disk on the stem-gear shaft to come to rest. It may come from either of two principal causes: too tight an adjustment of the clutch, or failure of the clutch-brake action. When the clutch is thrown completely "out," the flange nut of the clutch throw-out sleeve is brought up against the brake facing on the hub of the flywheel housing. If the brake facing is allowed to become covered with oil or grease, it will not stop the rotation of the sleeve, and thus causes dragging.

To remedy: Wash off the brake facing with a little gasoline.

Grabbing or stuttering: This condition causes the car to jump and shake as the clutch is let in, and shows uneven gripping of the friction or drive disk by the asbestos friction rings.

Cause: It has been found that this is nearly always caused by imperfect alignment of the clutch in installing.

To remedy: Take the clutch down and secure proper alignment of the stem-gear shaft. If the grabbing comes from a warped drive disk, caused by overheating from slipping, it will be necessary to replace the drive disk and friction rings.

At times, grabbing may be caused by the accumulation of dirt or foreign matter on the asbestos friction rings and drive disk.

To remedy: Wash out the clutch by cleaning it with kerosene, as described on the preceding page. Do not fail to oil the clutch after using kerosene, as explained under "Lubrication" (page 24).

Noise may develop at the three points on the thrust ring where it is driven by the dowel pins (P) (Fig. 25) in the flywheel.

Cause: The fact that the pins were not properly fitted at the time of installation, and the fact that the backlash causes wear in the slots of the thrust ring.

To remedy: Take down the clutch and replace the dowel pins with pins of proper fit for the thrust-ring slots.

Improper lubrication will cause the retractor collar bearing or the throw-out bearing to become noisy.

To remedy: Open up the oil holes in the stem-gear shaft, replacing the bearings, if worn.

These bearings may also become noisy if the bearing seat on the clutch sleeve is allowed to get out of line, or if the stem-gear shaft is out of line.

Cause: This sometimes results from hasty installation or from bad alignment of the throw-out yoke.

To remedy: Straighten the bearings on the sleeve and set the clutch-pedal yoke to bear evenly on the throw-out bearing.

Actual failure of the clutch to operate, or excessive noise when the clutch pedal is pushed out, indicating that the clutch spring or some of the operating members are worn or broken, and necessitating a removal of the clutch.

Ordinarily a washing and adjustment of the clutch will place all parts in good condition. Unless it is positively indicated that a removal is necessary, cleaning and adjustment should always take place before tearing the clutch down.

To Repair Clutch Brake

This brake is designed to stop the spinning of the clutch and to prevent gears clashing when shifting. To examine:

1. Press the clutch pedal down fully.
2. Examine the brake (see Fig. 26 showing the clutch-brake ring), and see whether it actually touches the collar or not. If it does not touch, the transmission must be removed. Note how far it comes from touching.
3. Remove the gearbox. The method of doing this may vary somewhat in the different cases.
4. Examine the clutch-brake friction band. If it is in good condition, it will not be necessary to install a new one, as a metal washer can be placed between it and the shoulder on the main drive pinion. This will raise it sufficiently to touch the brake. The thickness of this washer depends on the distance the clutch brake and flange were apart, as shown in Fig. 26.
5. Unscrew the clutch brake (this is a left-hand thread) and place the metal washer between it and the drive pinion. It is better to reline the clutch brake after washers amounting to ⅛" have been installed.

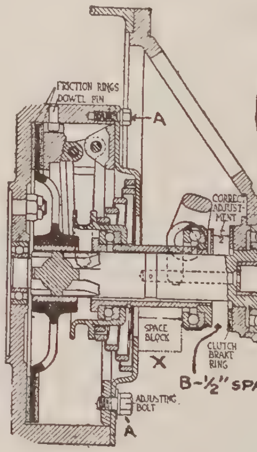

Fig. 26

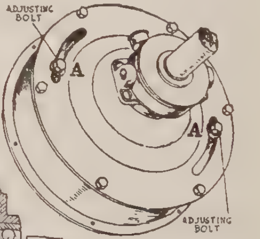

Fig. 27

6. If the clutch brake facing is worn very thin or is glazed, it should be removed and a new one should be riveted on in its place. Copper rivets should be used, and they should be countersunk well beneath the surface of the facing. (See Fig. 29.)

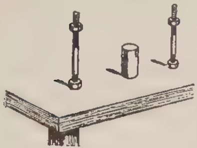
Providing the adjustment of the clutch is correct, and the friction rings are in good working order, the gearbox may now be assembled.

To Remove Clutch

This is necessitated by worn clutch rings, by actual failure of the clutch to operate, or by continued presence of oil after repeated cleanings.

1. Punch the remounting "line-up" marks on the cover and flywheel, so that the cover may be replaced exactly as removed. If the cover should

be replaced wrong, or shifted in remounting, the clutch will not operate properly.



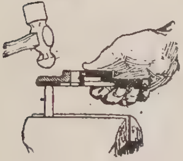


Fig. 28 (upper)
Fig. 29 (lower)

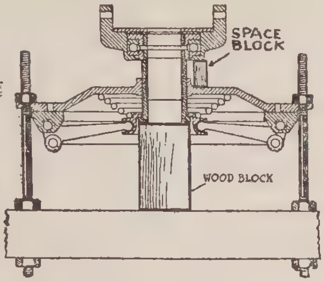

Fig. 30

Fig. 28. Details of a **simple clutch compressor** which can be easily constructed on the bench and used for disassembling and assembling a clutch.

Fig. 29. **The clutch brake friction ring** may be riveted to its flange, but the friction rings of the clutch should run free in their working seats.

Fig. 30. **The clutch compressor in use.** If an arbor press is at hand, it may be used in a similar manner: to hold the clutch in the "out" position.

2. Throw the clutch "out" and lock, by placing a block of wood, 3″ high and 4″ long (space block), as shown in Fig. 30, between the cover and the throw-out yoke.
3. Remove the clutch-cover bolts.
4. Draw out the clutch.

If all working members are in good condition and are not worn excessively, new friction rings should be slipped in place and the clutch should be reassembled. It may however, be necessary completely to dismantle the clutch, in order to replace the spring or some worn member.

To Disassemble Clutch

1. Place the clutch on the compressor shown in Figs. 28 and 30, and tighten the stud nuts.
2. Remove the space block (Fig. 30).
3. Unscrew the retaining collar.
4. Remove the stud nuts of Fig. 30, permitting the clutch to come apart.
5. Examine all parts for wear and replace all worn parts.

To Reassemble Clutch

1. Reassemble the clutch, using the compressor shown in Figs. 28 and 30.
2. Place the space block in position, and remove the clutch from the compressor.
3. Place the friction ring, then the clutch plate, in the flywheel, followed by the other friction ring.

Note. The two asbestos rings should be coated lightly on all sides with cylinder oil. See page 847 about oiling these clutch rings every 1,000 miles.

4. Then put the clutch assembly in place, making sure that the dowel pins, or set screws, are in place on the inside rim of the flywheel, and that they fit into the slots of the driving plate.
5. Replace the clutch cover bolts, making sure that the cover is in the same position as when removed.
6. Replace the transmission, drive shaft, etc.
7. Check up the adjustment of the pedals and clutch as outlined, and see that the clutch brake is working all right.
8. Grease all parts, and replace miscellaneous fittings.

POINTERS ON ADJUSTMENT AND CARE OF A MULTIPLE-DISK CORK-INSERT LUBRICATED TYPE OF CLUTCH

This clutch, as an example, is made with seven driving and seven driven members. They are provided with cork inserts and run in oil.

New corks may be inserted in the disks by the use of a special tool after the corks have been soaked in warm water to make them pliable. They are trimmed off so as to leave a projection of about 1/32″ on each side, and then they are ground to an even surface on the disk grinder.

A more convenient method for the average repairman is to use fine sandpaper. The disks should be trued by rubbing them on a flat surface which has a very thick coating of prussian blue or lamp black. The cork inserts should not project too far over the disk or the clutch will drag; 1/32″ is the maximum.

The clutch spring (S) (Fig. 31) **is not adjustable;** a new and stronger spring is installed if greater tension is required. The position of the pedal will shift toward the floorboard after the clutch has been in service a short time, because the inserts, when brought under the pressure of the clutch spring, will compress slightly.

If the pedal is not adjusted, it will cause a continuous pressure against the clutch and eventually produce slipping. There should be ¾″ clearance between the clutch pedal and the upper side of the floorboard. This is adjusted by loosening the lock nut at the end of the turnbuckle.

The levers of the clutch pedal may be changed to suit the requirements of the driver, there being two holes in the lever on the clutch-yoke shaft for this purpose. Under ordinary circumstances this should be connected to the inside hole, but if the car is to be driven by a lady the outer hole may be used.

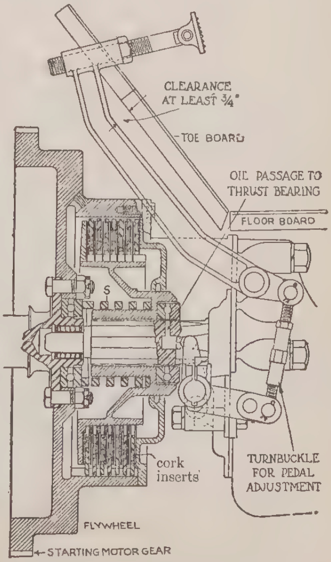

Fig. 31. Sectional view of a multiple-disk cork-insert lubricated type of clutch.

To remove the clutch it is first necessary to take off the gearbox; then the cap screws which attach the clutch-plate cover to the drum of the flywheel are removed, and the entire clutch assembly may be taken out.

To reassemble the clutch it is necessary to compress the clutch spring, which can be accomplished by using two 5/16″ studs about 3½″ long, threaded full length. They should be inserted in two opposite holes in the clutch drum. Then take the driven clutch member and install the disks on it—a plain disk first and then a cork disk, and so on.

Place the clutch plate over the hub of the driven clutch member and insert the spring over the front end of the hub of this part. The lugs on the outer edge of the driving disk should then be run in line. Next coat the gasket on the clutch plate thoroughly with shellac and allow it to dry until it becomes sticky.

The clutch assembly may be entered into the clutch drum of the flywheel and the two studs, mentioned above, can then be inserted in the drum and used to draw the clutch into position. Finally install the cap screws which hold the clutch-plate cover to the flywheel, and after removing the two studs tighten all of the screws firmly.

It is sometimes necessary to remove the main drive gear from the front end of the transmission and to use it as a guide, in order to be sure that the clutch is in proper alignment with the rear bearing in the rear end of the crankshaft which supports the front end of this main drive gear, otherwise there may be difficulty in getting the transmission into place.

HUDSON LUBRICATED MULTIPLE-DISK CORK-INSERT CLUTCH

The Hudson clutch is of the multiple-disk type with cork inserts. It is fully enclosed in the flywheel and runs in what is suitably termed clutch oil. The cork inserts become saturated with this oil, and maintain the velvety action so desirable, while the friction between the corks and steel disks is sufficiently great to prevent any tendency to slip.

Renewing the oil and lubricating the clutch throw-out collar are the only attentions necessary. The fact that the cork inserts become saturated with oil makes it comparatively difficult to abuse this clutch, as compared with other types. However, its action will be affected if instructions in regard to the quality and quantity of lubricant are not strictly adhered to.

Never put more than a half-pint of mixture in at one time. Always drain the clutch to remove the used oil before filling in any fresh oil (half kerosene and half good engine oil).

Clutch oil consists of one half-pint of kerosene and lubricating oil mixed in equal proportions.

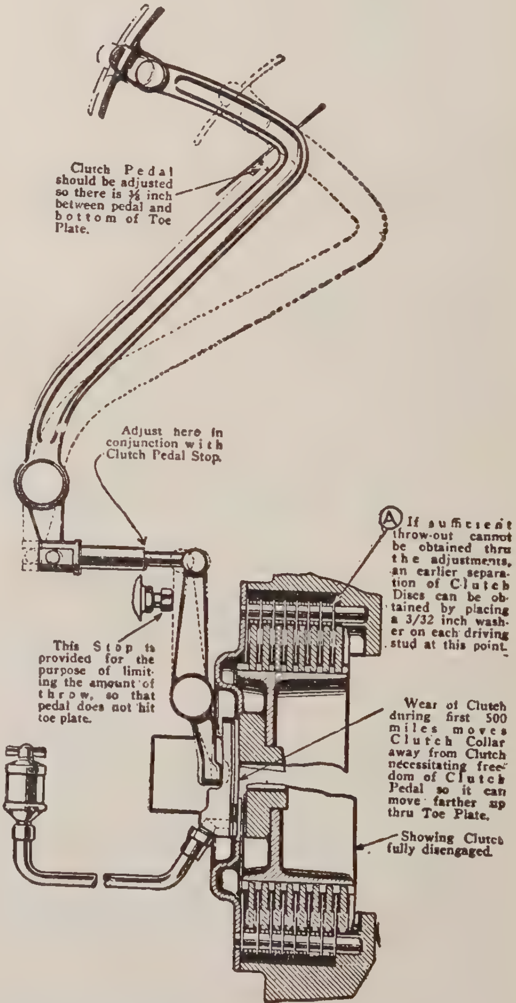
Clutch adjustment should be inspected occasionally. The adjustments are shown in the wording for Fig. 32.

Wear on the clutch parts is indicated by the pedal stopping farther away from the toe-board than usual. If the clutch is burned or abused, so that the corks swell up, the pedal will come back farther—nearer to the toe-board.

Do not slip the clutch when driving, except when absolutely necessary, and then only when you know it has sufficient lubrication to stand it. If you feel that you must do so, owing to lack of confidence in your ability to handle the car through congested traffic, remember that the lubrication of the throw-out collar will need more frequent attention.

The clutch throw-out sleeve is lubricated by the large grease cup. Clashing of gears and hard shifting is usually due to faulty lubrication at this point.

Note. **The usual cause of slipping of the lubricated disk type clutch** is a weak clutch spring or clutch pedal-linkage adjustment, which prevents the clutch plates from engaging. If this type of clutch **drags,** it is probably due to oil being too **thick.** If it grabs it is probably the result of lack of oil or improper clutch-spring adjustment.



Clutch Pedal should be adjusted so there is ⅛ inch between pedal and bottom of Toe Plate.
Adjust here in conjunction with Clutch Pedal Stop.
Ⓐ If sufficient throw-out cannot be obtained thru the adjustments, an earlier separation of Clutch Discs can be obtained by placing a 3/32 inch washer on each driving stud at this point.
This Stop is provided for the purpose of limiting the amount of throw, so that pedal does not hit toe plate.
Wear of Clutch during first 500 miles moves Clutch Collar away from Clutch necessitating freedom of Clutch Pedal so it can move farther up thru Toe Plate.
Showing Clutch fully disengaged.

Fig. 32. The Hudson lubricated multiple-disk cork-insert clutch.

THE REO MULTIPLE-DISK DRY-PLATE TYPE OF CLUTCH

This clutch is of the multiple dry-disk type, consisting of thirteen steel plates, seven of which are lined on both sides with asbestos. The remaining six plates are of plain steel and are placed alternately between the lined disks. These disks are designed to run dry, and the application of oil, regardless of the kind, will tend to ruin them. Details of troubles and adjustments are given on next page.

Evidence of Trouble

1. **Slipping clutch:** This is often caused by lack of proper clearance between the clutch opening fingers and the release plate. This clearance should never be less than 1/16″ or more than ⅛″ when the clutch is in. This necessitates an adjustment of the clutch opening fingers (see clutch adjustment below).

   Another cause of slipping clutch is too little tension on the clutch springs, contained in recesses in the flywheel, as shown in Fig. 35. The nuts on the engine end should be tightened enough to prevent the clutch from slipping, but not enough to make the pedal difficult to operate. Never tighten the clutch-spring nuts until the release fingers have been adjusted to the proper clearance. Neither of the adjustments mentioned will have any effect if the lining on the disks is worn so thin that the clutch casing seats on the flywheel, as shown in Fig. 35, at (**A**) and (**B**). When worn thus, the clutch must be removed.

   Continual slipping causes the disks to get very hot, warping the steel disks, as shown in Fig. 33, and raising the rivets on the lined disks so that they cause the clutch to chatter, with the possibility of grooving the disk and giving them a permanent warp.
2. **Noisy clutch—particularly when released:** This is due to a worn clutch-thrust bearing (see Fig. 35). A removal of the clutch and replacement of the bearing is necessary.

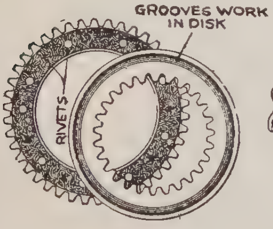


Fig. 33

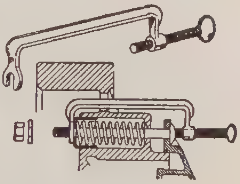

Fig. 34

Fig. 33. **If worn, the facing should be renewed,** and the rivets countersunk below the surface to prevent grooving the steel disks. The steel disks should be renewed if grooved or warped.

Fig. 34. The assembly is facilitated by the use of a simple **compressor,** applied in the manner illustrated. It is cast iron, though a similar one could be forged from bar stock. The main thing is to use a compressor of some sort.

To Remove Reo Clutch

1. Remove the floorboards.
2. Remove the starter driving chain.
3. Remove the two battery wires running to the starting motor.
4. After removing the two bolts holding the right end of the starter, and the single bolt at the left end, remove the starting motor.
5. Remove the short drive shaft, with its universals, that connect the clutch and gearbox.
6. Remove the brake rods.
7. Remove the bolts on the clutch cross-shaft and spring it up.
8. Remove the clutch cross-shaft.
9. Remove the nuts that hold the clutch-spring bolts at the rear of the flywheel. Remove bolts.
10. Pull the clutch out and remove it from the frame.
11. Place the clutch ring assembly on the bench with the clutch rings up.
12. Remove the snap ring, and then remove all friction rings. (Note how the rings are removed, so that they may again be built up in the proper sequence.)
13. Clean all parts with gasoline and scrape out the clutch-ring recesses both on the flywheel and the clutch hub.

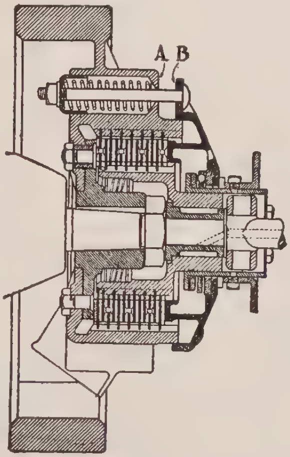

Fig. 35

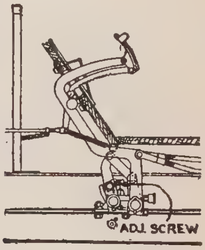

Fig. 36

Fig. 35. Clutch assembly. When the disks are worn out, surface (**A**) touches surface (**B**).

Fig. 36. To adjust clutch-opening fingers, turn the adjusting screw on the clutch pedal until the clearance between the fingers and the release plate is about 1/16″ when the clutch is in. The release plate should then spin freely.

To Repair Reo Clutch

If the asbestos faces of the disks are worn, they must be replaced. The split rivets holding them should be opened down below the surface, if the facing does not have to be renewed.

1. To replace facing: Cut off the heads of the old rivets, taking care that the disks are not sprung out of shape.
2. Examine each disk to see that it is not sprung or warped out of shape, and note whether the steel disks are grooved. If either is the case, the disks must be replaced.
3. Using each disk as a template, drill the rivet holes in its new facings. Countersink the facings slightly for the rivet heads. (The new facings can best be obtained from the car makers, and this should be done if possible.)
4. Using solid copper rivets, rivet the new facing to the disk.
5. Examine the ball and roller bearings of the clutch for wear and the clutch bushing for looseness. Replace with new ones, if any amount of wear is evident.
6. Use little grease in assembling the bearings, as the clutch must be run dry.

1. **When assembling the clutch:** Make certain that the rings are inserted in proper relation to each other. (An asbestos-faced disk goes in first.)
2. Slide the clutch back into place.
3. Using a clutch-spring compressor, as shown in Fig. 34, replace the nuts on the clutch-spring bolts. Do not tighten these nuts yet.
4. Replace the clutch cross-shaft.
5. Reconnect the brake rods.
6. Replace the drive shaft and universals.
7. Replace starting motor, wires, and driving chain.

To Adjust Reo Clutch

1. Adjust the opening fingers on the clutch throw-out collar, so that they strike the collar together. This is done by loosening the clamp bolts, holding them to the cross-shaft, and tapping them into alignment. If this is not done the gears will not shift readily.

2. Adjust the clearance of the opening fingers. This is done by loosening the lock nut on the adjusting set screw, as shown in Fig. 36, and turning the screw in to decrease the clearance, and out to increase it. This screw should be turned out until the clutch release collar spins easily on the drive shaft when the clutch is in.

3. Tighten the nuts on the clutch springs at the rear of the flywheel evenly, and until the clutch does not slip. These nuts should not be so tightened that the clutch pedal works with difficulty.

Maintenance

1. If the clutch starts to slip, adjust it at once.
2. Use no oil on the interior of the clutch, except as placed in the two oil openings in the drive shaft.
3. Do not drive with the foot on the clutch pedal. (*Motor World.*)

ADJUSTMENT OF BUICK "SIX" CLUTCH (1921)

The Buick "six" clutch is of the multiple-disk dry-plate type, consisting of steel plates operating between steel plates lined with asbestos and which are connected alternately to the flywheel and the clutch shaft.

Adjustment: When the facing on the clutch disks wears, adjustment can be made by moving the lock nut and the adjusting on the clutch-release rod to allow more clearance between the clutch-release bearing and the plates. When adjustment is properly made a clearance of 1/32″ should be between the ball-thrust bearing and the rear plate against which it operates.

Lubrication: Neither oil nor grease should be put on the clutch disks. The clutch is lubricated by two grease cups, one located on the clutch-release yoke pin and one on the clutch-release bearing retainer, both of which should receive attention at least once every 500 miles. A few drops of oil applied to the pins on which the disks slide will prevent squeaking.

Clutch and brake pedals require soft cup grease. Remove the floor board and give grease cups one or two turns. Keep filled with grease. There is one cup on each pedal hub.

The clutch release fork pin requires soft cup grease. Remove clutch cover and give grease cup one or two turns.

The clutch release bearing retainer requires soft cup grease. Give grease cup (outside of transmission housing) one or two turns.

The clutch pedal position can be adjusted by means of the set screw at the rear end of the clutch housing.

The proper handling of the clutch pedal and accelerator so as to make the motor "pick up" its load quickly, and at the same time prevent it from "racing" when the clutch is released, requires practice.

In changing gears, and especially when starting the car from a standstill, always let the clutch pedal come back gently. If the foot is suddenly removed from the pedal, it will let the clutch take hold with a violent jerk.

THE STUDEBAKER "LIGHT SIX" CLUTCH

The Studebaker "Light six" clutch is of the single-disk dry-plate type.

Operation of clutch: The driven member is a single malleable-iron disk placed between two friction plates. Six coil springs are used to exert pressure on the clutch toggle plate, acting upon friction plates and a malleable disk located between the toggle plate and flywheel (Fig. 38).

The clutch is released by the toggle-lever collar being pulled back against the three toggle levers which operate the toggle plate, thereby relieving the pressure on the friction surfaces.

The toggle lever should be adjusted so that, with the clutch pedal released, there is a slight play between the ends of the levers and the toggle-lever collar. This play must be the same for each lever, so that the clutch is released equally at all points.

To make adjustment, first loosen the lock nuts on the toggle-arm adjusting screws. Then turn the screws to the left to increase the play between the toggle levers and the collar, or to the right to decrease it.

Under no circumstances should the levers be tight against the collar when the clutch pedal is released, as the clutch will be partially disengaged, and slipping will result.

In the case of a new car, or after new friction disks have been installed, it may be necessary, after 500 to 1,000 miles of running, to readjust the three levers which may bind on the collar as a result of the friction disks running into a smooth surface and becoming thinner. After the disks have worn smooth, no further adjustment will be necessary for some time.

When disks become badly worn it will be necessary to replace them with new ones, which can be obtained from a Studebaker dealer or branch. These disks require no treatment before or after being installed.

Clutch brake: The braking action on the clutch occurs when the grease retainer nut of the clutch throw-out bearing is brought in contact with the leather-faced flange, which is a part of the flexible coupling spider, keyed to the clutch drive shaft (Fig. 38).

There is no adjustment to the clutch brake, and it requires no care except that of replacing the leather facing when worn.

TRANSMISSION TROUBLES

Transmissions used on most cars are of the selective sliding-gear type, with three forward and one reverse speed, as explained on page 28.

Most of the transmission manufacturers now mount the counter-shaft on ball or roller bearings instead of on bronze bushings. Several are mounting the gear set separately from the engine and clutch which, however, are continued as one unit.

The usual troubles are:

1. Stripped gears.
2. Bearings worn, permitting shaft to drop out of line.
3. Dogs or gear teeth worn.
4. Dripping oil from the gearbox.
5. Cracked gears, worn teeth, sprung shafts.
6. Gear-shift rod out of adjustment.
7. Gears will not stay in mesh.
8. Usually the teeth of the "intermediate gear" and external and internal "high and intermediate sliding gear" (Fig. 38) wear first.

The cause of dripping oil is either a loose gasket, or too much oil running out at the bearing, or a worn felt gasket that may be sometimes used. The amount of oil usually carried in a transmission is a quantity sufficient to reach to a center line of the secondary shaft (Fig. 39). The lower gears will splash oil to all parts.

Other troubles: When dogs become worn (see part No. 139, page 26) so that they slip out of engagement, they may be dressed up or squared by grinding. Most transmissions now use internal gears, as shown in Fig. 38 ("drive pinion" and "high and intermediate sliding gear").

Noise: In gearboxes where the shaft ends are supported by single-row ball bearings, with no provision for end-thrust adjustment, and are noisy, **replace the bearings.**

Considerable wear in the bearings will change the distance between centers of the transmission shaft. In such a case **replace the bearings.**

Difficulty in shifting gears: There are three reasons for this: (1) a sticking or dragging clutch, caused by heavy oil; (2) the teeth of the shifting gears being burred; (3) considerable wear in the bearings, throwing the shaft out of line, which also causes noise. **Gears should be shifted without a particle of noise.**

Gears do not stay in mesh: This trouble is usually the result of weak or broken springs in gear-shifting shaft, **plunger or lock** (see 31, page 858). **Gear-shifting forks** (26, page 858) fit into collars on the sliding gears, and it is through them that the gears are moved to the different positions.

There are two types of gear-shifting shaft plungers or locks: (1) those placed on the top (31, page 858); (2) those placed on the side (Fig. 40, pg. 857). **A notch is cut in the gear-shift rod or shaft** (23, page 858) and a **plunger** and spring engages in the notch. On some transmissions a **steel ball** is forced into the notch by a spring, the **purpose** being to hold the gear-shift rod rigid so that gears will not move out of mesh after being shifted. The spring can be replaced if the gears fail to stay in mesh.

Worn gears and loose bearings will also cause the gears to fail to stay in mesh.

End play may be discovered by grasping the universal joint behind the gearset and attempting to move it forward or backward. If looseness is found, adjustment is needed. If end play is allowed to develop, the gears are likely to be stripped.

To determine the cause of clashing gears: Remove the cover plate over the clutch and, with the rear wheel jacked and the car in gear, let the clutch in and out. If the clutch continues to spin after it has been thrown out, look to the clutch brake, or see if there is too close an adjustment, or whether heavy oil causes the gears to drag.

Note. Do not allow a nut or any chips of metal to lodge in the transmission case. It will strip the gears if caught between the teeth. This also applies to the engine and the differential.

Do not use waste to wipe out the interior of a transmission. It leaves lint.

Removal and Replacement of a Transmission

Dowel pins and shims: Dowel pins are usually provided on either side of the transmission to insure its alignment. Sometimes, however, it is necessary **in squaring up the transmission with the engine** to insert a thick shim on one side; consequently it is important, when removing the gearbox, to notice whether **there are any shims,** and if there are, they must be replaced when the unit is put back.

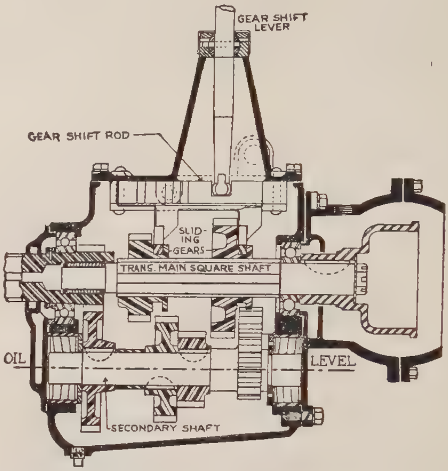

Fig. 39. Sectional view of a transmission. Note the oil-level line.

Bearings: The secondary-shaft in this example (Fig. 39) is carried on two Hyatt roller bearings. The bearing linings are a pressed fit in the case, and when they show wear they may be replaced at slight expense. The end thrust of this shaft is carried by two hardened steel washers, and a slight amount of end play is of no consequence.

Lubrication: The gearbox will usually hold about 2 qts. of oil, and should not be filled above the center line of the secondary-shaft. There are two oil rings provided on the main transmission shaft, and drains carry the oil back to the secondary-shaft bearings. Additional provision to prevent the oil from washing out through the bearings of the main shaft is made by thin steel washers which cover the inside of these bearings.

When replacing ball bearings in a gear-set case or on the shafts, care must be taken to see that the balls or races are not damaged from improper handling. Where the bearing is to be put on a shaft, the force should be applied to the inner race, using a piece of pipe and a hammer. If the bearing is to be forced into the gearset case, the driving effort should be applied to the outer or larger race in such a manner that no strain is imposed on the steel balls themselves.

Transmission-Gear Ratios

This subject is fully treated on pages 8, 9. See page 9 for examples of four-speed transmission.

STUDEBAKER LIGHT "SIX" TRANSMISSION

Type of transmission: The transmission is of the selective sliding-gear type, located at an intermediate position just behind the engine (Fig. 38). It consists of three shafts and a series of gears. Two of these shafts—the main transmission spline shaft and the pinion shaft—are in direct line with each other, the end of the main transmission spline shaft turning in the end of the pinion shaft. The third shaft, operated parallel with the pinion shaft and the main transmission spline shaft, is called the counter-shaft.

Neutral lock: The transmission is equipped with a neutral lock mounted in a hand-control base plate, and, when locked, it holds the sliding gears in neutral position (Fig. 40).

Transmission gears: The main transmission spline shaft carries two sliding gears of unequal sizes. These gears can be slid into mesh with gears of uneqal sizes on the counter-shaft. One of the sliding gears can also be moved into engagement with an idler gear supported by a transmission case, thus obtaining the changes of gear from "low" to "reverse."

Gear shift: See Fig. 3, page 630.

Lubrication of transmission: A heavy transmission oil should be used in the transmission. In addition, it is advisable to see that the transmission case is **thoroughly cleaned** out several times a season, as particles of steel from the gears, cuttings from the bearings, etc., all have a tendency to accumulate and, if not thoroughly cleaned out, will in time cause extra wear on the bearings. This can be done by taking out the cap screws on top of the transmission case cover and removing it altogether

with the gear-shift assembly. Unscrew the plug at the bottom of the transmission. After the oil has been drained out, kerosene or gasoline should be flushed over the gears, and the entire case should be washed out with kerosene or gasoline very thoroughly. The plug should then be replaced; new oil should be put in the transmission, and the cover and gear-shift assembly replaced, care being exercised to see that an oil-tight joint is made between the transmission case and the transmission-case cover.

Amount of oil carried in transmission: When the proper amount of oil has been added, it will stand just at the top of the oil-filler plug, which is located on the left-hand side of the transmission.

To adjust the pinion shaft (1) (Fig. 38) for wear, remove the retainer clamp bolt, and turn the retainer nut in the front end of the transmission case in a counter-clockwise direction until all end play is just removed.

Adjustment of the main drive shaft (2) (Fig. 38) is made by removing the bolts which hold the speedometer drive-gear housing to the transmission case, sliding the cover back far enough to give room for a spanner wrench. Then turn the bearing retainer in a clockwise direction until all end play is just removed.

DODGE DRIVE SYSTEM

To Adjust Dodge Clutch

The Dodge clutch is of the multiple-disk, dry-plate type. There are 7 disks held together by a heavy spring (6) (Fig. **A**, page 858). The 4 **driving** disks (9) (covered with wire-woven asbestos) are supported on 6 pins (3), pressed and riveted into the flywheel. The 3 **driven** disks (8) (plain) are carried on 3 pins (7) riveted to the clutch spider (4), which is keyed on the clutch shaft (32). Flywheel pins (3) are located outside, or above the clutch-spider pins (7), so that they can turn independently of the clutch-spider pins when the clutch is disengaged.

All disks are free to slide upon their supporting pins, and are held together by the clutch spring (6) when the clutch is "in."

To tighten the clutch spring: Compress it enough to allow the split washer (Fig. 41), which fits into one of three grooves cut on the clutch shaft, to be moved forward to the next groove. The two halves of this washer must fit securely into the groove so that the clutch-spring rear retainer fits snugly around it.

Care: Keep the foot off the clutch pedal except when using it, otherwise the disk facings and ball-bearing throw-out will wear excessively. Do not slip the clutch unnecessarily, as this causes the fabric to become glazed and to slip. Keep the drain in the bottom of the clutch housing open.

Lubricate the ball-bearing clutch release (12) by keeping the grease cup located on the toe-board to the right of the accelerator pedal well filled, and give it one complete turn every 100 miles. Make sure that the clutch-release grease tube (34) (Fig. **A**) is tightly connected and unobstructed.

Removal of Clutch and Gearbox

(1) Break the universal joint; (2) drop the emergency brake rod; (3) remove the exhaust pipe completely; (4) block up the engine at the rear, just in front of the bell flywheel housing; (5) remove the bolts in the rear engine arms (47); (6) remove the bolts holding the bell housing flange (10) to the crank case; (7) drop the foot-brake rod; (8) disconnect the flexible grease-cup tube running from the floor board to the clutch throw-out; (9) slide the unit to the rear and lift it out.

Disassembly of Dodge Clutch

(1) Remove the two lockscrews in the clutch throw-out yoke (visible from the clutch hand-hole); (2) remove the two nuts on the clutch throw-out yoke; (3) remove the clutch pedal (38) from its shaft and loosen the brake pedal (39); (4) drive out the clutch shaft (32) to the left; (5) lift out the clutch unit; (6) apply the clutch puller (Fig. 41) to the complete clutch disassembly; the puller consists of a cross-member with a bolt terminating in a hook perpendicularly placed at each extremity; the hooks engage pins on the clutch; (7) draw down on the puller nuts until the clutch spring is sufficiently compressed so that the split locking ring may be withdrawn; (8) remove the split locking ring; (9) ease up on the puller nuts, and then remove the clutch spring; (10) clutch plates may now be taken apart.

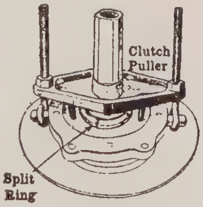

Fig. 41

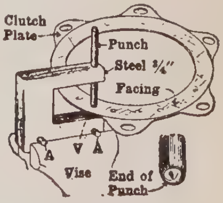

Fig. 42

To Replace Dodge Clutch

The facings come already cut and drilled, so it is merely a matter of riveting a new facing in place on the driving disks (9) (Fig. **A**). A tool especially designed for this purpose is shown in Fig. 42. The punch is made of a valve stem, hardened. In putting in the hollow rivets half of them should face one way and alternate ones in the opposite direction. This tool may also be used to rivet brake linings.

Dodge Rear Axle

This will now be considered with special reference to Figs. **A, B, C, D,** and **E,** on page 858.

Noisy Rear Axle

When there is a constant singing or humming noise in the rear axle, with the humming increasing with speed, and the rear axle mesh seems stiff when the clutch is thrown out, it is usually due to the adjustment of the drive pinion (54) to the driven bevel gear (63) being meshed too tight.

When there is noise and back-lash, which is more noticeable when the clutch is "thrown out," and there seems to be a loose, jerky motion in the rear when the clutch is "thrown out," it is probably due to gears (54) and (63) not meshing tight enough.

Remedy: First see if there is oil on the teeth of the gears, by taking out the filler plug and placing your finger on the gear. Often heavy grease will not throw all the way round.

Adjustment: Ordinarily the adjustment of the drive pinion (54) is sufficient. If not, the driven bevel gear (63) must also be adjusted.

Note: On other makes of cars having **"helical" gears** the same rules apply.

In the later Dodge axle, only one adjusting ring is used at (67) Fig. **C**, the adjustment of propeller shaft bearings being made by hexagonal nuts at forward end of bearing retainer, it being necessary to remove the propeller shaft to make this adjustment.

To Adjust Drive Pinion

The whole drive shaft (52) (Fig. **C**) can be adjusted **endwise** to obtain the exact position of the driving pinion (54) which is rigidly attached to it, in relation to the driven bevel gear (63) bolted to the differential. Two adjusting rings (67), fitted against the two Timken bearings (53), can be screwed forward or backward to obtain the proper position of the bevel driving pinion (54). These rings can be reached by removing the ring lock (71) (Fig. **D**). All that need be done is to back off one adjusting ring (67) (Fig. **C**), and screw the other one ahead, in whichever direction it is desired to move the bevel driving pinion (54). Be sure that each is holding its bearing rigidly before replacing lock (71).

Adjustment of Bevel-Driven Gear

To test if the bevel gear (63) **is running quiet,** jack up the rear axle and run the engine, with the gears in direct drive, about 20 m.p.h., as indicated by the speedometer.

After adjusting the bevel driving pinion (54) as explained above, and if it is still noisy, remove the rear-axle cover plate and the two adjusting ring-lock screws (56), and readjust the bevel driven gear (63) to the new position of the pinion.

The large bevel driven gear (63) **can be moved either to the right or to the left in order to insure its quiet engagement with the driving pinion** (54), by operating the two bearing adjusting rings (66) (Fig. **C**) in a manner similar to those used in adjusting the drive pinion. After adjusting, they are locked in place by the adjusting-ring lock screws (56) (Figs. **C** and **D**).

Removal of Rear-Axle Shafts

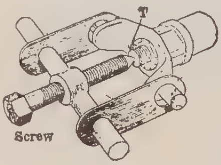
The rear axle is of the seven-eighths floating type,[1] permitting the removal of the drive shaft (58) (Figs. **C** and **E**) without jacking up the car.

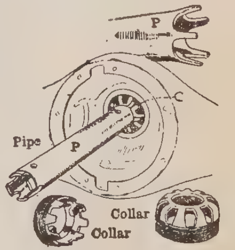
To remove rear axle shafts[1] (58) and flanges (82), simply unscrew the nuts on bolts (80), which hold the flanges to the hub of the wheel and remove them together with the axle shafts. If one axle shaft should stick, remove one on the opposite side, and drive or push the other one out with a long rod.

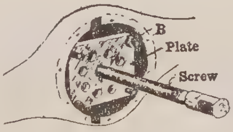
Lubrication of the rear axle: Use 5 pints,[2] if empty, of gear lubricant, or enough to fill the rear axle up to the level of the lower plug (62) (Figs. **C** and **D**). If grease leaks out from the rear wheels, the housing is too full.

To Disassemble Differential

(1) Remove axle shafts (58); (2) remove the inspection plate; (3) take the caps off the bearings and lift them out; (4) remove the cotter pins and nuts on the 4 studs which hold the differential unit together, and disassemble.







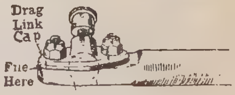


Fig. 43 (upper)

Fig. 44. **To remove the drive pinion** (54), a plate is bolted to the 4 studs and pressure is applied to the shaft by the screw.

Fig. 45. **To remove the front bearing,** adjust collar (C) and turn to the left with a screwdriver. A special wrench for this purpose can be made of a piece of pipe (**P**).

Fig. 46. The drag link cap is filed to give adjustment.

Dodge Transmission

The Dodge transmission (page 858) main sliding-gear shaft is mounted on ball bearings at either end, and looseness means replacement of the bearings. The counter-shaft is mounted on bronze bearings. If the gearset is kept properly lubricated with clean oil, none of these bearings should need replacement in a good many thousand miles of driving. Not more than 2 quarts of gearset lubricant should be used in the case. The level should be inspected every 1,000 miles and, if it has fallen so low that the gears on the main shaft do not dip well into the lubricant, the supply should be replenished so that they do. The level should be kept ½″ below the main sliding-gear shaft.

REMOVING, DISASSEMBLING, AND ASSEMBLING TRANSMISSION (MITCHELL "F")

Removing the transmission from the car: Remove the two bottom floor boards and lift out the front-seat cushion as well as the stool on which it rests. This will completely expose the transmission.

Disconnect the rear universal-joint member and, placing a jack under the transmission, raise it just enough to take the load off the transmission hanger links. Remove the two large hanger link nuts on top of the frame cross-member.

The transmission, still connected to the torsion tube, can be lowered to the ground by lowering and then removing the jack. Take out the 8 cap screws holding the transmission to the torsion tube; the transmission can then be taken out from under the car.

---

[1] Semi-floating type now used. **To remove rear-axle** shafts, first remove rear wheels.

[2] 4 pints in semi-floating type.

Disassembling the transmission: With the transmission out of the car, remove the cover and clean out the lubricant. Removing the drain plug at the bottom of the transmission case will aid in this operation.

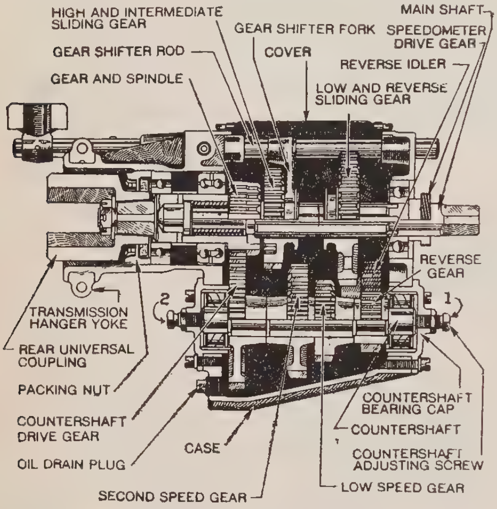

Fig. 47. Mitchell model "F" transmission used as an example.

Drive out the rear main-shaft ball bearing when the splined main shaft can be removed through the rear opening. In doing this the sliding gears will come off the main shaft and can be lifted out through the cover opening.

Care should be taken not to let the sliding gears drop as they come off the main shaft, since they may fall on the counter-shaft gears and get chipped. The small roller bearing supporting the front end of the splined shaft in the gear and spindle and the grease retainer may come out with the shaft, or may stay in the gear and spindle. Watch for them to see that they do not fall into the bottom of the transmission case and become misplaced.

Remove the pins holding the gear-shifter forks on their rods, and the rods can then be pulled out through the front of the case and the forks removed through the cover. In removing the rods it will be necessary to pull them out against the action of the spring locks which prevent the gears from coming out of mesh.

Remove the nut holding the universal-joint coupling to the front end of the gear and spindle and remove the coupling. Remove the lock holding the front-bearing packing nut and unscrew this nut.

Loosen the lock screws holding the large main gear and spindle double-row ball-bearing in place, and the gear and spindle complete with its bearings can then be removed by forcing it into the case and lifting it out through the cover opening.

Remove the front and rear counter-shaft bearing caps by taking out the cap screws which hold them in place. The counter-shaft roller bearings should be removed with the caps. The counter-shaft can then be moved back, tilted, and taken out of the case through the cover opening.

The gears can be removed from the counter-shaft only by the use of an arbor press. They should not be removed unless it is necessary to replace them.

The reverse idler gear can be removed by taking out the cotter pin in the end of the spindle and forcing the spindle into the case which removes the gear from it, when the gear and spindle may both be lifted out through the cover opening.

Assembling: When replacing the gear and spindle in the transmission case, do not set up the main-bearing lock screws tight enough to bind the bearing. They should be set up just tight enough to keep the bearing from turning in the case.

When reassembling the transmission and torsion tube, be sure that the speedometer drive gear on the transmission main shaft meshes with the small pinion in the front end of the torsion tube.

Adjusting the transmission: The only adjustment on the transmission consists of the two screws (1 and 2) (Fig. 47) located in the centers of the counter-shaft bearing caps. In reassembling the transmission, the counter-shaft should be so located in the case that the main counter-shaft drive gear is in full mesh with the large external gear on the gear and spindle. The adjusting screw should then be set up so that there is no end play on the counter-shaft, but allowing the counter-shaft to rotate freely without cramping or jamming.

The tension on the gear-shifting lever can be varied, and any tendency to rattle can be lessened by adjusting the splined nut found where the lever enters the floor boards. Remove the lock and unscrew this nut to decrease tension, or screw it down to increase tension and remove rattle. The ideal adjustment is such that there is little or no rattle and the lever does not bind or cramp in shifting gears.

Lubricating the transmission: The transmission is lubricated by filling it to a little above the center line of the counter-shaft with a high-grade semi-fluid lubricant of about the consistency of 600-W steam-engine oil. It will take about 2 quarts of oil to fill the transmission case to this point.

UNIVERSAL JOINTS

There are two types of universal joints in general use: the mechanical angular type, shown in Figs. 48 and 49 and the flexible-coupling or fabric type shown in Fig. 50.

The Spicer Universal Joint

A very popular type of universal joint is the Spicer, shown in Figs. 48 and 49. This universal joint can be used with an angular-drive or straight-line drive system, as explained on page 24.

The forward universal joint is provided with a dust cap (D) and a felt washer (W) on the rear end of the sleeve into which the end of the drive or pro-

Fig. 48. **Spicer universal joint showing the forward,** or splined end of the drive shaft in place. The right end of this forward joint is connected to the transmission shaft.

peller-shaft slides. This cap should be turned to the right occasionally in order to keep the felt washer tight and prevent the leakage of grease. Both joints have flax packing (P) between the two parts of the pressed-steel casings.

This packing can be tightened by loosening the casing-adjusting screw (S) and turning the casing-adjusting nut or ring in a right-handed direction.

If the packing in the front universal joint is allowed to leak grease, the joint will not only suffer from lack of lubrication, but the grease will be thrown up on to the emergency brake, rendering the brake inoperative.

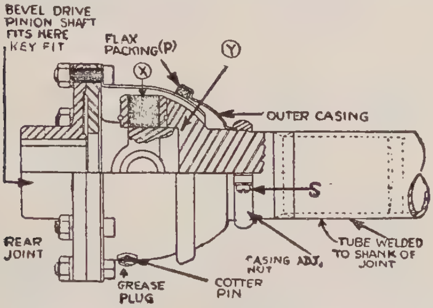

Fig. 49. This is the **rear universal joint** which is connected to the rear end of the drive shaft at the right end of the joint, and to the bevel-pinion drive shaft at the left end. Note that the splines are not used in this rear joint.

Lubrication: Every 1,000 miles remove the grease-hole plugs and fill with heavy gear oil or light cup grease. Too much grease will work out; about one-third full is the correct quantity.

Note. An "O" will be found on upper end of the propeller shaft tube (Fig. 48); a corresponding "O" will be found on the shank or rear end of the forward universal joint. When the propeller shaft and the universal joint are assembled, these two "O's" must be in line (as shown in Fig. 48), that is, the **yoke (Y) and journal (X) of the forward universal joint must be parallel to corresponding yoke and journal of the rear universal joint** (Fig. 49), otherwise the rear transmission bearing will be subjected to undue strain and excessive wear, and a jerky motion will be given to rear wheels.

Assembling: When the universal joints have been disassembled and are assembled again, care should be taken to see that the holes in the flange and the inside casings are matched up in such a way as to bring the **oil hole** (which is closed by a threaded plug) opposite an open space in the joint, and not opposite one of the lugs, which would prevent the introduction of grease through the hole. By removing this plug the user of the car can at any time inject additional oil or grease by the use of an ordinary grease gun, if the holes are matched.

Many of the joints are now fitted with a spring of suitable strength to give just the right pressure on the packing between the inner and outer casings. These require no attention from the operator. (Address of mnf'r.: Spicer Mfg. Co., South Plainfield, N.J.)

The Fabric Flexible Universal Joint

A type of flexible joint, connection, or coupling, as it could be termed, is shown in Fig. 50. This joint is generally used with drive shafts of the straight line drive, or what is nearly so, as explained on page 24. What angular movement there may be is the result of the flexibility of the flexible disks. These joints can be used with angular-drive systems (see page 24) where there is not too great an angular movement.

On each end of the driving, or propeller shaft, spiders (S) and (S1) are securely attached. Another spider (S2) is attached to the transmission shaft at the forward or driving end, and still another (S3) at the rear end which is attached to the drive pinion shaft.

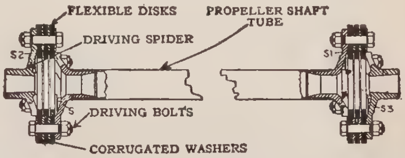

Fig. 50. The Thermoid-Hardy flexible connection, or joints that are used at each end of the propeller or drive shaft, instead of universal joints.

Three flexible disks, made of thermoid composition, are placed between the spiders and held securely by means of bolts and corrugated washers.

Note that with the use of these joints a splined shaft, as shown in Fig. 48 is not necessary.

By removing a few bolts the shaft may be removed.

Make sure that all bolts are kept tight, otherwise the holes in the fabric may tear out. New disks can be obtained at supply houses. Lubrication is not necessary.

The popularity of the fabric universal joint (Fig. 50) is to a large extent attributable to the poor lubrication methods used on many of the form-metal universal joints.

The lubrication systems, in some cases, were designed correctly enough, but, when assembled in the car, they were not within observation of the owner or driver and consequently received but scant attention. This could result in only one thing, and that was rapid wear with its accompanying knocks and lost motion. Some of the molded universal joints have been very much improved in this respect, and the Lincoln, for instance, makes provision for lubricating the front universal from the front gear case.

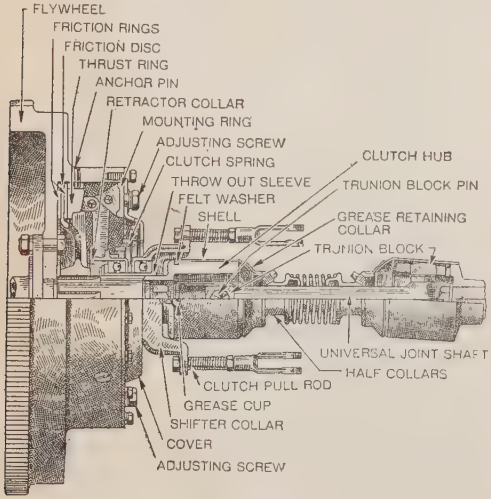
Disconnecting a Universal Joint and Clutch Mitchell Model "F" as an Example

Purpose of universal joint: Owing to the fact that the transmission is rigidly fastened to the front end of the torque tube and swings with it, there exists a certain amount of disalignment between the transmission and the clutch. For that reason a rigid drive or connection cannot be used, and a universal joint is employed. By means of hardened steel blocks sliding in hardened steel jaws the universal joint is given a flexible action which takes care of disalignment. See Fig. 51.

Removing the clutch and universal joint from the car: Disconnect the front universal joint member by compressing the grease retaining collar spring, taking out the half-shells and sliding back the cuff or housing. Slide the spring, rear grease-retaining collar, and cuff forward on the universal-joint shaft, and remove the whole universal-joint assembly.

Disconnect the clutch pull-rods by removing the clevis pins. Place two wood blocks 1⅜" thick between the clutch cover and the ends of the clutch pull-rods, thus relieving the cover of spring, pressure when the 12 capscrews holding the drive in the three anchor pins, and the rings can then be readily removed.

Remove the nut holding the clutch hub on the crank shaft, when the whole clutch assembly can be slipped off the end of the crank shaft, the friction rings and disk remaining in the flywheel. To remove the friction disks, as when renewing them, drive in the three anchor pins, and the rings can then be readily removed.



.Fig. 51. Mitchell universal joint and clutch.

Disassembling the clutch: With the clutch removed from the car, exert pressure on the retractor collar and, removing the locking wire and blocks from the flange nut, unscrew this nut (left-hand thread), and the whole clutch can be disassembled as the pressure on the collar is released.

Adjusting the clutch: To adjust the clutch, loosen the two adjusting screws in the slotted holes in the clutch cover. Depress the clutch pedal, and push these screws ⅛″ to ¼″ in a clockwise direction to overcome slipping, and counter-clockwise to overcome dragging. Release the clutch pedal and tighten the adjusting screws.

When the screws have reached the end of their slots, a new pair of threaded holes will have entered the beginning of the slots. Transfer the screws to the new holes, and continue to adjust as occasion requires. When these holes, too, have reached the end of the slots, all possible adjustment will have been taken up and new friction rings should be put in the clutch.

After the clutch has been properly adjusted, it would be well to see that the clutch pedal does not strike the under side of the floor board, as this will cause the clutch to slip. If such is the case, it can be corrected by adjusting the clutch pull-rods until the clutch pedal operates freely through the floor board. (See also Index for Borg & Beck clutch.)

Lubricating the clutch and universal joint: The grease cup on the clutch pull-out yoke should be filled and turned down completely once a week, or every 500 miles.

Cup grease should be packed into the front and rear universal-joint housings through the plugs in the half-shells. This can be conveniently done with a grease gun, and should be done every 1,000 miles.

Removing Universal Joint Chevrolet "490" as an Example

For another example of removing a universal joint the Chevrolet 490 is shown as illustrated below. Note the procedure as explained under the illustration.

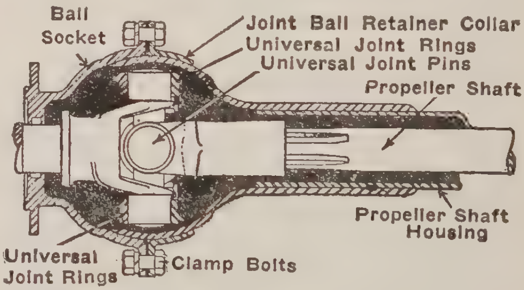


Fig. 52. The Chevrolet "490" metal universal joint. **To remove,** first remove the axle from under the car, take out the five cap screws holding the joint ball-retainer collar, and pull the ball joint from the socket. Remove the four clamp screws holding the two universal-joint rings together, and separate the rings. The nut holding the universal-joint yoke to the transmission shaft can then be removed and the yoke pulled off the shaft.

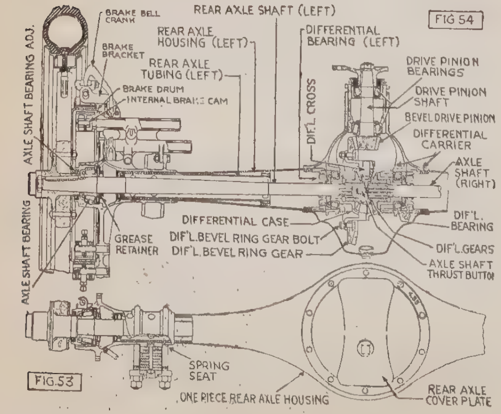
PARTS OF A REAR AXLE



Figs. 53, 54. Names of parts of a rear axle (one-piece type housing). See also page 875.

INSTRUCTION No. 73

REAR WHEELS, DIFFERENTIALS AND REAR AXLES FOR PASSENGER CARS: Types; Adjustments, and Repairs[1]

TYPES OF REAR AXLES

This subject is also treated on pages 15 and 16. **Types in general use** are the "plain live" (used on the Ford (pages 1096, 1097); the "semi-floating," which is used most (about 42 per cent of the cars use this type); the "three-quarter floating," which is extensively used, and the "full-floating."

To find the make and type used on different cars see Index, "Specifications of Passenger Cars."

The S. A. E. distinctions between the types of rear axles are as follows:

Dead axle: An axle carrying road wheels with no provision in the axle itself for driving them.

Live axle: General name for type of axle with concentric driving shaft. See also pages 15, 16.

Plain live axle: Has shafts supported directly in bearings at center and at ends, carrying differential and road wheels. (The plain live axle is practically obsolete.)

Semi-floating axle: Has differential carried on separate bearings, the inner ends of the shafts being carried by the differential side gears, and the outer ends supported in bearings.

The semi-floating axle shaft carries torsion, bending moment, and shear. It also carries tension and compression if the wheel bearings do not take thrust, and compression if they take thrust in only one direction.

Three-quarter floating axle: Inner ends of shafts carried as in semi-floating axle. Outer ends supported by wheels, which depend on shafts for alignment. Only one bearing is used in each wheel hub.

The three-quarter floating axle shaft carries torsion and the bending moment imposed by the wheel on corners and uneven road surfaces. It also carries tension and compression if the wheel bearings are not arranged to take thrust.

Full-floating axle: Same as three-quarter floating axle except that each wheel has two bearings and does not depend on the shaft for alignment. The wheel may be driven by a flange or jaw clutch.

The full-floating axle shaft is relieved from all strains except torsion, and in one possible construction, of tension and compression.

Advantages of the semi-floating axle (by Packard Motor Car Co.): In the semi-floating axle, the wheel hubs can be made slightly smaller and, because of the location of the bearings, the stresses in the rear axle can be kept lower than in the full-floating type.

There is a slight advantage also in the bearings, as the full-floating type have to use a bearing with a smaller ball, since it must fit around the rear-axle tube. In the semi-floating type, the bearing has a smaller bore, and therefore larger balls can be used, as the bearing has only to go over the axle shaft.

Another advantage is that the rear wheels can be more readily removed when replacements are necessary, wheels being replaced oftener than shafts. Still another advantage claimed is that of lubrication, as the outer bearings can be lubricated from the inside, and an oil retainer can be placed on the outside, while the full-floating type must have a separate supply of lubricant for the rear-wheel bearings.

Rear-axle ratios (see pages 8 and 9). **Types of drive** (see page 6).

TIMKEN REAR-WHEEL BEARINGS; ADJUSTMENT AND LUBRICATION

As an example of the semi and full-floating types of rear axles, and the method of attaching the axle shafts to the rear wheels, and of how the bearings are placed, we will use the Timken rear axles and wheels.

Rear-axle housing is made in "one-piece" or "two-piece" type. Fig. 53, page 862, shows a one-piece type, and Fig. 56, a two-piece type. The halves (H) are termed **right and left halves.**

The bevel-gear housing (Fig. 54) is that part where the bevel gears are enclosed. The **differential carrier** is that part which carries the differential. On some it is bolted to the axle housing, as in Fig. 19, page 871, and on others it is integral with the axle housing, as in Figs. 54, 55. The **rear-axle tube** is shown in Fig. 54, one right, the other left. **Rear-axle shafts** (semi-floating in this example) are right and left. The **rear-axle housing cover** is the plate over the one-piece housing. The **rear-axle spring seat** may be under or on top of the housing. Other parts are shown in Figs. 53, 54.

Removing Rear-Axle Shafts

On "full-floating" and "three-quarter-floating" type of rear axles, the axle shafts can be withdrawn without removing wheels.

On most of the "semi-floating type" of rear axles, the axle shafts can be withdrawn without removing rear-axle assembly, but wheels must first be removed and then the outer wheel bearing nuts and bearings (see pages 15, 16, 864, and 883).

On a "plain live axle" having a two-piece or divided rear-axle housing, the complete rear-axle assembly must be removed in order to remove the rear-axle shafts. See pages 880 and 1096.

Removing Differential

On those types of floating rear axles having a "one-piece" housing and a **cover plate** and where the "differential carrier" is **integral with the rear-axle housing,** the differential can be removed by removing the axle shaft, then removing the differential bearing caps from the carrier integral with the axle housing (Fig. 55), after which the differential can be withdrawn at the rear of the housing.

On those types of rear axles having a one-piece housing with "differential carrier" bolted to rear-axle housing (Figs. 18, 19, page 871), the differential with drive pinion can be removed by withdrawing axle shafts, loosening differential carrier, and removing complete assembly (Fig. 19, page 871), through the **front** part of the axle. Then the differential can be disassembled and adjusted on the removed carrier.

On those types of rear axles having a "two-piece" or divided rear-axle housing which is bolted together in the center, the complete rear-axle assembly must be removed from the car in order to remove the differential, as shown in Figs. 56, page 862 and 41, page 880, Fig. 28, page 921, and Fig. 39, page 1096.

Semi-Floating or Fixed Hub Types[2]

Timken fixed-hub or semi-floating rear axles are used on light and medium-weight passenger cars. In this type of construction the wheel is keyed to the axle drive shaft, the shaft revolving in a bearing mounted in the housing just inside the wheel. See Fig. 1, page 864. This bearing should be cleaned, greased, and adjusted at least once a year; more often if the service is severe.

---

[1] See Index under Truck axles.

[2] See also page 883 for later types with oil seals.

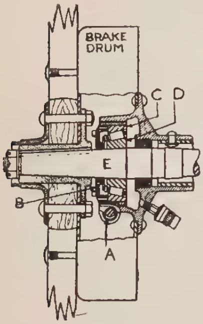

Fig. 1

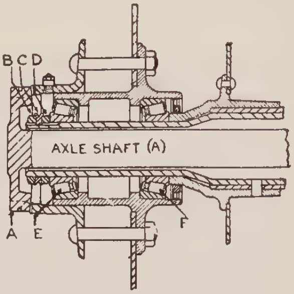

Fig. 2

Fig. 1. Timken **rear-wheel hub** as used with the **semi-floating rear axle** (see also page 883).

Fig. 2. Timken **rear-wheel hub** as used with the **full-floating type of axle.**

To clean the bearing, remove the wheel from the axle shaft, using a wheel puller if necessary.[1] Now release the locking finger (**A**) which prevents the bearing adjusting ring (**B**) turning, and unscrew this ring from the housing, carrying with it the bearing cup (**C**). The ring having been removed, **pull out the axle shaft** (**E**) on which is pressed the bearing cone (**D**), and the rollers. With a stiff brush and gasoline or kerosene clean off all old grease from the bearing cup, cone, and rollers, and from the end of the housing into which the adjusting ring is screwed. In order thoroughly to remove all old grease, the bearings should occasionally be placed in a solution of washing soda and water and brought to a boil.

Lubrication of bearings: After carefully cleaning and drying the bearing, cover well with good, clean cup grease free from acid and dirt, grit, and other solid matter. Also pack the end of the housing with grease.

Adjustment: Now replace the shaft with the bearing cone and rollers and screw on the adjusting ring carrying the bearing cup. The **adjustment** of the bearing is made by turning up this ring.

In adjusting wheel bearing, remember that the two drive shafts, right and left, come in contact in the center of the differential spider (see Fig. 3, page 865). If the bearing on one side is adjusted in too far, while the bearing on the other side is too far out, the spline end of the shaft will project through into the other side of the differential. This will either lock the differential or cause the end of the shaft to be twisted off. Care must be used, therefore, to take up the same amount on both right and left-hand bearings.

Screw up the bearing adjusting ring (**B**) (Fig. 1) until all end play is taken out of the shaft and until the shaft turns stiffly when revolved with a wrench placed on the nut on the shaft end. Then back off the ring one notch and lock in this position by means of the locking finger. The wheel may now be replaced, care being taken to tighten up well on the nut on the end of the shaft and to lock it with a cotter pin.

Full-Floating Type

Timken full-floating rear axles are used on heavy passenger cars. In this axle the entire weight of the car is carried on the axle housing; each rear wheel has two bearings mounted in the hub similar to the front wheel (Fig. 2). These bearings should be cleaned, re-greased, and adjusted at least once a year—more often if the service is severe.

To remove the bearings, take off the hub cap (not shown) jack up the wheel, and pull out the axle drive shaft (**A**). Wipe the grease from the end of the housing tube and the lock nuts. Now take off the outer lock nut (**B**), the thin lock washer (**C**), and the inner lock nut (**D**). The wheel may now be removed. Kneel directly in front of it and, grasping the rim with both hands, pull toward you. Be careful not to allow the outer bearing (**E**) to fall to the floor, which may bend or otherwise damage the cage.

To clean parts: With a stiff brush and gasoline or kerosene, clean all the old grease from both outer and inner bearings and from the inside of the wheel hub. Occasionally both bearings should be placed in a solution of water and washing soda and brought to a boil. This cleans off any grease behind the rollers which may not have been removed by the brush.

Lubrication of wheel bearings: When the bearings have been thoroughly cleaned and dried, replace the inner bearing (**F**) on the axle tube, covering it well with good clean grease free from all acid, grit, or solid matter. Care should be taken to see that there is no dirt on the paddle. Repack the space in the hub between the two bearings and cover the outer bearing with grease.

Replacing wheel: Now replace the wheel, and, holding it firmly in position, slide the outer bearing on the tube end, pressing it firmly into the hub. Screw up the inner lock nut, turning it up tight against the bearing so that the wheel binds, at the same time revolving the wheel to be sure all working surfaces on the bearing come into contact.

Now back off the nut enough to allow the wheel to turn freely, but not enough to give any noticeable looseness or end play. Replace the lock washer and screw up the outer lock nut tightly against it.

Bearing adjustment: Before replacing the axle shaft, be sure that your bearing adjustment is right. The wheel should be loose enough to oscillate, that is, when spun, it should come to a stop and then start to turn back in the opposite direction, but not loose enough to have any amount of shake. Check this adjustment after tightening up the outer lock nut, as it is sometimes possible, when using a large wrench, to turn the nut so tightly against the inner nut as to destroy the adjustment.

Lubrication of wheel hubs, etc : Having obtained a good bearing adjustment, cover the end of the tube and the lock nut with grease, and slide in the drive shaft. Fill the hub cap with grease and screw it on the hub, being careful to get it tight.

---

[1] See Index under "Wheel pullers."

Cautions

1. **Don't jam lock nuts so tight that the wheel binds.** A wheel should oscillate when given a slight spin (in other words, come to a stop and turn slowly back in the opposite direction).

2. **Don't allow the lock nuts to be so loose that you can shake the wheel and feel the play in the bearings.** Too loose an adjustment will damage a bearing just as rapidly as too tight an adjustment.

3. **Don't take rollers, cone, cage, or cup from one bearing** and substitute these parts in another bearing even though it bears the same number. After a bearing has once been used, the parts differ from an unused bearing one to two one-thousandths of an inch—not enough to see, but enough to cause trouble and expense if parts are substituted. If a bearing must be replaced, because of damage, replace the entire bearings.

4. **Don't hit the cage with a hammer to drive a bearing on a spindle;** you will bend the cage and damage the bearings.

5. **Don't use a screwdriver or other sharp tool back of the cage to pry a bearing off a spindle**—you will bend the cage. If a bearing cone sticks, be sure the tool is placed behind the edges of the cone. A slight pressure is sufficient to release the cone from the spindle.

6. **Don't let bearings fall on the floor;** you may bend the cage which keeps the rollers in line.

7. **Don't use grease or other lubricant that contains acid or has acid-forming qualities.** Use only a good grade of clear medium cup grease having no solid matter in suspension.

8. **Don't drive cups in hubs or other retainers, nor cones on spindles, with a hammer** where a pressed fit is required.

ADJUSTMENT OF TIMKEN REAR AXLES;[1] GEARS, PINION, AND DIFFERENTIAL BEARINGS[2]

There are three conditions which make adjustment of gears and bearings necessary—objectionable noise, excessive back lash in the gears, and a loose pinion or differential bearings.

Timken-Detroit fixed-hub or semi-floating rear axles are built in two sizes—current series, 5151 and 5152 (Fig. 3) for light cars, and 5301 and 5302 (Fig. 4) for cars of medium weight. **Full-floating axles** for heavy cars are built in one size only—current series 5762 (Fig. 5). The construction of these three axles is shown in detail in Figs. 3, 4 and 5. The **principles of adjustment** are the same in any case; the figures show the slight differences in the details of design.

To adjust for elimination of noise,[2] remove the clamp bolt and lock at (**A**), and turn the sleeve (**B**) containing both the pinion bearing and the pinion shaft one notch to the left. Replace the clamp bolt and lock, and run to see if the noise is lessened or increased. If the noise is less, turn the sleeve to the left until the quietest point is found; if it is increased, turn the sleeve to the right until the best point is found. Do not forget to replace the clamp bolt and lock each time before running to test your adjustment.

To take up excessive back lash,[2] remove the cover (**F**). Now loosen the differential-bearing cap bolt-lock wire (**G**), and disengage the lock (**H**) from the adjusting rings (**J**) and (**K**). When this has been done, loosen the right-hand adjusting ring (**J**) and tighten the left-hand ring (**K**), thus forcing the ring gear against the pinion. Turn both rings the same number of notches until the proper amount of back lash, approximately five one-thousandths of an inch, has been obtained. After adjusting, be sure that the lock is replaced and is held by the wires before replacing the cover.

To adjust the pinion-shaft bearing, loosen lock nut (**C**) and then tighten up on adjusting nut (**D**) until the shaft will turn freely but with only very slight end play. The end play should be about five one-thousandths of an inch after tightening the lock nut. Tighten up the lock nut (**C**) and peen over the washer (**E**), so as to lock both nuts.

If noisy gears result from this adjustment of the bearings, eliminate the noise by the adjustment described above.

Adjustment of the differential bearing is made by tightening up on the adjusting rings (**J**) and (**K**) after releasing the lock (**H**). Tighten up on these rings until the differential turns freely, but without end play. If excessive back lash results from this adjustment, take up as outlined above for elimination of back lash.

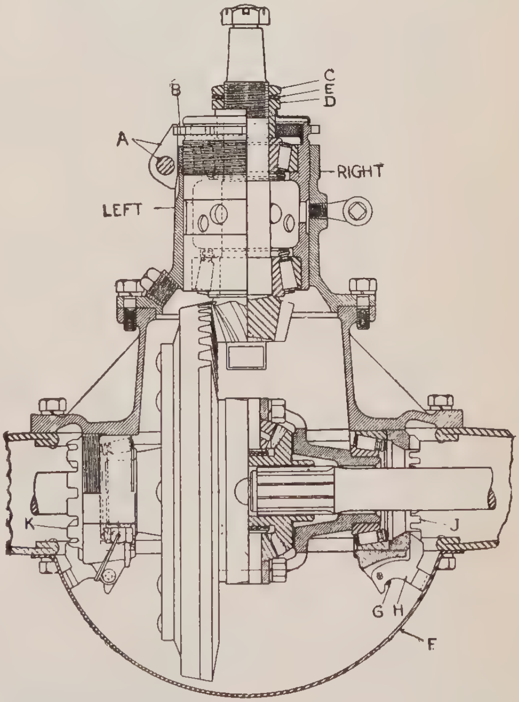

Fig. 3. Timken fixed-hub or semi-floating rear axle, types 5151, 5152 for light cars.

Lubrication: The **pinion and ring gear** and the **differential gears and bearings are lubricated** by the oil in the axle housing. Keep the housing filled to the level of the oil hole in the bowl with a good quality of **light steam cylinder oil.**

To lubricate the drive-pinion bearings, keep the sleeve (**B**) well filled with a good quality of heavy lubricant free from acid, grit, or other solid matter.

Lubricant can be introduced into this sleeve through the street ell at the side of the carrier casting, and this point should receive special attention when the axle is first put into service. Be sure that the sleeve is filled to the height of the lip, and put in additional lubricant from time to time to make up for any leakage.

---

[1] **Timken axles** (Figs. 3, 4, 5, and Fig. 6, pages 865, 866, and Fig. 7, page 867) **could represent either a semi-floating or a full floating axle because the differential supports the inner ends of axle shafts.** The next principal feature which determines whether it is a semi-floating or full-floating axle is found in the type of hub used. See also pages 15 and 863.

If the semi-floating wheel hub (Fig. 1, page 864) **is used,** it is termed a semi-floating axle.

If the full-floating wheel hub (Fig. 2, page 864) **is used,** it is termed a full-floating axle.

[2] See also page 910 for later types.

Gears are properly adjusted:

1. When the axle is quiet.
2. When the gear teeth engage for their entire length.
3. When there is but little back lash between the gears.
4. When there is no end play in the pinion shaft.
5. When all adjustments are securely locked.

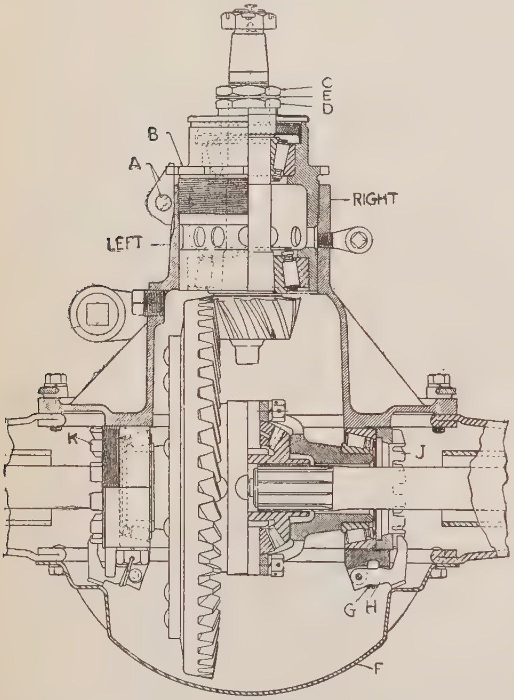

Fig. 4. Timken fixed-hub or semi-floating rear axle, types 5301, 5302 for cars of medium weight.

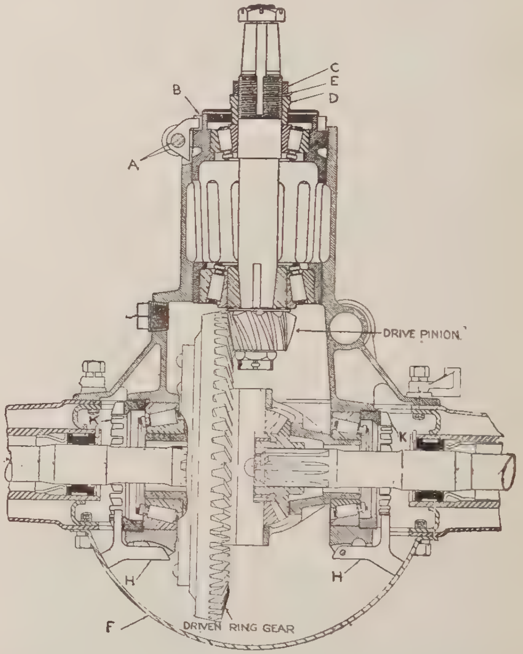

Fig. 5. Timken full-floating rear axle, type 5762, for heavy cars.

OLD TYPE REAR AXLES (TIMKEN)

The preceding instructions are intended to cover particularly the Timken-Detroit axle now being produced.

The following description and figures cover the adjustment of axles as formerly designed, where these designs differ to any extent from the present type. See Figs. 6 and 7.

Gear and Bearing Adjustment of Timken Rear Axle Shown in Fig. 6

1. **Before making adjustments for elimination of noise or back lash,** take up all looseness, if any, in the bearings. To do this, remove bolts (**A**) and locking key (**B**). Turn the slotted ring (**C**) toward the right, while holding ring (**D**) in its original position, until the bearings are free from end play, at the same time allowing the pinion shaft to turn freely.

To take up differential bearings, remove the locking wire in cap screws (**L**) and loosen the screws one half-turn. Release locking finger (**J**) and turn the right-hand adjusting ring (**F**) toward the differential until the bearings are free from end play, at the same time allowing the differential to turn freely.

2. **When adjusting to eliminate noise,** remove bolt (**A**) and locking key (**B**) as directed above, and turn rings (**C**) and (**D**) one slot toward the left and repeat until the quietest point is found. If the noise increases, adjust in the opposite direction. Always turn rings (**C**) and (**D**) together when adjust-

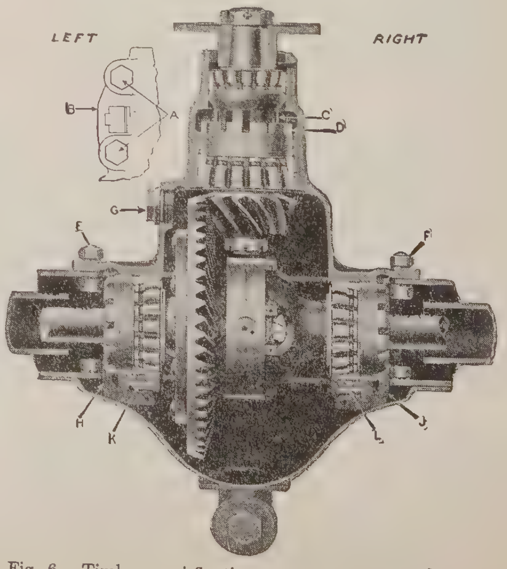

Fig. 6. Timken semi-floating rear axle, as referred to in the text. Models are 5230, 5240, 5241, 5752, and 35C axles. The cars which formerly used this axle are as follows: Hudson (5241); Jordan (5241); Westcott (5240); Chalmers (35C).

ing for this purpose, by using a tool broad enough to engage the slots in both rings.

3. **When adjusting to take up back lash in the gears,** remove the wire and loosen cap screws (K), (L), one half-turn. Release locking fingers (H), (J). Back the adjusting ring (F) away from the differential and turn the adjusting ring (E) toward the differential (right-hand thread on both) until the gear is forced toward the pinion, so that it has about .005″ back lash, or barely perceptible looseness.

If the gears are so far out of mesh that no results can be obtained through the method described above, or if new gears have to be placed in the axle, remove peep-hole plug (G) for observation, and set the gears with backs flush, as a starting-point, and proceed again as directed above.

If noise results from taking up loose bearings, proceed as in paragraphs 2 and 3 as required.

After making adjustments, make sure that all locking keys, cotters, wires, etc., are replaced and that all bolts and cap screws are properly drawn up. If a car is run to try the effect of any adjustments, all bolts and cap screws must be properly tightened.

Gear and Bearing Adjustment of Timken Rear-Axle Shown in Fig. 7

1. **To eliminate noise,** loosen nut No. 1 at (A) and then loosen nut No. 2. Remove the cover at (B), and loosen clamp bolt No. 4. Turn the slotted adjusting cup toward the left one notch, and tighten up nut No. 2, then nut No. 1, just enough to let the shaft run freely without end play. If this lessens the noise, loosen nuts No. 1 and No. 2, and turn the adjusting cap another notch, and repeat this operation until the quietest point is found. If the noise increases, adjust in the opposite direction. When final adjustment is made so that the pinion shaft has no end play, back off nut No. 2 one quarter-turn and tighten up on nut No. 1. Bend the washer over one flat of each nut, tighten up clamp bolt No. 4, and replace the cover.

2. **To take up back lash,** back the adjusting ring at (D) toward the differential, and turn the ring at (C) against the bearing cap which will force the ring gear toward pinion. These rings have a right-hand thread and are threaded to bearing carrier. Before turning the rings, loosen the cap screws in the bearing cap one half-turn after removing the locking wires. The proper amount of back lash should be approximately .005″, or barely perceptible looseness. When proper adjustment is made, make certain that the locking pins are in the back slots of the rings, tighten the cap screws, and replace the locking wires.

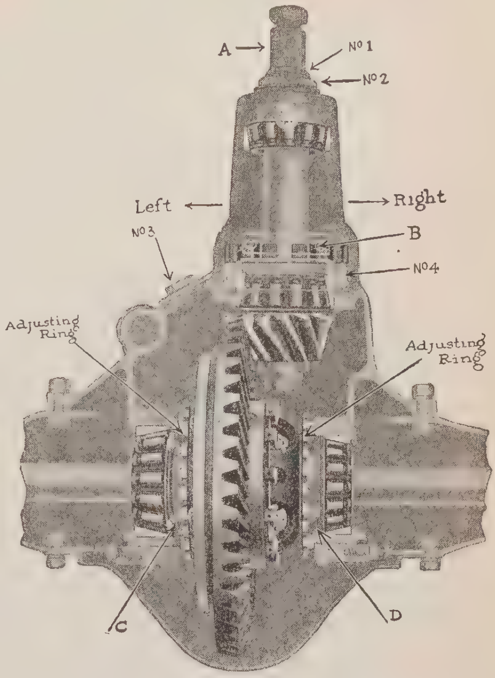

Fig. 7. Timken full-floating rear axle, as referred to in text. Model numbers are 5741, 5742, 5395, 5396, 538, and 574. Cars which formerly used this axle are as follows: McFarland (5742); Hal (5395); Daniels (5396); Dorris (5396).

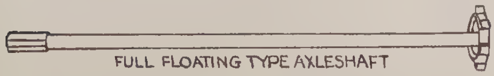
3. **To take up looseness in bearings on the drive-pinion shaft,** loosen nut No. 1, tighten up nut on No. 2 enough to let the shaft run freely without end play, back off one quarter-turn, and tighten up nut No. 1. If noisy gears result, proceed as in paragraph 1. For taking up looseness in differential bearings adjust rings (C) and (D) away from the differential, after loosening the cap screws and locking the wires, as directed in paragraph 2. **Adjust each ring until the differential runs free without end play,** and if back lash results, proceed as indicated in paragraph 2.

If gears are so far out of mesh that no results can be obtained through the method described above, or if new gears have to be placed in the axle, remove the peep-hole cover No. 3 for observation, and set the gears with backs flush, as a starting-point, and proceed as above.

THE TIMKEN AXLE SHAFTS

From the differential the power is carried to the wheels by the axle shafts. They must be strong—strong enough to resist the greatest possible torsion under any conditions of travel. Yet they should be as light as is consistent with perfect safety.



FULL FLOATING TYPE AXLESHAFT

FIXED HUB OR SEMI-FLOATING AXLE SHAFT

Fig. 8

Where the shaft enters the differential it is enlarged, the end is **splined,** and steel is left back of the splines—a very important matter.

At its wheel end the shaft of the **full floating axle** is enlarged to form an integral (not welded) disk or "driving dog" (Fig. 8), which fits into the driving plate of the hub and turns the wheel (Fig. 2, page 864). In the fixed hub or **semi-floating** type of axle shaft, the wheel end is keyed (Fig. 8) to the wheel (Fig. 1, page 864).

TIMKEN ROLLER BEARINGS

The subject of bearings is treated on page 19. An explanation of the Timken roller bearing which takes a thrust or radial load is given below.

The different places on a car where roller or ball bearings are generally used are the front wheels, the transmission, the pinion drive shaft, the differential, and the rear wheels.

The parts of a Timken roller bearing are shown in illustration below (Fig. 9), and are as follows: (1) the cup or outer race; (2) the roller bearings; (3) the cone or inner race.

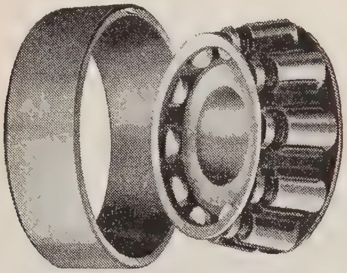


Fig. 9. **Timken tapered-cone type of roller bearing.** Used for wheel bearings, axle bearings, and different parts of the car. The part to the left is called the cup or outer race in which the rollers revolve. Note that the cone, or inner race, is the part underneath the rollers. This part fits onto the shaft and the cup fits into the bearing space.

The cone should have a **floating-fit** on all **non-rotating shafts,** such as front-wheel spindles and full-floating rear-axle sleeves.

The cones should have a **press fit** on all **rotating shafts,** such as semi-floating rear-axle drive shafts, pinion shafts, worm shafts, belt-pulley shafts, and transmission shafts; except where it is necessary to move the cone on the shaft to make adjustment, in which case the cone should have a light-press fit. (Be sure that all cones are seated firmly against the shoulders on the shafts.)

Cups: The ideal mounting for all Timken cups is a **press fit** in such mountings as wheel hubs, pinion housings, differential housings, belt pulleys, worm-shaft housings, and transmissions. Where the cup must be moved to make adjustment, it should have a **light press fit.** (Be sure that all cups are seated solidly against the shoulders in their mountings.)

On mountings where shim adjustment is used, the cups are usually pressed into a retainer or cup-holder which, when installed, is bolted to the housing with shims between the flange of the retainer and the housing. Adjustment on such mountings is made by moving the retainer farther into the housing until all end play is taken out of the bearings.

This can be done by removing the retainer and taking out one or more shims. If adjustment is made too tight, causing a bind in the bearings, one or more shims should be added.

The subject of direct mounting and indirect mounting of bearings on a worm shaft is explained under the discussion of truck rear axles (Timken), as is also the subject of how to compute the worm-gear ratio.

The adjustment and lubrication of the front and rear wheel bearings, transmission, and differential are given in the explanations of the different Timken axles and wheels in this instruction, and also in the instruction dealing with front wheels and under the truck rear-axle subject.

ADJUSTMENT OF COLUMBIA THREE-QUARTER FLOATING REAR AXLE

The Columbia rear axle, illustrated below, is the model 50,000 Columbia three-quarter floating type of rear axle, as used on passenger cars weighing 3,200 to 4,000 lbs., equipped for road service. Some of the cars using this axle are the Cole, King, Premier, National, Du Pont, Kenworthy, and Ogren.

To remove axle shafts: Unscrew the six acorn nuts on the axle flange and pull out the shafts (Fig. 10).

To remove the differential assembly: Having first taken out the axle shafts, remove the ten cap screws on the face of the carrier, as indicated on **2,** Fig. 10, remove the cam brackets which extend over the face of the carrier and which come off freely after the cap screws are out, and the carrier will then fall out of the housing. All brake connections may remain intact during this operation.

To adjust drive pinion bearings: This is required only when the drive pinion shaft is loose, that is, when you can move the drive pinion shaft forward or backward. This can be determined by prying between lock nuts and carrier (Fig. 10). This adjustment is made with the two nuts (Fig. 10) where it reads: "Never loosen these two nuts unless end-play has developed."

To adjust drive pinion: Remove the locking plate (2, Fig. 10) on the neck of the carrier, held in position by two screws and lock washers, loosening the locking bolt next to this plate which clamps the pinion adjuster in the neck of the carrier. Insert a flat tool, usually a blunt screwdriver, into the notches on the pinion adjustment and turn either to right or left as you wish the pinion closer to or farther away from the ring or master gear.

Turn the pinion adjustment to the right, if you desire to move the drive pinion forward (toward front of vehicle), or to the left, if you desire to move the drive pinion backwards and thus bring the back faces of the drive pinion and ring gear to proper position. Move the adjustment only one or two notches (not complete turns) in one direction or the other until the quietest running position has been secured. Replace the locking plate and tighten the locking bolt.

Adjustment for noise: Put the pinion closer for "drive noise," and farther away for "coasting noise," see "Gear Contact."

To adjust ring gear: Do not make this adjustment unless absolutely necessary and after having tried the other adjustments. The thrust of the drive pinion always forces the ring gear toward the **left** rear wheel (left as when seated in car); consequently the adjustment is usually towards the **right-hand** rear wheel in practically every case, owing to excess wear on the left-hand differential bearing. This adjustment is made by turning the left-hand differential bearing adjustment (**A**) (Fig. 10). Sometimes the adjustment may have to be made on the right-hand adjustment (**A**) (Fig. 10); this should not be done however, unless you can pry against the ring gear and it shows a slight end play toward the right.

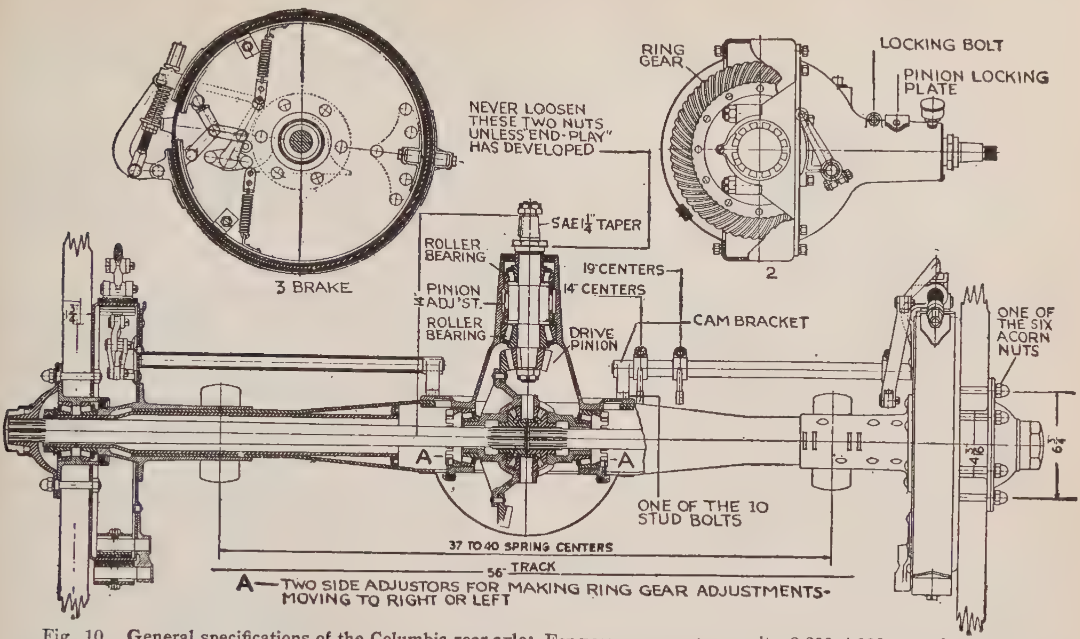

Fig. 10. **General specifications of the Columbia rear axle:** For passenger cars: capacity 3,200–4,000 pounds, equipped for road without passengers; three-quarter floating type; one-piece rear-axle housing, with full-length reinforcing tubes; heavy-duty tapered roller bearings; alloy steel spiral bevel gears, case hardened and heat treated; adjustment provided for pinion and differential; alloy steel pinion shaft and drive shafts scientifically heat treated; sixteen-inch adjustable internal and external brakes. See page 891 for description of the brakes. **Lubrication:** Use Whitmore's No. 9 in summer and Whitmore's No. 33 in winter, or Mobiloil "C," or Polarine "A," or Enarco medium.

Note. To reach the differential bearing adjusters (**A**) (Fig. 10), it is first necessary to remove the locking wires and to loosen two cap screws and remove the caps (not shown in the illustration).

If it has been finally determined that the ring gear must be moved to secure proper gear contact, the whole assembly must be moved, by releasing the adjuster locks on each side and then backing off one of the adjusters (A) a notch or two in the direction you wish to move the ring gear, following this by screwing **in** (toward the ring gear) on the adjuster (**A**) on the **opposite** bearing. Thus you are moving the whole assembly and maintaining the bearing adjustment.

The differential ring gear is always placed on the left side of the differential (left side as when seated in the car), because the crank shaft and propeller shaft revolve clockwise, and thus drive the rear wheels forward. See Fig. 10, and also Fig. 3, page 6. Owing to this fact, the thrust is always to the left side of the differential, and thus there is more wear on the left bearing.

BEVEL GEAR CONTACT

Proper gear contact and properly lubricated gears will assure the efficient transmission of the engine's power to the rear driving wheels, providing that the differential and pinion bearings are performing their functions properly.

In order to understand more clearly the meaning of **"gear contact,"** the following terms are illustrated and described.

Terms Used in Describing Gear Contact

Pitch line: A line drawn near the middle of the tooth (see Fig. 11).

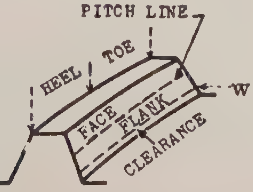

Fig. 11. Descriptive terms as used in connection with gear teeth.

Working depth: That part of a tooth which is opposite the end of the tooth with which it meshes, see (W) (Figs. 12 and 11).

Clearance: The distance from the working depth to the bottom of the tooth (see Figs. 12 and 11).

Face: That part of a tooth which lies between the pitch line and the end of the tooth (see Fig. 11).

Flank: That part of a tooth which lies between the pitch line and the working depth (see Fig. 11).

Toe: The inside or smaller half of a tooth (see Fig. 11).

Heel: The outside or larger half of a tooth (see Fig. 11).

Backlash: The difference between the thickness of a tooth and the space into which it meshes (the play) (Fig. 12).

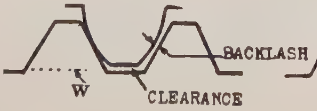

Fig. 12

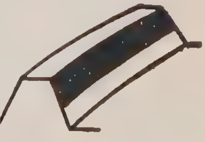

Fig. 13

Fig. 12. Explanation of backlash, clearance, and working depth (W).

Fig. 13. Full-face contact (shown in black).

Gear Contact as Applied to Columbia Rear-Axle Gears[1]

The complete driving assembly is adjusted, locked and tested at the Columbia plant, then tested and readjusted if necessary by the manufacturer, under the vehicle; consequently it is not often necessary for the user to adjust any of these parts, except possibly the bearings.

The pinion shaft and gear revolve in a fixed carrier and may only be moved directly forward or backward. The **ring gear** also revolves in the same fixed carrier and may only be moved directly toward one rear wheel or the other. The **bearings** hold these parts from moving in other directions, consequently, proper **gear contact** may be secured by moving the pinion or ring gear in the proper directions, as the axis of each should remain fixed.

Familiarize yourself with the names of the gear-tooth faces (Fig. 11), so that you may understand the other illustrations (Figs. 12 to 17).

Backlash: All contacting gears must have a certain amount of play or space between the teeth, that is, the tooth of one gear must never entirely fill the space between two teeth of the mating gears (see Fig. 12). This avoids excess wear, breakage, noise, or decreased efficiency. Too much "backlash" is just as destructive as too little. The practical limits of "backlash" to which gear manufacturers work are .005″ minimum to .015″ maximum (five to fifteen one-thousandths of an inch). There may be slight variations from these figures.

The desired gear contact under load is a full-face contact along the entire length of each contacting tooth (see Fig. 13). If the gear cutting, heat-treating, and mounting has been perfect, the proper "backlash" is shown when gear teeth show good contact—running from 75 per cent to full-face contact of tooth.

Flank contact (Fig. 14) is caused by the pinion gear being **adjusted too far back** (toward the rear of the vehicle). This condition often **decreases** the "backlash" and usually causes a grinding noise.

Partial face contact (Fig. 15) is caused by the pinion gear being **adjusted too far forward** (toward the front of the vehicle). This condition **increases** the "backlash" and may cause tooth chipping.

Toe contact (Fig. 16) is caused by moving the ring gear **too far toward the right** rear wheel. This also **decreases** the "backlash," and may cause tooth chipping or breakage.

Heel contact (Fig. 17) is caused by moving the ring gear **too far toward the left** rear wheel and **increasing** the "backlash" to undesirable limits.

Never adjust gears until you know the existing tooth contact. To determine this, remove the rear cover plate and thoroughly clean the pinion and ring gear of oil. Mix powdered red lead with light oil to the consistency of paste and paint a number of the teeth on the ring gear.

Jack up the car (both wheels) and run in high gear for a few minutes, then throw into reverse and run for a minute or so, applying the brakes at intervals to make **close** tooth contact, then examine the teeth on the ring gear and the paint will clearly show the tooth contact existing.

Then remove the inspection **plug (oil-filler plug)** and actually view the contact when possible, by throwing light on the pinion gear while the cover plate is removed. If not correct, cautiously proceed to adjust the pinion gear or ring gear, as previously explained.

ADJUSTMENT OF SALISBURY REAR AXLE; THREE-QUARTER FLOATING TYPE

The trade name or term applied to this construction would be "Pressed Steel Type," and is **three-quarter floating** in design.

To remove the axle shafts: This can be accomplished without the use of the jack, as the full weight of the car can still be left on the wheels, or with the axle shafts removed, since there is no possibility for the wheels to come off. Remove the wheel-drive flange (F) (Fig. 18) by unscrewing nuts (N). The flange with the axle shaft can then be pulled out.

To remove the wheel for any purpose, such as for replacing the wheel bearing, this can be done after the flange and axle shaft are removed. The wheel, with the hub and bearing, is held in place on the axle tube by lock nuts and washers. With these removed, the wheel with hub and bearing can be pulled off.

To remove the bearing from the hub, first remove the spring wire, and the bearing lock nut can then be unscrewed and the bearing removed.

The differential gear carrier (Fig. 19) **as a unit can be removed from the axle proper,** after first disconnecting the propeller shaft and universal joint, by removing the carrier screws which bolt it to the housing. First, however, the axle shafts must be pulled out.

In order that the spiral bevel ring gear (G) (Fig. 18) **and drive pinion (P)** may operate correctly, they must be in perfect alignment, that is, the differential axis must be in the same plane as the pinion axis; at the same time there must be a correct amount of back lash between the pinion and the gear. To that end two means of adjustment are provided.

The differential on which the ring gear (G) (Fig. 18) **is mounted may be moved toward either side,** as required, by turning one of the adjusting nuts (A) to the left, and turning the other to the right an

---

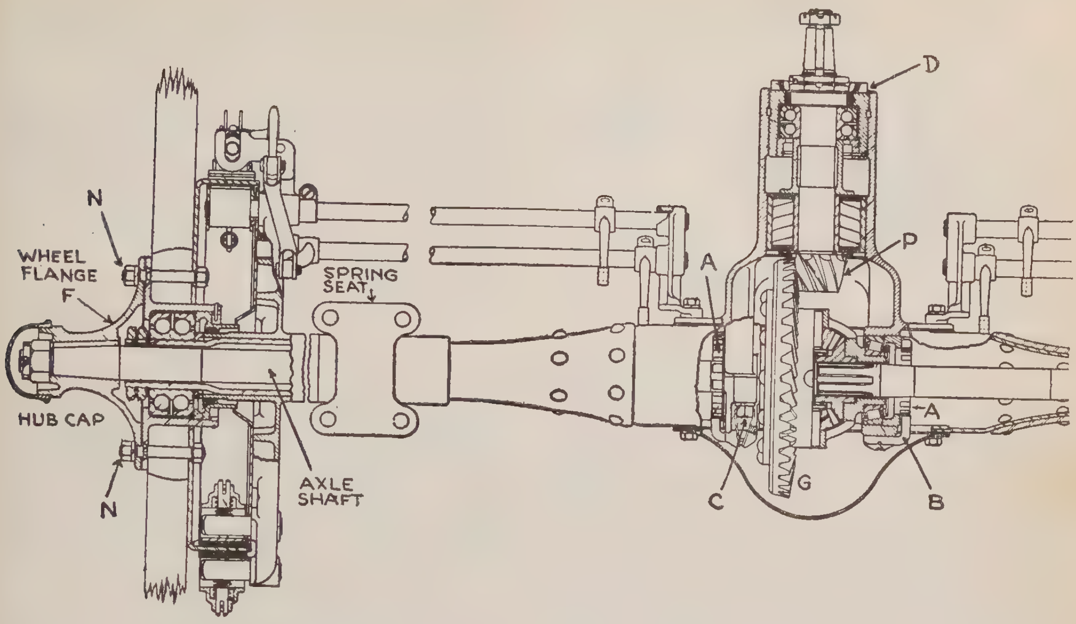

Fig. 18. Salisbury rear axle; three-quarter floating type.

equal amount, after the locking fingers (B) have been removed, and the screws (C) in the bearing caps have been loosened.

The drive pinion (P) may be moved forward or backward by turning the adjusting sleeve (D) in which the pinion shaft is mounted. Moving the pinion-shaft adjusting sleeve or the differential adjusting rings one notch is equivalent to approximately four one-thousandths (.004″) inch at the point of contact between the pinion and ring gear.

The amount of back lash necessary to insure quietness of action is ordinarily between ten one-thousandths (.010″) and twenty one-thousandths (.020″) of an inch, depending upon the cut of the gears and the variation which takes place in their manufacture. The proper amount of back lash or clearance should be arrived at, however, only after it is known that the ends of the teeth on the pinion are flush with either the inner or outer ends of the teeth on the ring gear.

To arrive at the proper running position of these gears, in order that their teeth may have a full line contact and at the same time operate with quietness, see explanation given on pages 870, 874.

Brakes on Salisbury Rear Axle

There are four points of adjustment on each set of brakes (Fig. 20). The adjusting screws (E) and (H) are the means of providing the proper **clearance at the rear of the internal and external bands** when released, and should be adjusted to allow an opening between the brake drum and the linings on the brake bands of not more than 1/32″.

The adjusting nuts (K) which control the setting of the **lower halves of the external bands** are next to receive attention in the proper order of adjustment. The jam nuts must be loosened and the adjusting nuts regulated to give a maximum clearance of 1/32″ around the lower halves of the bands. Should the linings touch the drums at any point, as a result of their not being a true circle, a screwdriver should be inserted and the band forced away. When the adjusting nuts are properly regulated, they should be relocked by the jam nuts.

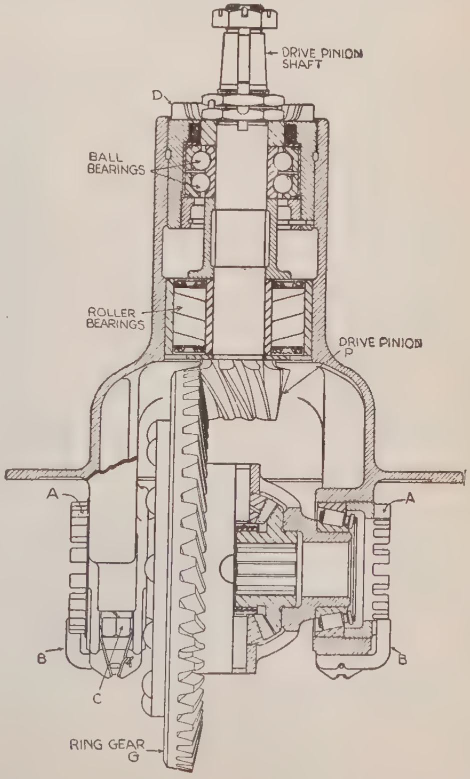

Fig. 19. Differential gear carrier unit. The words "differential gear carrier," or "gear carrier," refer to the unit in which the gears are carried. On this axle, note that the entire unit is removable.

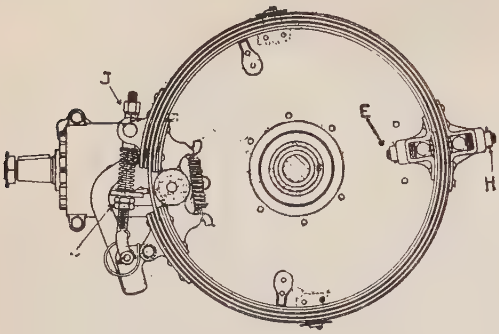

Fig. 20

The clearance between the top halves of the external bands should be regulated to a maximum of 1/16" by means of the nuts (J). This difference in clearance of 1/32" between the upper and lower halves is rendered necessary by the action of the bell cranks, which tend to tighten the upper half to the drum sooner than the lower half is tightened.

When the brakes are released, the pedal should be close to the floor board and the centers of the eyes of all levers on the cross-shafts in the frame should be from 1" to 1¼" to the rear of the shafts. The levers carried on the brake spiders should be as far back as allowable with the rods furnished, and these rods should not be shortened when the brake linings wear. This would disturb the proper setting of the brake levers and would prevent proper brake action. All adjustments should be made at the bands where the wear occurs.

ADJUSTMENTS OF THE OLDSMOBILE MODEL "47" REAR AXLE

The rear axle used on the Oldsmobile model "47" car is a three-quarter floating type, in which the differential is carried on separate bearings, and the inner ends of the axle shafts are supported by the differential side gears. The outer ends of the axle shafts are supported by the wheels which are mounted on large roller bearings and revolve on a race or bearing fastened to the axle housing. With this type of construction it will readily be seen that the drive shafts are subjected only to the driving torsion, and the bending moment imposed by the wheel on corners and uneven roads. The axle housing supports all the load of the rear end of the car.

Torsion tube and third member: The drive pinion shaft is mounted in a set of two bearings (see Fig. 21). At the pinion end is a large radial bearing, in which the shoulder of the pinion rides. This is the pinion bearing and serves to give the alignment to the shaft and pinion. A little farther up the shaft is mounted a double radial bearing which takes all thrust imposed upon the propeller shaft by the action of the pinion in the ring gear. All of these bearings and the adjusting mechanism are incased in a strong housing to which is attached a long tube entirely enclosing the propeller shaft. The tube assumes the torque imposed on the axle.

The differential assembly is mounted on two large Hyatt roller bearings, designated in Fig. 21, as (**M**). The side thrust on this bearing that is naturally set up by the wheels on uneven roads is taken up by the differential thrust bearings (**F**) and (**I**).

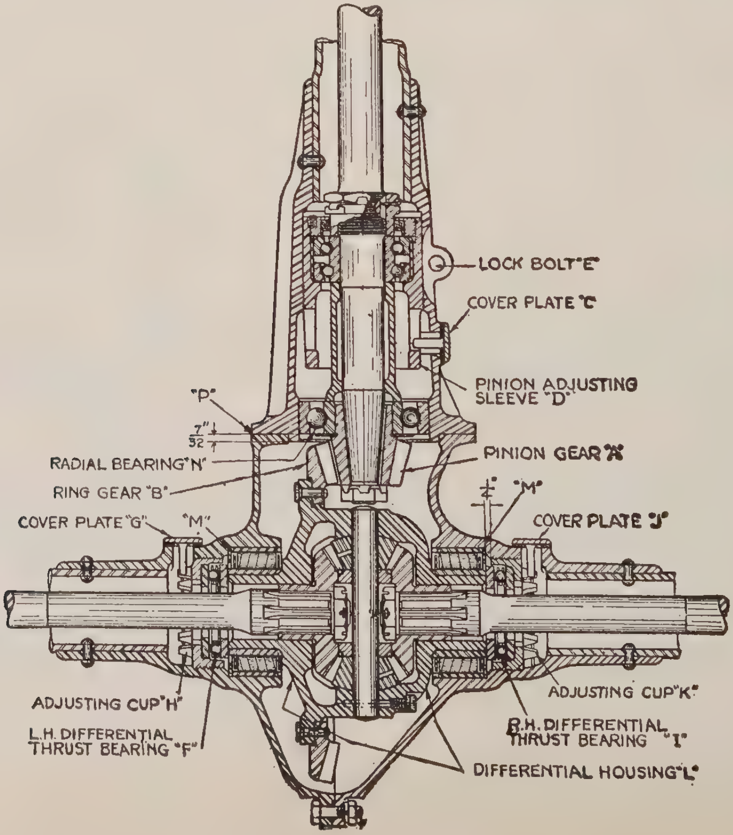

Fig. 21. Oldsmobile (model 47) rear axle

The axle shafts are driven directly by the two differential gears, through which the splined ends of the shafts pass, being securely fastened by large castle nuts and special washers. The outer ends of the shafts are tapered and keyed into the hubs of the wheels, the hubs being held from slipping off the shaft by a nut, which is held in place by a star washer, one lip of which is bent up against the nut. This star washer has a spline which fits the keyway and keeps it from turning.

Adjustment Instructions

Adjustment of axle or differential gears: First find out under what conditions the noise appears, and investigate to see whether the axle is properly filled with heavy or semi-fluid oil. The capacity is one quart up to the level of the filling or inspection plug.

1. **Noise occurs on straight pull ahead:** The difficulty generally results from the teeth of the pinion gear (A) bottoming in the ring gear (B). This may be relieved by loosening the lock bolt at (E) and then opening the cover plate at (C), in the third member housing, and turning the pinion adjusting sleeve (D) outward two notches, or more if necessary, a notch at a time. Do not touch the adjustment of the differential-bearing cup.

2. **Noise occurs on straight coast ahead:** The difficulty is generally the result of the teeth of the pinion gear (A) not meshing deep enough in the ring gear (B). This may be overcome by loosening the lock bolt at (E), and then opening cover plate at (C) in the third member housing and turning the pinion adjusting sleeve (D) inward two notches or more, if necessary, a notch at a time. Do not touch the adjustment of the differential-bearing cup.

3. **Noise occurs on turning corner to right or left:** This is generally the result of end play at the differential thrust bearing (F) or (I). Open the cover plates (G) and (J), and then loosen or back off the adjusting cup (K), four or five notches toward the outer end of axle. Then tighten or turn the adjusting cup (H) against the differential housing (L) until all back lash has been take up between the pinion (A) and the ring gear (B). Now back off or loosen cup (H) by turning out three notches toward the end of the axle. Now tighten the adjusting cup (K) by turning toward the center until it is snug, with the wheels revolving.

4. **Adjusting after installing new ring gear:** With the two halves of the axle disassembled from each other, screw both the adjusting cups (H) and (K) toward the outer end of the axle housing, or until the distance from the inner edges of the cups (H) and (K) to the 1/16″ metal stop rings (M) for the Hyatt bearing is ¼″. With the adjusting cups in this position, no difficulty will be experienced in assembling the two halves of the case with the differential and axle shafts assembled. Firmly bolt both halves together and then assemble the third member in position and tighten. The axle is now ready for adjustments as in paragraphs 1, 2, or 3. above.

5. **Installing new pinions:** In installing a new pinion gear (A) where it has not been necessary to remove the pinion shaft, leave the adjustment of the ring gear as it is, and adjust as explained above in paragraphs 1 and 2, as may be necessary, depending on whether the noise occurs on coasting or on straight pull ahead.

6. **Installing new pinion when necessary and to remove pinion shaft from third member:** Reassemble so that the rear side of the radial bearing (N) in which the pinion (A) revolves is set approximately 7/32″ from the extreme end of the shoulder on the flange of the third member. The backs or ends (see Fig. 28, page 874) of the teeth on the ring and pinion should be flush when assembled. To get this, measure from the face of the pinion-housing flange on the gear case at (P) to the bottom of the teeth at the outside diameter of ring gear (Q) (Fig. 28). Adjust the pinion so that a like dimension is obtained from the face of the pinion housing to the flange to the point of the tooth at the outside diameter (R) (Fig. 28).

Following are a number of suggestions relative to adjustments and inspection. **Read carefully.**

When axle is torn down: Inspect all bearings and parts very carefully when removed, and when reassembling use only the parts which are in good condition.

Single-row ball bearings may have a slight angular movement, or a rock as the action of a ball joint, but must not have any radial looseness or movement up and down.

Clean bearings thoroughly with gasoline, and make sure that the races and balls are in good condition and free from all foreign matter. The bearing should spin freely and quietly.

Roller bearings should be washed in gasoline, and races and rollers should be inspected for defects or foreign matter. These bearings should not have more than .003″ movement radially.

The thrust bearings at the end of the differential should also be cleaned and inspected.

The life of the gears in a way depends on the bearings, and a worn or defective part replaced is money well spent.

The gear housing must be free from all chips, dirt, etc., for a little foreign matter here will ruin the entire unit in a very short time.

When assembling, make sure that every part is in its place and securely locked.

Preliminary adjustment of gears: The backs or ends of the teeth on the ring and pinion should be flush when assembled (see Fig. 28). To get this, measure from the face of the pinion-housing flange on the gear case to the bottom of the teeth at the outside diameter of the ring gear. Adjust the pinion so that a like dimension is obtained from the face of the pinion-housing flange to the point of the tooth at the outside diameter.

Adjust the differential to the left, so that the pinion can enter freely, and then assemble the third member to the axle.

Shellac the point between the two halves of the gear housing and make sure that the faces at the pinion-flange connection are flush. If they are not, there will be a leakage of oil.

Adjustment of gears: Move the differential to the right or left, as required, to get from .005″to .008″ back lash (Fig. 31, page 874).

Through the oil-filler hole in the gear housing, paint both sides of the four teeth in the three equally spaced locations on the ring gear. Use thin white lead.

By turning the bevel gear around several times the lead will be wiped off of the gear tooth, showing where the contact or load is taken on the tooth. The contact to work for is as shown in Fig. 23 or a contact showing slightly heavier on the toe than on the heel, but over the full length on the tooth.

Fig. 24 shows a heavier contact at the heel of the tooth. This denotes too much back lash between ring and pinion, and will eventually break off the heel. To overcome this, move the differential toward the pinion, but be sure to have some back lash.

If the contact still shows heavy at the heel, change gears, as some part of the axle is out of alignment.

Fig. 25 shows a heavy contact at the toe or small end of the tooth. This is not bad, but the load should not be centered here as it will eventually break off the toe. To correct, move the differential away from the pinion, but under no circumstances should a gear be run with heavy contact at the heel resulting from too much back lash.

Fig. 27 shows contact at the top of the tooth, and Fig. 26 shows it on the flank. Either of these will cause noisy gears. To overcome, adjust the pinion toward the center line of the axle for Fig. 27, to get full-depth contact, as shown in Fig. 23. Noise almost always can be eliminated by the adjustment of the pinion.

Testing after Adjusting the Mesh of Gears

After this has been accomplished, install the axle under the car, connect to power plant, and, with wheels off the floor, start the engine. Apply the brakes slightly, adjusting these so that there is an equal amount of friction at both wheels. Watch the tooth contact through the filler hole in the gear housing. If correct results have not been obtained, paint the gears again and readjust the gears as mentioned previously. The car may be run not to exceed one mile without oil as a check on the adjustment.

If further adjustment is necessary, it should be made, as the gears must have contact over the full length of the tooth to carry the load. Oil will not deaden the noise, but is a lubricant.

Gear Contact as Explained in the Oldsmobile Instruction Book

The following illustrations and legends will make clear the meaning of terms used in connection with these explanations.

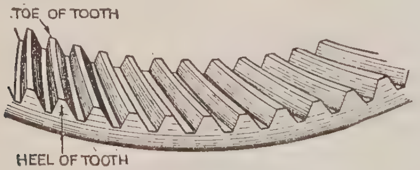

Fig. 22. Section of spiral-tooth ring gear.

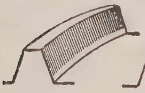

Fig. 23

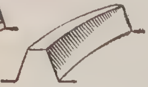

Fig. 24

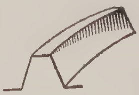

Fig. 25

Fig. 23. Shows correct contact. Gears set up this way give best results for noise and wear.

Fig. 24. Shows heavy contact on heel of tooth. Gears set up this way will eventually break off at the heel. To correct, move the ring gear toward the pinion, but make sure that there is back lash, as gears cannot run tight.

Fig. 25. Shows heavy contact on toe of tooth. Gears set up this way will eventually break off at the toe. To correct, move the ring gear away from the pinion.

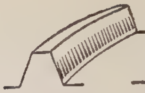

Fig. 26

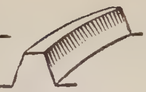

Fig. 27

Fig. 26. Shows heavy contact on the flank of the gear tooth. Gears set up in this way are noisy. To correct, pull the pinion out until contact comes to the full working depth of the gear tooth without leaving the lowest point of contact. See Fig. 23.

Fig. 27. Shows heavy contact on face of gear tooth. Gears set up in this way are also noisy. To correct, move the pinion in until the contact reaches the lowest point on the gear tooth. See Fig. 23.

Putting the Rear Axle Together (Oldsmobile "47")

When putting the axle together make an inspection of the following points:

1. **Before the ring gear is mounted on the differential,** inspect the ring-gear seat of the differential case to determine whether it runs true with the bearing hubs. If it runs out more than .002", face it off in a lathe to make it run true.
2. **When riveting ring gear on the case,** make certain that it is riveted tight. Ring gear should not run out more than .008", using the bearing hubs of the differentials as centers.
3. **When driving the pinion on the shaft,** see to it that it does not ride the key; also that it is driven on tight. The pinion must not run out more than .004" on the shaft.
4. **Inspect all bearings for wear:** Bearings which are pitted or chipped should be replaced by new ones. Ball bearings and straight roller bearings should not have more than .003" play between the inner and outer races.

5. **Outer races of bearings must be a snug fit in bearing holes,** and the inner races must also be a tight fit on the shafts or differential hubs.
6. **Make sure that all parts which go on the inside of the gear housing are thoroughly cleaned.** Any chips, grit, or other hard substances grind out the bearings and gears very quickly.
7. **All studs and nuts must be a good fit in the threads** so as to hold the gears and bearings in place. If these are loose, they will let the gears vibrate.
8. **When all the parts mentioned above are looked after,** assemble the parts in the axle.

   Paint four teeth on the ring gear in three different places, with a thin coat of white lead, and start to adjust the gears until all paint is wiped off of the portions shown shaded in Fig. 23. Wherever the paint is wiped off is where the contact occurs.
9. **After the axle is adjusted:** Put it under the car and jack up the rear wheels; paint the teeth of the ring gear again, which can be done through the oil-level hole; apply the brake load while running the car jacked up in this manner, and note where contact occurs. If it changes much from what it was when assembled, it shows that there is looseness in the axle, and it must be corrected.
10. **After all this is done,** the car may be taken out for a one-mile test without grease in the axle housing, except on the bearings, which should be packed when assembled. This will tell what can be expected as far as noise is concerned. Grease will not deaden the noise very much, it only acts as a lubricant. If you find it advisable to make further adjustments to make the axle quieter, before filling up the case with oil and turning the car over to a customer, paint the gears up again and make certain that you have contact as illustrated in Fig. 23.

   Full tooth contact is required to carry the load.

Unless there is something radically wrong with the rear axle, it need not be taken apart. However, if the gears are worn or damaged they should be replaced. In the majority of cases the only work necessary on the rear axle consists of replacing the lubricant and adjusting the gears.

ADJUSTMENTS OF STUDEBAKER "LIGHT SIX" REAR AXLE

The rear axle consists of a bevel-drive pinion, and ring gear, differential gears, and rear-axle shafts, all of which are enclosed in an oil-tight case. The rest of the rear axle is made up of rear wheels, bearings, brakes, and tires.

The rear axle is of the semi-floating type. Axle shafts are provided with end-thrust adjustments (in case of wear on the bearings) located at each end of the axle housing (Fig. 32). Note that at the inner end of each axle shaft is a hardened steel thrust-button. This serves to prevent wear on the axle shaft at this point, and also minimizes adjustment of the bearings.

To remove end play: Any excessive end play in the shafts may be taken care of by removing the rear wheel (in the tool kit is a puller provided for this purpose); then take out the clamp bolt (Fig. 32), and turn the adjusting nut to the right until proper adjustment is reached.

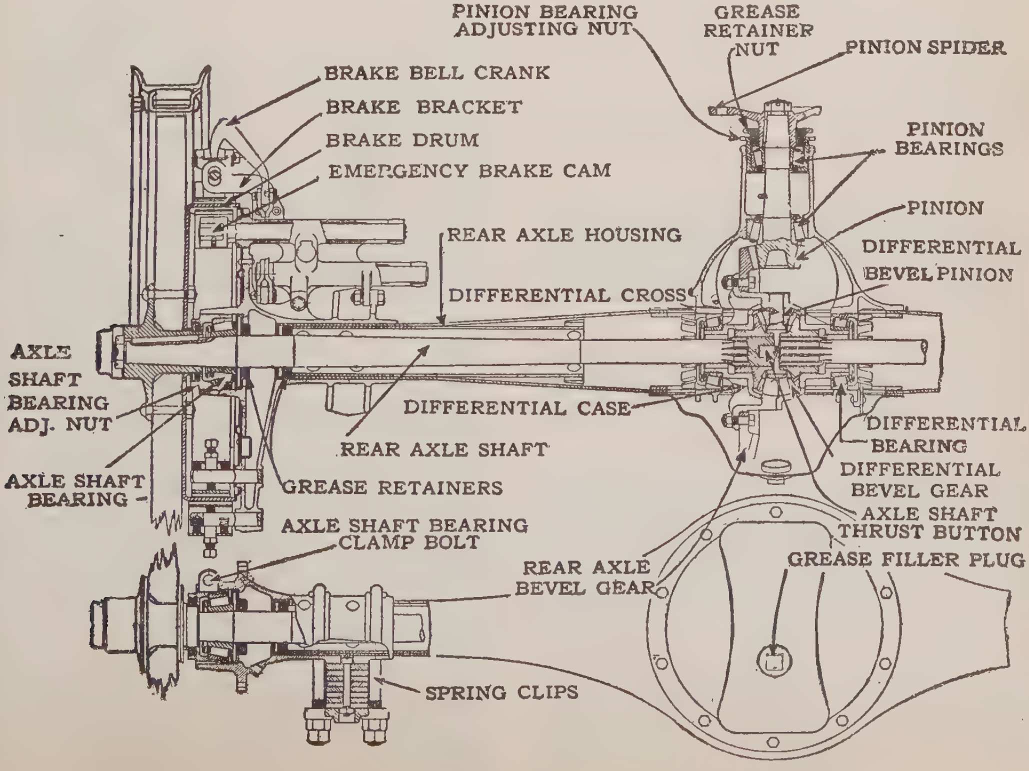

Fig. 32. Longitudinal section of Studebaker "Light Six" rear axle.

Care should be exercised to see that the same distance is maintained between the outer face of each adjusting nut and the end of the rear-axle housing. If this is not done, the rear wheels may be shifted out of line with the front wheels.

Adjusting bevel-drive pinion and ring gear: If wear develops between the bevel-drive pinion and ring gear, it will necessitate adjusting the bevel-drive gear and pinion closer together (Fig. 32). This adjustment may be made by removing the differential case cover, cleaning out all old grease, and loosening the two differential clamp nuts. The differential adjustment nuts can now be moved either out or in, whichever way the bevel gear is to be moved. When one adjusting nut is turned out, the other is turned inward the same amount. This does not affect the tightness of the Timken bearings, but simply moves the whole differential sidewise.

In reassembling parts, be sure that the bearing retainer lock is properly put in place.

The end-play adjustment of the drive pinion may be taken care of by removing the clamping bolt and retainer lock, and turning the bearing cage in a counter-clockwise direction, until proper adjustment is reached (Figs. 33 and 32).

The differential consists, essentially, of a case, made in two halves, bolted together, and a spider or cross with four arms which are clamped between the two halves of the case. A small bevel pinion runs on each of the arms of the spider and meshes with a side bevel gear carried in each half of the differential case. The case is mounted on Timken bearings and carries a bevel driving gear on its outer circumference. Axle shafts, which drive the wheels, extend through the case and fit into the side bevel gears which are bored out and splined to receive them.

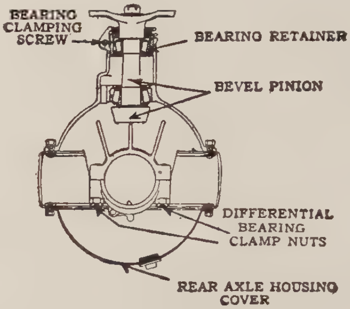

Fig. 33. Section of rear axle through pinion.

Care of differential: It is advisable, at least once a season, to clean the differential thoroughly. This can best be done by removing the cover at the rear of the housing and washing it out with gasoline. Repack with fresh lubricant (light grease or heavy oil), being careful to replace the cover with the gasket in perfect condition. It should be lubricated regularly through the plug in the cover with a good light transmission grease or a very heavy oil. Grease can be inserted through the plug hole only with a grease gun. This tool is in the regular tool kit accompanying the car.

ADJUSTMENTS OF MITCHELL MODEL "F" REAR AXLE

The Mitchell "F" rear axle is of the full-floating type and carries Timken roller bearings inside and outside.

Note: This could be termed a seven-eighths floating axle; see pages 15, 16.

Removing the rear axle from the car: Run a rope under the rear end of the frame, and with a block and tackle raise the rear end of the car clear of the ground.

The rear axle will be held up by the rear springs, so that the caps of the spring saddles on the axles can be readily removed. While the car is raised and there is plenty of room to work, disconnect the brakes by removing the clevis pins where the brake rods join the levers on the axle.

Lower the transmission as in removing it from the car, disconnecting the front universal joint (see page 862). The complete universal joint will drop with the transmission.

Lower the car until the wheels rest on the ground and the rear springs have dropped far enough so that the spring seats clear the axle. Roll the axle back on the wheels until it is in back of the spring seats, when the car should again be raised until the fenders clear the wheels and the axle can be rolled out free of the car. It is well to block the car in that position to avoid the danger of it dropping.

Disassembling the rear axle: The following instructions are for the complete disassembly of the various units which make up the rear axle. In making any specific adjustment or repair, only as much of the work as may be necessary for the job in hand should be done.

With the rear axle clear of the car, remove the transmission from the forward end of the torsion tube by taking out the eight cap screws which hold it in place. Remove the torsion tube from the rear-axle housing by taking out the eight cap screws which hold it in place. The grease retainer will remain in the torsion tube and the propeller shaft can be drawn out at the rear of the tube. It will be found convenient to mount the rear axle assembly on horses at this point.

Removing wheels: Take off the nuts holding the driving flanges to the rear wheels and pull out the flanges together with the drive shafts. Care should be taken not to tear the paper gaskets between the flanges and the wheels, as these gaskets are necessary to prevent the escape of lubricant from the wheel hubs.

If it is desired to remove the flanges from the drive shafts, the hub cap should be removed and the large nut under it taken off, together with the washer under the nut. The flanges may then be pressed off the drive shafts in an arbor press.

Removing wheel bearings: With the shafts and flanges out, the nuts on the ends of the rear-axle tubes controlling the adjustment of the wheel bearings will be exposed. Remove the nuts and tongue washers after taking out the lock springs, when the wheels complete with roller bearings, grease retainers, and brake drums can be pulled off the ends of the rear-axle tubes.

The grease retainers and bearings can then be taken out of the wheels. Unless they are worn or damaged, the bearing outer cups should not be removed from the hubs, as they are pressed in at the factory.

Removing differential: Remove the cover from the back of the differential and clean out the grease by scooping it out of the bottom of the rear-axle housing and draining the remainder off through the drain plug. Remove the lock wire holding the differential-bearing cap nuts from turning, and remove these caps together with the differential adjustment locks.

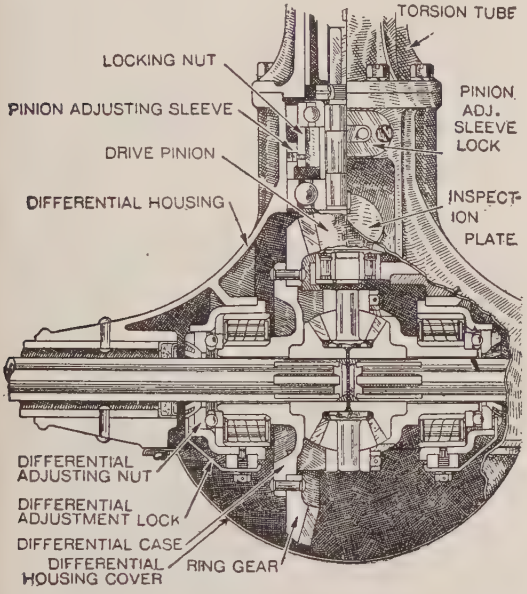

Fig. 34. Mitchell model "F" rear axle.

Back off both adjustments to give the differential end play and, cramping the differential assembly slightly to the right, so that the rivet heads will clear, lift the assembly out of the axle through the rear opening. The differential can be completely disassembled by taking out the eight cap screws holding the two parts of the split case together.

The ring gear being riveted to the differential case, it should not be removed unless it is necessary to replace the gear due to wear or breakage. In cutting off the old gear, great care must be taken not to spring the flange on the differential case to which the gear is riveted. Before mounting the new gear, swing the case between centers on a lathe and check the face of the flange to see that it runs true. If it does not, a light truing cut should be taken off the face of the flange. In riveting the new gear in place, care should again be taken not to spring the flange. To make sure, the case with the gears mounted should be again swung in a lathe and tested to see that the face of the gear runs true.

Removing drive pinion: Remove the locking plate holding the pinion adjusting sleeve in place, and screw this sleeve out through the front of the rear-axle housing. The pinion with its shaft and bearings will come out with it.

Remove the locking ring from the pinion-bearing lock nut and take off the nut and the grease retaining washer. The pinion which is integral with the pinion shaft can then be removed from the adjusting sleeve, together with the large rear bearing, and the bearing can be removed from the pinion shaft. The small roller bearing at the rear of the pinion can be removed by taking off the locking ring and sliding the bearing off the end of the shaft. Take the small front bearing out of the adjusting sleeve. The set screw holding the bearing-sleeve lock nut in place can be removed and the nut taken out of the sleeve.

Removing the rear-axle gears alone: With the axle in place under the car, the ring gear together with the differential can be removed from the rear-axle housing, as described in the foregoing instructions, after the drive shafts have been taken out.

To remove the pinion it will be necessary to drop the transmission, disconnect the torsion tube where it joins the rear-axle housing, and unscrew the pinion adjusting sleeve, together with the pinion and bearings, through the front of the torsion tube.

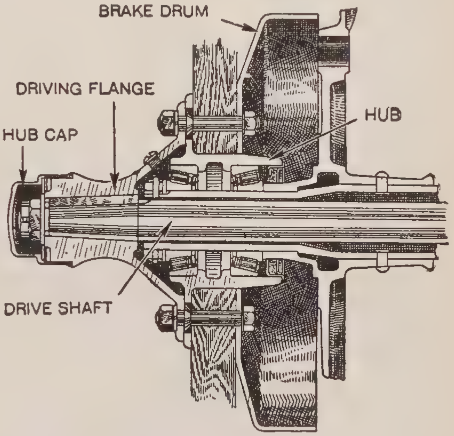

Fig. 35. Mitchell rear wheel hub showing bearings, flange, and brake drum.

Adjusting the rear-wheel bearings: Examine the two bearing cups in the hub to see that they are in good condition, and free from dirt or grit. Cover them with a thick coat of cup grease, and put the inner bearing in place.

Place the grease retainer in the hub and tap it lightly until it is driven in flush with the hub.

Place the wheel on the end of the axle tube and slide it in position, being careful to see that the brake drum is centered in the brake bands. Place the outer bearing in position, put on the lock washer, and then the nut, and draw it up until it is flush with the end of the tube. If the wheels revolve freely and there is no end play, the adjustment is correct and the nut on the end of the tube can be locked with the locking ring.

With both wheels thus mounted, put in the drive shafts and flanges, and fasten them with the nuts and lock washers to the wheel-flange bolts.

Adjusting the pinion bearings: In reassembling the drive pinion with its bearings and adjusting sleeve, put the small front bearing in the adjusting sleeve so that the projecting side of the inner race is about flush with the end of the sleeve having a thread on the outside. This face of the bearing is usually marked "Thrust Here." Screw the adjusting-sleeve lock nut in the adjusting sleeve so that it clears the small bearing by at least ¼″.

Mount the large bearing on the pinion shaft with the projecting side of the inner race toward the pinion. This surface of the bearing is usually marked "Thrust Here." Slide the tubular inner spacer on the pinion shaft following the large bearing.

Mount the pinion adjusting sleeve with the small bearing in place on the pinion shaft, followed by the grease-retaining washer and the pinion-bearing lock nut, which should be drawn down tight and locked in place with the locking ring, making sure that the adjusting-sleeve lock nut is not bearing against the small ball bearing when the pinion-shaft lock nut is tightened.

By prying through the openings in the pinion adjusting sleeve, screw the adjusting-sleeve lock nut back against the small bearing until there is no end play between the bearings, but they rotate without cramping. Lock the lock nut in place with the small set screw. This is the adjustment for taking up wear in the pinion bearings.

The small bearing on the end of the pinion shaft can then be mounted in place and locked with its locking ring.

Adjusting the driving gears: With the differential bearing caps mounted in place, the ring gear can be moved to the right or left by screwing and unscrewing the serrated adjusting nuts. The pinion is moved into mesh by turning the pinion adjusting sleeve to the left (as the operator faces the front of the car) and vice versa. The ideal adjustment is attained when the two gears mesh along the full length of the pitch line of their teeth and the back faces of the teeth are flush with just a few thousandths back lash. Before locking the adjustment it should be checked by revolving the ring gear a few times to be sure that none of the washers have moved out of place and give a false adjustment.

In general, movement of the pinion in and out of mesh causes small change in the back lash, but a large difference in the pitch-line bearing. If the pinion is out of mesh too far, the bearing of the teeth will be out toward the point of the ring-gear teeth, above the pitch line. If the pinion is too far in mesh, the teeth mesh at the root of the ring-gear teeth below the pitch line.

Movement of the ring gear in and out of mesh causes comparatively small difference in the pitch-line bearing, but causes a large change in the amount of back lash. With the ring gear **too far out of mesh,** the ring-gear tooth will bear at its outer side, showing there is too much back lash. With the ring gear **in mesh too far,** the ring-gear tooth will mesh at its inner side, showing that there is not enough back lash.

When the gears are **properly adjusted** and the adjustment is checked by rotating them, the adjustment of the pinion should be locked by mounting the locking plate, being sure that the finger on the lock goes down through one of the openings in the pinion adjusting sleeve. The ring-gear adjustment should be locked by locking the serrated adjusting nuts with the locking fingers fastened to the bearing caps with set screws.

Lubricating the Mitchell rear axle: Once every season, or every 5,000 miles of running, the lubricant in the differential should be removed and the differential should be cleaned out. Fill the differential with about three pints of semi-fluid lubricant of about the consistency of 600-W steam-engine oil. The old lubricant can be removed through the rear-axle housing cover and drained through the drain plug in the bottom, while the new lubricant can be poured in through the opening in the cover after the cover has been mounted on the rear-axle housing. At that time some lubricant should be poured in through the pinion-adjustment lock plate to lubricate the pinion bearings.

Lubrication of the Mitchell rear wheels: Once every season, or every 5,000 miles, the rear wheels should be removed from the axle, cleaned out, and packed with fresh cup grease. If grease leaks out around the brakes, it is a sign that the level of the lubricant in the differential is too high, or that the cup grease in the wheels is thinned out. In the former case some of the lubricant should be drained off, while in the latter case, fresh lubricant can be added through the plug in the driving flange.

DIFFERENTIALS: DISASSEMBLY AND ASSEMBLY

The principle of operation of a differential is explained on pages 17 and 18.

The type of differential gear in general use is the bevel-gear type with helical or spiral teeth. The differential or compensating gear assembly is shown in Fig. 36.

The differential **ring gear** (see Fig. 13, page 18, and Fig. 3 page 6) is always **placed on the left side** (when seated in the car).

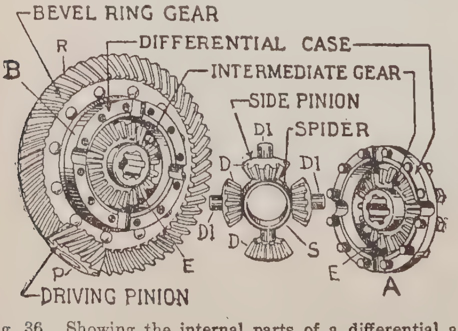

Fig. 36. Showing the **internal parts of a differential** and how the axle shafts fit into each of the intermediate gears and how part (A) is bolted to part (B). Note the pinion shafts (D1) to which the differential bevel gears (D) are fitted, and which rotate on these pinion shafts.

The bevel pinions (D) are then meshed with the two intermediate and larger bevel gears (E), the latter being connected to the axle shafts.

The drive pinion (P) is connected with the drive shaft, and the driving power is thus applied to the large ring gear through the differential housing, to the intermediate bevel gears (E), to the axle shafts, and thence to the rear wheels.

The action of the differential, or compensating gears (D) is explained on pages 17 and 18.

Note in this example and in the case of most all other differentials, that the large bevel-ring gear (R) and the drive pinion (P) are of the bevel type of gears with helical or spiral cut teeth instead of straight teeth.

When replacing a driving pinion (P) with one of a different diameter or a different number of teeth, it is always necessary to replace the driven ring gear (R) also, because the teeth will mesh too tight at either the big end of the tooth or the little end of the tooth, owing to the fact that the teeth are cut at a different angle when not mated.

When replacing drive pinion (P), it is of course necessary to remove the drive shaft on which the drive pinion is mounted.

Replacing driven-ring gear (R): Ring gears are usually riveted to the differential housing. Thus it is necessary to remove the assembly for this operation.

Either the cold or hot rivet can be used. At the factories where they have special power riveting machines, the work is done with cold rivets and in one-tenth of the time. The average blacksmith or repairman, however, will probably find it better to heat the rivets, which is often done where there is only a hammer to work with.

In placing a ring gear on a differential, one of the greatest causes of noisy gears is the fact that the differential flange to which the ring gear is attached is often out of true and should be carefully trued up before fastening the ring gear to it. See page 873 for adjusting after installing.

Removing differential. There are two types of **rear-axle housings,** the **one-piece type** (Fig. 54, page 862) and the **two-piece type** (Fig. 55, page 862). The differential can be removed from axles of the one-piece type by removing axle shafts and then removing the rear-axle housing cover plate (Figs. 53, 55, page 862). On the two-piece type, as shown in Fig. 41, page 880, and Fig. 39, page 1096, the rear-axle assembly must first be removed. See also page 863.

REMOVING THE DIFFERENTIAL (CHEVROLET "FB" AS AN EXAMPLE)

The Chevrolet model "FB" uses a semi-floating type of rear axle. Note that the axle shaft is keyed to the hub (Fig. 37) and the bearing runs between the housing and wheel hub, and not on the axle shaft.

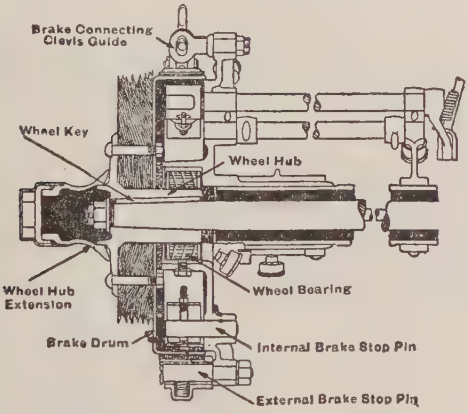

Fig. 37

To remove the differential it is first necessary to remove the various parts as explained below.

To remove the rear axle assembly: Place two jacks under the rear spring brackets and raise rear of car enough to take the weight off the springs.

Remove the clips and bolts holding the springs to the axle and disconnect the brake pull rods, which operate between the foot pedals, hand-brake lever, and rocker shaft on the propeller-shaft housing.

Disconnect the brake pull rods from the operating levers on the rear-axle housing by removing the yoke pins. **Slide the axle assembly from under the car.**

Remove the four propeller-shaft housing bolts, clamping the housing to the axle housings, and lift the assembly off (see Fig. 38).

Remove the hand hole plate shown in Figs. 38 and 39. Clamp the housing in a vise with the hand hole on top. Remove the thrust-bearing adjusting cage lock bolt.

Turn the propeller shaft so that the hole in the pinion-shaft adjusting nut is in line with the milled slots in the end of the thrust-bearing cage.

Secure a small steel pin ⅜" square and 1" long, and place it through the slots into the hole in the shaft. With a large adjustable wrench gripping the splined end of the propeller shaft, turn counterclockwise or from left to right. This will cause the thrust-bearing adjusting cage to turn with the propeller shaft. Continue to turn until the cage is free, permitting the entire assembly to be removed through the drive-gear end of the housing. Should there be any difficulty in unscrewing the cage, insert a large screwdriver into the split clamp at the point where the thrust-bearing adjusting-cage lock bolt was removed, and open the jaws of the clamp slightly.

To remove the propeller shaft, remove the small wire passing through the head of the adjusting-nut lock screw. Remove the lock screw. Unscrew the pinion-shaft adjusting nut as far as it will go. Pull out the cotter pin holding the drive-gear nut and remove the nut. Slip a flat piece of steel between the back of the drive pinion and the lower end of the propeller-shaft housing. With a lead hammer or a piece of wood held against the end of the propeller shaft, drive the pinion shaft.

The bearings and spacing washers can then be taken off the shaft. The rear wheels are keyed on the tapered ends of the axle shafts and held in place by a castle nut and cotter pin.

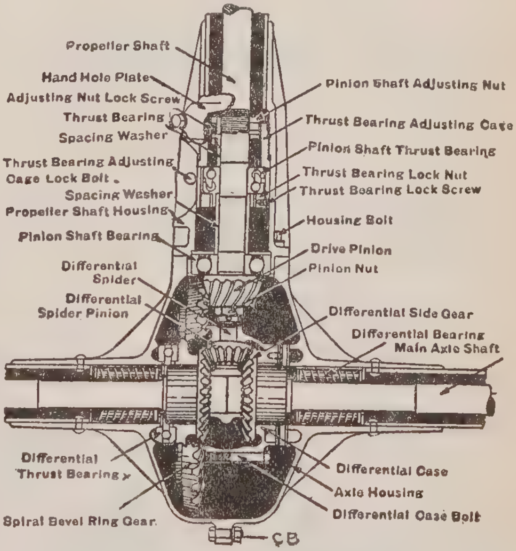

Fig. 38. Sectional view of Chevrolet model "FB" rear axle and differential and drive pinion. To lubricate, use 600W oil.

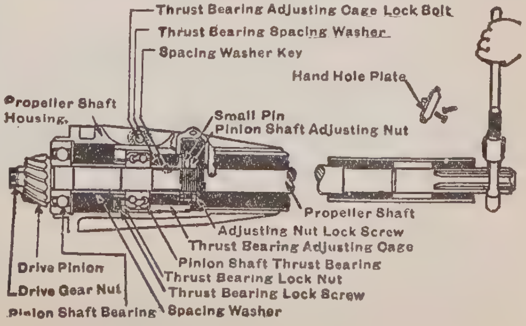

Fig. 39. Sectional view of Chevrolet "FB" propeller shaft.

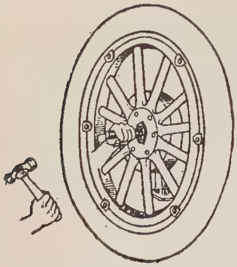

Fig. 40. Method in removing the Chevrolet rear wheel.

To remove the rear wheels, remove the hub caps. On model "FB" also remove the hub extension by using the hub cap wrench and turning counter-clockwise. Remove the cotter pin holding the nut on the shaft. Loosen the castle nut, but do not remove it entirely.

With a bar held against the castle nut, as shown in Fig. 40, deliver several sharp blows on the bar. When the wheel is free on its key remove the castle nut and the wheel can be pulled off.

The axle housings (**H**) (Fig. 41) are in two halves, right and left, held together by a number of clamping bolts (**CB**) (Fig. 38). Remove these bolts and slide the axle housing off the shafts.

In order then to remove the differential, note that the differential gear case is in two halves (**A**) and (**B**) (Fig. 41), held together by clamping bolts or screws, which when removed permit the cases to be separated.

The two parts (**A**) and (**B**) can then be separated, after which the axle shafts with the two halves can be withdrawn.

The differential gears (**E**) are keyed and pinned to the axle shafts. After removing the pins, the gears (**E**) can be pressed off the axle shafts.

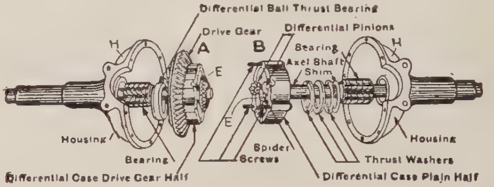

Fig. 41. Illustrating how the **differential case is divided** into two parts (**A**) and (**B**), and which parts must be separated in order to remove the differential. The axle shafts are then removed from the gears (**E**).

DISASSEMBLY AND ASSEMBLY OF A MAXWELL "25" REAR AXLE AND DIFFERENTIAL

The Maxwell "25" rear axle is a semi-floating type of axle.

Evidence of Trouble

1. **Any excessive grinding or humming** indicates that the gears are either worn, broken, or poorly adjusted.
2. An intermittent catch, occurring perhaps only every 100 miles, indicates that parts of one or several teeth are broken, and are catching in the gears.
3. Actual failure of the axle to operate. (Any of these necessitates a **removal of the axle from the car,** tearing down and replacement of defective parts, with readjustment.)

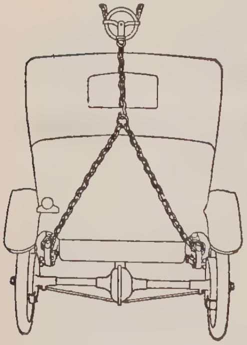

Fig. 42

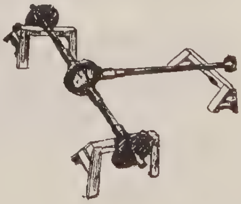

Fig. 43

Fig. 42. The car is readily lifted by a chain block and sling. One man can do the work, and the car is held without danger of falling.

Fig. 43. Three horses form a serviceable **axle stand,** though a special stand could readily be made. Never attempt to dismantle or assemble a part on the floor, but get the work up where it is accessible and clean.

To Remove Axle

1. Block the front wheels.
2. Raise the rear of the car as shown in Fig. 42.
3. Disconnect the brake rods at the point of connection to the brakes.
4. Remove the clips holding the axle to the springs.
5. Draw the axle and housing out to the rear. The drive shaft slips out from the universal, and must be caught to prevent possibility of injury to the splined end.
6. Place the axle on three horses arranged as shown in Fig. 43.
7. Remove the hub caps.
8. Remove the axle nuts.
9. Using puller shown in Fig. 44, remove wheels.

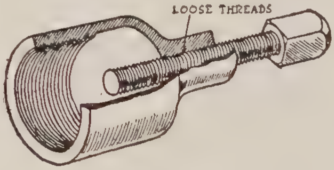

Fig. 44 (upper)

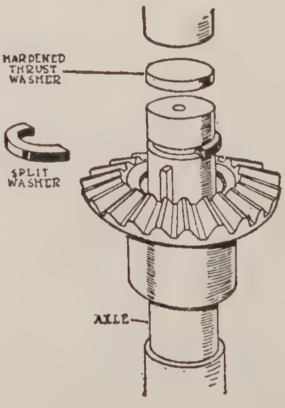

Fig. 45 (lower)

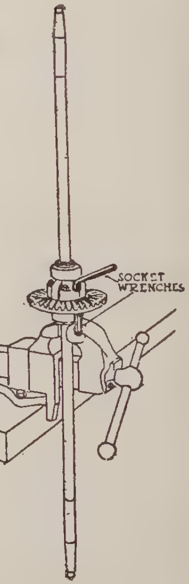

Fig. 46

Fig. 44. The feature of this **rear-wheel puller** is that the screw is hardened tool steel, loosely threaded into the cap. The end play permits a sharp blow on the screw to loosen the sticking wheel.

Fig. 45. Do not attempt to remove the **side bevel gear** from the axle drive shaft until the **split washers** have been removed in the manner shown.

Fig. 46. The differential may be most readily assembled and adjusted, if caught in the vise in this manner. Two socket wrenches are used to do the work.

10. Remove the torque tube and drive shaft. Save the gasket.
11. Catch the grease in a pail.
12. Remove the nut from one end of the axle truss rod.
13. Remove the differential-housing bolts.
14. Pull off the differential-housing halves.
15. Place the differential in a vise as shown in Fig. 46; pull the cotter pins from the bolt ends and remove the differential casing nuts, allowing the two halves to come apart.
16. Remove the split washers from the end by driving the gear down, as shown in Fig. 45.
17. Remove bearings and all parts; wash and clean with gasoline.

General Repairs

1. **After cleaning, examine all parts for wear.** Go over the gear teeth, to see if any are broken or worn. Also note whether the drive-shaft bevel gear has been wearing evenly along the teeth. The face of the teeth should be bright all over. Any breakage or perceptible wear necessitates a replacement of the gear.
2. Draw the drive shaft from the torque tube. Clean and examine the bearings.
3. If the axle has been disabled by a collision, the shaft should be caught between lathe centers, tested, and trued up, if bent.
4. If any serious bend is found in either of the shafts, the two halves of the rear-axle housing should be bolted together, tested for alignment in the lathe, and straightened.
5. When the large ring gear on the differential must be replaced, its bearing on the differential casing should be trued up in the lathe, as shown in Fig 47.

The Reassembly

1. Replace the shaft bearings, differential housing halves, and shaft gears, making certain that the split washers are in place.
2. Replace the differential cross-gears on the differential cross and holding shaft in a vise, as shown in Fig. 46, and bolt the halves together. (Be certain that the thrust washer is in place between the ends of the shafts.)
3. When the halves are bolted together, there should be about 1/64″ end play between the two halves of the shaft. If they are tight, take the differential apart and file a little from the end of each shaft.
4. Rebolt the halves, and holding as shown in Fig. 48, turn the two shafts in opposite directions. The axles should turn easily all the way around.

   Note. If sticking is noted in any place, catch the assembly in a vise, as shown in Fig. 46, and with the tang of a file, find by feeling which cross-gear is causing the sticking. If new cross-gears have been installed, try changing the sticking gear for a new one from stock. (Or if new side gears have been installed, try changing the side gear.)
5. Replace the cotter pins in the differential casing. Clip the ends over, away from the cross-gears.
6. Using horses as shown in Fig. 43, slip the halves of the rear-axle casing in place, after packing all bearing and gears with non-fluid oil.

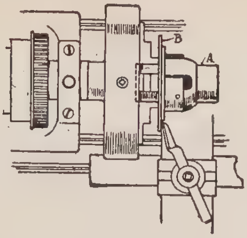

Fig. 47

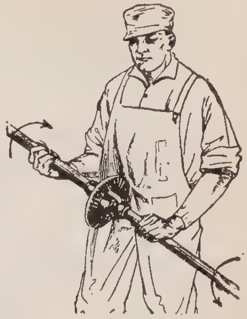

Fig. 48

Fig. 47. Breakage of the ring gear usually springs the **differential housing flange.** By catching the entire housing in the lathe and **trueing it up** by the surface (**A**), the ring gear seat (**B**) may be refaced with a light cut.

Fig. 48. In **testing the adjustment of the differential gears,** grasp the assembly in this manner, and turn the axles in opposite directions. They should turn freely all around.

7. Bolt the halves together. (Do not pull one nut up tight until the others are snug.)
8. Now get the torque tube and drive shaft ready for assembly. The shaft should turn freely in the housing. All bearings should be packed in grease.

   Note. If a new drive-shaft pinion has been fitted, make certain that the bent ends of the cotter pin in the end of the drive shaft do not interfere with the thrust bushing (see Fig. 49).

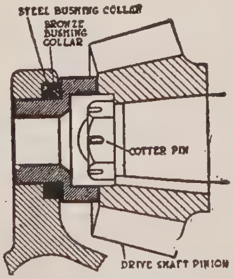

Fig. 49. The cotter pin in the drive-shaft pinion lock nut should not interfere with the **thrust bushing,** and the bushing collars should be inserted in the manner shown.

9. Fill the axle housing with a good grade of non-fluid oil until the ring gear dips well into the oil.
10. Place first the bronze washer on to the drive-pinion thrust bushing, then the steel washer, and insert the bushing into the rear-axle housing.
11. Replace the torque-tube gasket and slip the torque tube and drive shaft into the axle. Bolt in place.
12. When all bolts are tight, the drive shaft should turn freely under the action of a pipe wrench. If any sticking is noticed, additional gaskets should be placed between the torque tube and the axle. If any slack exists in the gears, the gasket should be replaced by one made of thinner paper.
13. Make certain that the brake levers work freely. Oil well. Note whether the brake bands are wearing evenly and are in good condition. Reline, if necessary.

14. Replace the wheels. Fill the hub caps with medium cup grease.

    (Note. It is always advisable to grease the rear springs with graphite and grease at this point.)

15. Roll the axle beneath the car and, with one man guiding the drive shaft, slip it into the universal. The splines may not line up at first, and hence it may be necessary to crank the engine slowly by hand until the two slide together.

16. Let the car down on to the axle; bolt the spring shackles to the axle; reconnect the brake levers.

    (Note. For the first 200 miles, at least, fill and screw down the grease cups two or three times, to make certain that all bearings have an abundance of grease.)

The points on the differential assembly that should be particularly watched are indicated on the illustration to the right (Fig. 50). (*Motor World.*)

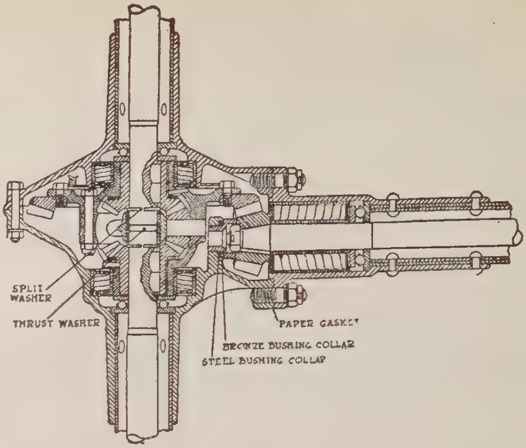

Fig. 50

THE POWRLOK OR "M AND S" DIFFERENTIAL

With an ordinary differential as shown on page 18, when one rear wheel gets into a soft spot it will turn or spin. With this differential, nothing of the kind happens because the angle of the worms (D) and (M) is such that, while the side gears on axle shafts (A) and (B) can drive the worms, the **worms cannot drive the gears on axle shafts** (A) and (B). As a consequence, the differential is locked, or the axle is like a solid axle, so far as the movement of the wheel in relation to the differential is concerned.

When both wheels are firm on the ground and can travel freely, the differential is enabled to act in the usual manner when turning corners, etc., by reason of the fact that the **gears on the axle shaft (A) and (B) can drive the worms.**

This device (Fig. 51) prevents skidding to a great extent and insures positive traction at all times.

(Mfd. by the Powrlok Co., Cleveland, Ohio.)

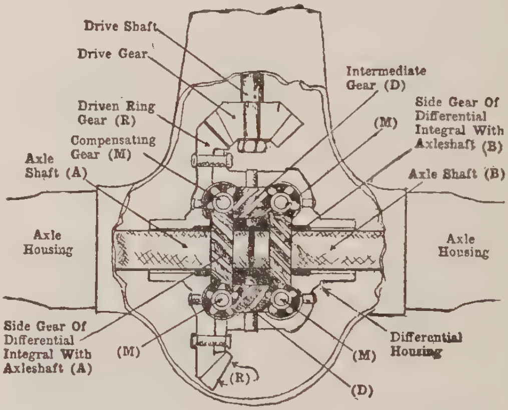

Fig. 51

OIL LEAKAGE FROM REAR AXLE; ADJUSTING FRANKLIN REAR AXLE

Preventing the grease or oil in the differential housing from making its way to the brake bands and thus causing inefficient braking was a big problem to manufacturers some years ago, but the difficulty has been overcome largely in all the present types. In all the axle housings on the market, some precaution is taken to prevent this leaking, usually, by means of a **felt washer,** termed an "oil retainer" or "grease retainer," and in nine cases out of ten when a leak occurs despite this, the condition is caused by **placing too much oil or grease** in the housing, or by **using too light** a grade of oil. Some axles use a heavy oil and others a light grease.

Methods of preventing oil leakage can be observed by referring to the various illustrations of rear axles. Note felt washers in rear axles on pages 883, 877, 875, 871, 869, 864, 858.

As an example of a method of preventing oil leakage, the Franklin rear-axle system will be used.

The Franklin series "9-B" has a semi-floating axle. Adjustments are possible on the wheel bearings, bevel gear and pinion, and the differential carrying bearings. The felt washers on the axle are also taken up from time to time (Fig. 52, next page).

To take up the pinion-shaft packing, loosen the lock for the washer retainer and screw in the retainer until the packing fits snugly around the shaft. To replace the packing it is necessary to disconnect the drive line and remove the universal-joint flange.

The axle-shaft felt washer is taken up by removing the wheel with the special wheel puller. The felt washer on the inside of the wheel hub is replaced. The retainer that holds the other felt washer into the end of the axle housing can be removed by taking out the three small screws. If this felt washer shows wear, it should be replaced.

If oil comes out of the axle at the drive-pinion shaft or at the wheels, examine the level of oil in the gear case. This should be within 2″ of the filler hole. Examine also the packing on the pinion shaft and the felt washers on the axle shafts. **600-W oil is used in rear-axle differential case of Franklin.**

Bearing and Pinion Adjustment

The bearings for the rear-axle drive shaft should be adjusted so that there is very little rock or play. The fact that the rock is perceptible is not necessarily an indication that the wheels are too loose. To adjust the bearings, screw their retainers up tight and then loosen them two notches each. See that each axle shaft extends the same distance from the housing. Take the measurements for this from the faces of the bearings to the ends of the axle housing. When the adjustment is completed, see that the bearing-retainer locking device is securely screwed into position.

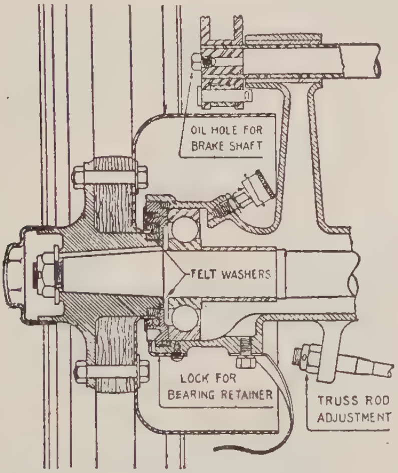

Fig. 52. Sectional view of the Franklin model "9B" rear wheel, showing the location of the felt washers.

The bevel gears on the Franklin are positively adjusted by shims. There are no screw adjustments except the one that takes up bearing wear on the pinion shaft (Fig. 53).

To mesh the pinion deeper into the bevel-drive gear, withdraw the pinion unit and remove one of the thin shims between the pinion housing and the rear-axle housing. The meshing of the gear and pinion may be inspected through the large plug hole in the left front side of the gear case. The edges of the gear teeth should be approximately flush.

To move the bevel gear sideways, take out the drive shafts and the bevel-gear unit, after which the unit can be shimmed in the necessary direction.

Pinion-Shaft End Play

If the bearings of the drive-pinion unit permit the pinion shaft to have end play, the axle is prone to become noisy, particularly when the brake is applied and when the car is coasting. To take up this end play, disconnect the rear universal joint and take off its flange. Then remove the housing, and after loosening the lock nut, make the adjustment with the nut. These bearings are very sensitive to adjustment and must not be made too tight. This adjustment is sometimes more easily made if the pinion unit is taken out and put in a vise.

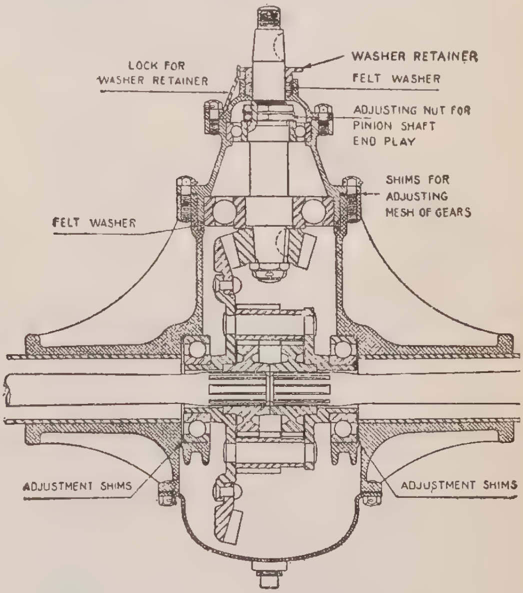

Fig. 53. Sectional view of the Franklin model "9B" rear axle, showing the points of adjustment.

Truss-Rod Adjustment

The truss rod under the gear case should be examined every 1,000 miles, and should be adjusted so that it sounds taut when struck. Keep it adjusted this way, but avoid pulling it up too tight, as the strain is likely to cause the gear case to leak oil.

The wheel-hub bolts should be tightened after the first 1,000 miles of running, and after that can be tightened every 5,000 miles. (*Motor World.*)

TIMKEN-DETROIT REAR WHEELS WITH OIL SEALS

Later types of semi-floating or "fixed hub" types of rear wheels than those shown on page 864, are Fig. 54 which has a single bearing, and Fig. 55 which has two bearings. The numbers are 5014, 5140, 5142, and 5143.

A feature of these types is the hydraulic compression cup leather (Q) which, when properly assembled, is absolutely oil-tight. The oil seal is also used on the Timken rear-axle drive pinion shaft (see page 910). See also the **shim adjustments of bearings.**

To clean and lubricate (Fig. 54): **Remove wheel** from axle shaft. Remove cap screws (**H**) which hold the bearing cage (**I**) in place. Now remove the cage, carrying with it the cup (**J**). **Pull out axle shaft** (**L**) on which is pressed the roller bearing. Clean, as on page 864. Cover bearing with cup grease. Pack end of housing with grease. Replace shaft (**L**) with bearing cone and rollers and cage (**I**) carrying bearing cup.

Adjustment of bearings: Add or remove shims (**K**). Screw up (**H**) until shims (**K**) are tight and shaft turns freely when revolved with a wrench placed on nut (**N**). When this condition is attained, add one of the thinnest shims to one of the bearing cages; this will give approximately .005" end-play. Replace wheel and tighten nut (**N**), and lock with cotter pin.

When making adjustment it is advisable to remove the oil seal by removing locking washer (**P**), cup leather (**Q**), and spring (**R**).

To clean (Fig. 55): **Remove wheel** from axle shaft. Now remove cap screws (**H**) which hold the outer wheel-bearing cage (**A**) and the inner wheel-bearing cage (**B**) in place. **Pull out axle shaft** (**L**), carrying with it the bearing cages, cones, and cups. This assembly is removed in one unit. Now place the axle shaft in a vise and remove the two short cap screws (**C**). The outer cage (**A**) and the inner cage (**B**) can now be taken apart.

Adjustment of bearings: Add or subtract shims as the case may be, being careful not to get the bearings too tight. Proper adjustment is .005" loose, or the thickness of the thinnest shim. Clean as on page 864.

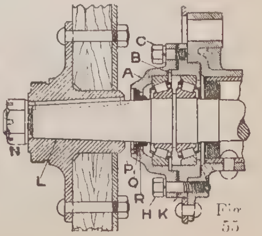

Fig. 55

INSTRUCTION No. 74

BRAKES: Types; Care and Adjustments

TYPES OF BRAKES

There are two kinds of brakes generally used on automobiles: (1) the external brake; (2) the internal brake.

The external brake is usually a contracting band brake consisting of a steel band, lined with an asbestos fabric that is placed around the circumference of the brake drum which is mounted on the rear wheel hubs, as shown in Fig. 1.

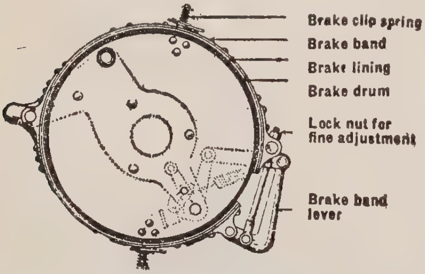

Fig. 1. The **external** contracting band brake. Note the brake-band lever which is connected with the foot pedal and draws or contracts the band around the brake drum.

The operation of the external band brake is usually by means of the brake-band lever connected with the foot-brake pedal. There are different methods employed for connecting this lever, and although the construction may vary, the principle or purpose —of contracting the band around the brake drum— is the same.

The internal brake is of two general types: (1) those using an expanding brake **shoe** (Fig. 2); (2) those using an expanding brake **band** (Fig. 3).

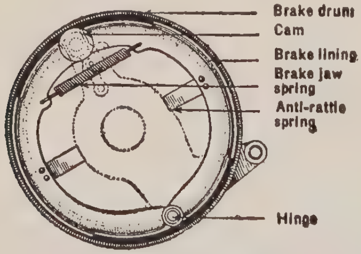

Fig. 2. An **internal** brake where metal **brake shoes** of hinged type are used. The shoe on this brake is lined with a fabric material, but sometimes we find this shoe without lining and made of metal, such as bronze. The brake shoes are caused to expand and tighten in the periphery of the brake drum by action of a **cam** connected with the hand-brake lever.

The internal brake using brake shoes (Fig. 2) can be of plain metal, such as bronze, or of metal lined with fabric, and are usually hinged.

Where metal-to-metal brakes are used, a constant and extravagant supply of oil is required to prevent excessive wear. The inconvenience and uncertainty of lubrication, together with the cost of renewing the expensive brake shoes, renders this type of brake unsatisfactory.

When the brake-shoe type is used, it is generally lined with an asbestos fabric, as shown in Fig. 2.

Operation of the internal shoe type of brake is usually by means of a **cam** which is connected with the hand-brake lever, thus expanding the shoes inside of the drum when pressure is applied.

The internal brake using an expanding brake band is shown in Fig. 3.

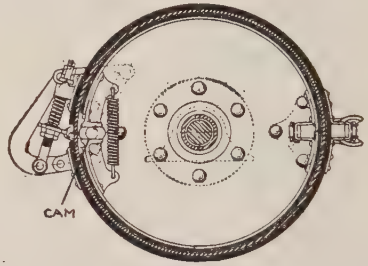

Fig. 3. An **internal** brake using an **expanding band** which is expanded inside of the brake drum by action of a **cam** connected with the hand-brake lever. Observe also that the **external** band brake on the outside of the brake drum is operated by a **lever** similar in principle to that shown in Fig. 1, but of slightly different construction.

The internal brake band is made of steel, lined with an asbestos-fabric brake lining.

Operation of this internal brake band (Fig. 3) is by means of a **cam action.** The cam is connected with the hand-brake lever, and when the lever is operated, the cam separates the two ends of the brake band, causing it to expand, thus tightening itself in the inner side of the brake drum.

Another method of operating the internal brake band is by means of a **toggle joint action** instead of a cam, as shown in Fig. 4. This method of operation is the method in general use.

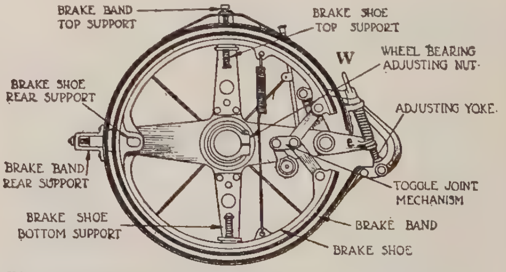

Fig. 4. Note that the **internal** brake band is operated by a **toggle joint** instead of by a cam action. Also observe that the **external** brake is of the band type, and that the lever for operating the external band is similar in principle to that shown in Figs. 2 and 3, but of slightly different construction (Dodge brake).

It will thus be observed, that **the external brake is of the contracting band** type and is operated by a **lever or fulcrum action.**

The internal brake is either a **shoe** or a **band** of the **expanding** type, and can be operated by a **cam action** or a **toggle-joint** action.

With this in mind, the classification of almost any type of brake can be determined instantly.

Brake Drums

Brake drums can be divided into two classifications: (1) the **single** brake drum; (2) the **double** brake drum.

On most makes of cars the brake drums are mounted on the inner part of the hubs of the rear wheels, and are **single brake drums.** There is usually an **internal** brake operating **inside** of the drum and the **external** brake operating on the **outside** of the brake drum.

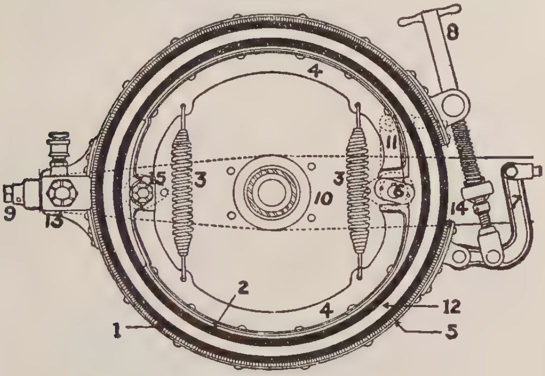

Fig. 5. The Locomobile double brake drum:

(1) Running brake drum
(2) Hand-brake drum
(3) Hand-brake shoe springs
(4) Hand-brake shoe
(5) Running brake band
(6) Hand-brake actuating cam
(7) Running brake bell lever
(8) Adjusting wrench for brake band
(9) Adjusting bolt fore and aft
(10) Distance rod
(11) Hand-brake lever
(12) Air space for cooling
(13) Running brake bracket (rear)
(14) Running brake bracket (front)
(15) Hand-brake shoe bracket

On the Locomobile, for example (Fig. 5), note that there are two brake drums, termed a "double brake drum."

The double brake drum, as stated, has two drums (1) and (2) (Fig. 5). The foot-brake lever connects with the fulcrum lever (7) attached to the contracting band (5) operating on the outside of the drum (1).

The hand-brake lever connects with lever (11) which actuates a cam (6), thus expanding the brake shoe (4) on the inner side of the drum (2).

Air space (12) between the drums keeps them comparatively cool and permits the use of one brake without the heating of the other drum.

The hand adjusting screw (8) is provided for adjustment of the foot brakes.

Mounting of brake drums: The brake drums are usually mounted on the hubs of the rear wheels.

Four-Wheel Brakes

This type has the advantage of equalizing the braking strain on the four wheels, eliminating skidding, and making possible quick stops at high speeds with a very smooth action. It also lengthens the life of tires, and the brakes are effective until the last bit of brake lining is gone. The four-wheel braking operation is usually operated on the **hydraulic, mechanical,** or on the **air** principle. The **Packard single-eight** and **Rickenbacker** use four-wheel brakes **mechanically** operated, using internal expanding shoes, cam actuated. Means are provided at base of foot brake pedal to step up the motion of the brake pedal by means of a differential type equalizer on the Rickenbacker and a planetary type on the Packard.

The Duesenberg car employs a hydraulic four-wheel brake for the foot brake, and a transmission brake for the hand brake. On this car, the brake drums on the four wheels are forgings 16″ in diameter.

In order to obtain a perfect braking surface, the drums are ground. Fins are machined on the outer edges to provide strength with lightness, and for radiating purposes. The four brakes are operated by hydraulic pressure. A master cylinder is connected to the brake pedal, and the liquid is forced through the lines running to the four wheels by a piston in the master cylinder.

By the term "hydraulic" is meant liquid pressure. One of the fundamental laws of physics is that pressure exerted by a liquid or gas, is equal and undiminished in all directions. Therefore, if we have a system of pipes all connected together and filled with a liquid, pressure exerted in any part of the system will be transmitted equally to all other points in the system. Founded on this principle, Duesenberg brakes are always equalized. Since air can be compressed and liquid cannot, we use liquid for the transmission of power or pressure.

A small cylinder in each of the four brakes has a piston which is forced upward by the liquid entering the cylinder. The piston at the brake operates a toggle arm, which in turn expands the two brake shoes in each brake. All four of these brakes are operated simultaneously by the service brake pedal. An interesting feature of the brakes is that, owing to the floating arrangement of the piston and toggle, the brakes are self-centering and consequently self-equalizing. When the brakes are applied, they provide equal pressure against the drum.

Water is used as the brake operating fluid in summer time, and an anti-freeze solution in winter.

The Christensen four-wheel air brake is used on fire apparatus and commercial trucks of large size, manufactured by the Christensen Engineering Co., Milwaukee, Wis.

LOCATION AND OPERATION OF BRAKES

Most of the cars are fitted with rear-wheel brakes, and therefore we shall confine our attention to this type.

The external brake is usually operated by a foot pedal, and is called the **foot brake.**

The internal brake is usually operated by a hand lever, and is called the **hand brake**—formerly known as the emergency brake. See pages 12 and 13.

Sometimes a brake pulley is mounted on the external part of the transmission shaft and connects with the hand lever. It is then called the **transmission or propeller-shaft brake,** but is usually operated by the **hand lever.** Therefore it would also be termed the hand brake.

The band brake is the most popular type of brake for both internal and external use.

Brake Connections

The foot-brake pedal and hand-brake lever are usually connected with the internal and external brakes in the rear-wheel brake drums by means of **rods,** and sometimes by **flexible wire cables.**

Brake Rods

Examples of how the connections are made with **brake rods** are shown in Figs. 6 and 7.

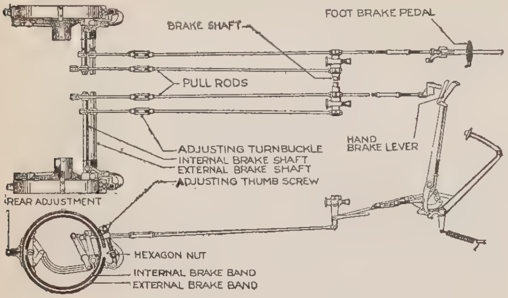

Fig. 6. Brake connections where rods connect the foot-brake pedal and hand-brake lever with external and internal bands. The foot pedal operates the external brakes, and the hand lever operates the internal brakes. Note that an **internal band brake with a toggle action** is shown.

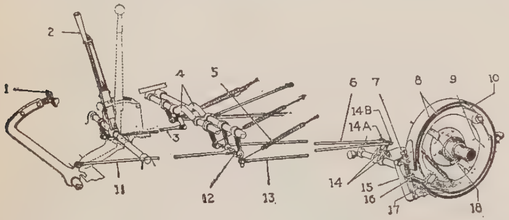

Fig. 7. Brake connections where rods connect the foot-brake pedal and hand-brake lever with an external band and an internal brake shoe. The foot pedal operates the external brakes and the hand lever operates the internal brakes. Note that the clevises (14) are used for "distance" or "pedal and lever adjustments," whereas the brake-band lever (15) is used for "brake-band clearance" adjustment. Note that the **internal brake shoe has a "cam" action.**

(1) Foot-brake pedal
(2) Hand-brake lever
(3) Hand-brake forward rod
(4) Brake shafts
(5) Pull-back springs
(6) Hand-brake rear rod
(7) Foot-brake adjustment
(8) Brake linings
(9) Hand-brake shoes
(10) Brake drum
(11) Foot-brake forward rod
(12) Foot-brake equalizer
(13) Foot-brake rear rod
(14) Foot and hand-brake adjusting clevises
(15) Foot-brake band lever
(16) Foot-brake centering nut
(17) Hand-brake operating cam
(18) Anti-rattler springs

The adjustment of the external contracting brake (Fig. 7), which is the foot brake, is similar to the adjustment explained on page 889 (Fig. 10).

The adjustment of the hand brake (Fig. 7) can be tried by pulling the wheels by hand to determine that equal braking effort is applied to both rear wheels when the **hand-brake lever** is partly set, and that both lock at the same time with the wheels jacked up.

Adjustment is made at clevis (**14A**). The two clevises (14) are mounted on a tube within a tube. The clevis (14A) attaches to the inner tube and operates the cam (17); clevis (14B) is attached to the outer tube and operates the external brake lever (15). When the brake lever is released there should be no dragging of the brake shoes on the drum.

Brake Cables

The Lexington series "S" car is an example where a **flexible-wire brake cable** is used instead of rods.

On this car both the hand and foot brakes are unusual in their construction.

The hand brake operates upon a drum located on the rear of the transmission.

The foot brakes are on 16″-diameter-brake drums attached to the rear wheels and in the form of contracting bands. The band brake is operated through a spring-tensioning device, so that it is possible to bring the car to a stop with very light pressure. The foot brakes are operated by a cable guided to each rear wheel by a heavy tube attached to the frame (see Fig. 8).

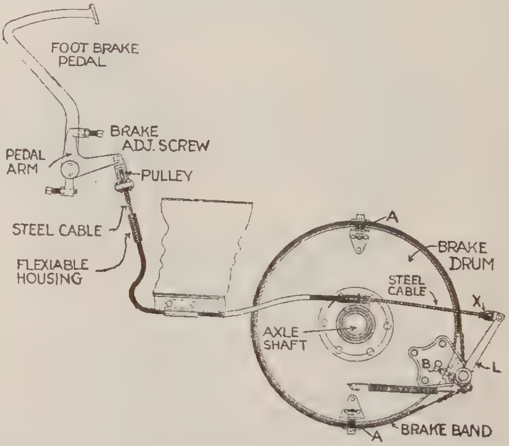

Fig. 8. **Principle of the brake operation on the Lexington "S":** A steel cable is connected to one lever passed around a grooved pulley attached to a pedal arm and back to a lever on the opposite drum, making the best form of equalizer. Over this cable is a flexible housing of closely wound steel wire, covered with a weather-proof material to keep out mud and water.

The rear ends of the housing are anchored to the axle; the forward ends are anchored to the frame near the pedal. Since the housing is practically noncompressible, it is evident that what cable is pulled out at the front end must come in at the rear end, thereby setting the brake.

The inner and outer members being flexible, any movement of the axle resulting from road conditions is not transferred to the pedal.

A simple screw and lock nut serves to take up any slack in the cable resulting from wear of the lining. If any great amount of wear in the lining causes too much pedal travel, by setting up the brake-lever stop screws at the rear drums as close as they will go without causing the bands to drag, and then taking up the slack in the cable at the pedal end, the brakes can be kept in first-class condition until the lining is worn out.

A little engine oil squirted into the housing at the front end every few weeks will keep the cable free.

CARE AND ADJUSTMENT OF BRAKES

As the safety of a car depends on its brakes, they must be kept in the best possible condition. They should bind tightly when pressure is applied to them, and be free and clear when the pedal or lever is released. A brake band or shoe that binds when the pressure is released produces friction, and makes the car hard-running.

A common brake trouble is slipping, generally the result of oil or grease working out of the rear axle. It is also caused by poor adjustment, or worn linings. Therefore the first and most important precaution is to stop any leak by putting in a washer. Poor adjustment may be cured by **readjustment.**

In the case of oil or grease working between the surface, **clean the brake lining** by washing out the oil with a little gasoline or kerosene, applied with an oil gun, and then stop the leakage of grease out of the rear axle. This is usually done by the replacement of a felt washer (or "grease retainer" washer. See "Studebaker axle," page 875) on the inside of the hub. The excess oil is generally due to too much oil in the differential casing, which works out into the brake drums.

Slipping caused by worn linings may be remedied to some extent by taking up the adjustment, but if it is too much worn for this, they must be replaced.

Replacing the worn lining is not difficult, as the brake lining is held to the steel band by copper rivets.

Because the application of the brake generates heat, leather linings would be burned if kept in contact too long. For this reason, the brakes are usually lined with fabric, called Raybestos, Multibestos, or Thermoid.

If, when applying the brakes, the car has a tendency to skid to one side, this indicates that one wheel is free and the other dragging. In such a case the brakes are not equalized in adjustment. Therefore the brake resistance should be equalized.

The operator can save considerably by applying his brakes gradually. For instance, if a stop is to be made, instead of dashing up to the stop and applying the brakes with full force suddenly, simply coast to the stop and apply the brakes gradually, or even not at all. This of course, requires practice.

If a brake squeaks, it is dirty and dry, and needs cleaning by removing and cleaning with a stiff brush and gasoline. The dirt clogs the pores in the surface of the lining and glazes it over, which causes the squeak. Brake squeaks are also caused by improper clearance or high points between the brake drum and the brake band.

Brake drag is usually due to insufficient strength of the releasing mechanism, such as the springs; or the connections may be adjusted too tight, or there may be insufficient clearance at the bands.

Lubrication of brakes: While asbestos lining requires practically no lubrication on account of its high resistance to heat, it is advisable to apply a few drops of thin oil to the brake shoes or bands occasionally, or about every 2,000 miles. This maintains a smooth surface on the brake drum.

See that the hinges, cams, toggles, and lever bearing are kept well supplied with oil. If an external contracting brake should **chatter,** apply three or four drops of oil to the friction surfaces. If this does not relieve the "chattering," look to the "clearance" of the lower part of the external brake band, or to looseness in the parts of the internal brake mechanism.

Inspection of Brakes Before Adjustment

Points to consider when starting to make adjustments of the brake mechanisms are: Do the brakes merely need adjustment, or do they need an overhauling? If a car has been run for a long time, it is advisable to make an inspection as follows.

1. **Inspect the bearings in the rear wheel hubs,** to see if they are in good condition. If the bearings are loose or worn, this will make a difference in the adjustment of the brakes, especially when adjustment is made with the car jacked up and when it is made with the car on the ground under its weight. The adjustment can be tested by grasping the wheel on each side of the car, when jacked up, and "feeling" for looseness.
2. **Inspect the rear wheels to see if they are out of line.** If they are, it is probably the result of having skidded against the curb and having slightly bent the axle shaft or having thrown the wheel out of line. This will affect the brake adjustment. Test by spinning the wheel when the car is jacked up.
3. **Inspect the parts** of the brake mechanism to see if they are loose; if so, tighten.
4. **Inspect the joints and parts to see whether they** are rusted or caked with dirt and grease; if so, clean.
5. **Inspect the brake linings to see if they are coated with oil or grease;** if so, clean with gasoline or kerosene, by removing the wheels with the drums. Find the cause of the grease or oil being on the brakes, and remedy it.
6. **Inspect the brake linings to see if they are worn.** If slightly worn, "clearance adjustment" will take care of the difficulty. If badly worn, a new lining will be needed. Also see if the lining has worn down to such an extent that the rivets have cut the brake drum; if so, the wheel must be removed and the brake drum smoothed down with emery cloth, or, in bad cases, the brake drum must be turned true, and even perhaps on a lathe. If the band is not entirely worn down, the brake band can be adjusted for clearance.

Testing the Brake Action

After the conditions enumerated above are attended to, and the parts are cleaned, replace the wheels and proceed to test the brake action as follows:

1. Jack up the rear axle, with the brakes in a complete "off" position. Note the **clearance of the internal bands** around the drum, which should be uniform and about 1/64″. On the external band, this will extend to within only about 3″ or 4″ of the end of the band, where the clearance will be greater.
2. To test the **internal brake band for clearance,** use a thin piece of metal, inserting this between the drum and the band from the inner side of the brake support.

For a more elaborate and sure test, both for holding power and, what is equally important, the equal action (termed "equalizing action") of the right and left brake bands, proceed as follows:

1. Block the front wheels securely to prevent the car moving forward or back.
2. Jack up the rear wheels until they are entirely clear from floor.
3. Put all brakes on both sides in complete "off" position.
4. Start the engine, run it slowly, and transmit the power to the rear wheels, as when driving in low gear.
5. Engage the brakes carefully and lightly, and note the action of the wheels, which will show clearly any inequality between the right and left adjustment. Both brakes should stop at the same time when the brakes are applied.

On some cars without equalizers the adjustment is made by lengthening or shortening the brake rods, by screwing off or on the yoke ends which connect to the brake cams.

Some cars are fitted with brakes in which the adjustment is made by varying the position of the brake-operating lever and slotted clevis on the brake cam shaft. Usually there is a hand adjustment on the contracting brake.

Sometimes all the overhauling the brakes need is a cleaning out of the drums with kerosene, applying a little also on the brake linings. If grease or oil works its way to the brakes, either too much is being carried in the differential, or the felt washers in the axle need replacing. Brake lining is expensive, and very often the old material will serve, if properly handled, with kerosene and a little oil to raise the fiber.

When going over the brake system, be sure to inspect the clevis pins, etc., for wear (see Fig. 7, page 886). These parts frequently are overlooked, and the result is an unpleasant rattle on the road. Oil should be applied to the joint.

Average Brake Adjustments

There are three adjustments to be considered when adjusting brakes: (1) brake-rod adjustment; (2) brake-pedal and lever adjustment; (3) brake-band clearance adjustment.

Brake-Rod Adjustment

The first adjustment of brakes should always be made in the brake rods rather than in the brake itself. Tighten up on these rods so as to get the proper travel in the brake pedal or hand lever. The adjustment of the brake pedal and hand lever is thus made through the rods, by seeing that the foot-brake pedal and hand-brake lever are in "off" position and the rods adjusted so that there is no binding. This can be tested by jacking up the wheels and observing if there is a drag. Adjustment can be made by a threaded adjustment at the front end of the rod, by screwing in one direction to lengthen and in the opposite direction to shorten the pull. The lever (see 15, Fig. 7) on the external brake should be in toward the band, in order to allow for full leverage.

Dragging of the brakes may be caused by too short an adjustment of the rods.

Before adjusting the brake bands, see that the **pull-back springs** are operating properly and lengthen the rods.

If the brakes will not hold, be certain that the brake lining has not become saturated with oil or grease; wash them off thoroughly with gasoline or kerosene if necessary.

When the proper brake action cannot be obtained by further adjustment of the brake rods, then adjust the brakes themselves.

Adjustments of External Brakes

Usually, ordinary external brake adjustment for clearance is all that is required, and this can be done without removing the wheel.

Clearance adjustment of the external brakes is very important. If the band touches the brakes at different points of its circumference, the brake will drag at that point, which of course consumes extra power and causes wear on the lining. The purpose of adjusting this **clearance** is to relieve the drag, or to take up on an excess of clearance due to wear of the lining.

The proper clearance on most brakes is about 1/64″ to 1/16″ all round. Usually this clearance can be taken up as follows:

1. By adjusting the **lever,** as at **(A)** (Fig. 10, page 889);
2. By adjusting the **rear clearance** of the band, as at **(D)** (Fig. 10, page 889).
3. By adjusting the **lower half of the band** for clearance, as at **(E)** and **(F)** (Fig. 10, page 889);
4. By adjusting the **upper half of the band** for clearance, as at **(G)** (Fig. 10, page 889).

This is ordinarily sufficient.

The top half of the brake is usually given slightly more clearance than the bottom, because the drum, revolving in a forward direction, has a tendency to draw the top half of the band to the drum.

A thickness gauge is handy to place between the brake lining and the drum when adjusting clearance.

The foot brake requires more adjustment, because it is used most. The hand brake is mostly used for locking the wheels when standing and at intervals in conjunction with the foot brake on steep hills; therefore it requires less attention.

After adjusting the brakes, notice if the wheels turn freely when the foot-brake pedal and hand-brake lever are in the "off" position.

If the wheels do not turn freely, or if they drag, the brakes are adjusted too tightly.

After adjusting the brakes, while the wheels are jacked up, then test and readjust.

Many repairmen, with the wheels on the ground, and after making adjustment, move the car backward and forward to see if the band drags. If this is done, be sure that both brakes are adjusted equally, as sometimes the weight of the car on the wheels will alter the adjustment.

Adjustments of Internal Brakes

The internal brakes are of the "toggle"-acting type or of the "cam"-actuated type, as previously explained.

As an example of adjusting clearance in the "toggle"-acting type of internal band brake, see Figs. 11 and 12, page 890. In order to make this adjustment, it is necessary to remove the rear wheels. Refer to page 889, and note the adjustments as there explained. See also, Figs. 17 and 18, pages 891 and 892.

As an example of adjusting clearance in the "cam"-acting type of internal brake, see Fig. 14, page 890, also Figs. 19 and 9, pages 892, 889.

Ordinarily, **the only adjustment required for the internal brake** is to adjust the pull rods or clevis.

If the brakes seem to be too tight after the car has just been washed, it is due to the fact that the brake lining, which is composed of a combination of closely woven wire and asbestos, has swelled slightly from the water. In a very short time this condition will disappear.

In adjusting the brake bands, be sure to take up the same amount on both right and left-hand brakes. If care is not exercised in making the adjustment, one brake may set before the other, thus destroying the braking effect and causing one wheel to lock and slide over the ground, wearing off the tread of the tire very rapidly. Also be careful not to set the bands up so tightly that they drag and will not release when the foot is removed from the pedal.

Stopping Car at Various Speeds

The average distances in which a car should be stopped by the brakes at various speeds on average and on good roads, are approximately as follows: 15 m.p.h., 20 ft.; 20 m.p.h., 38 ft.; 30 m.p.h., 85 ft.; 40 m.p.h., 160 ft.; 50 m.p.h., 240 ft.

THE STUDEBAKER "LIGHT SIX" BRAKE ADJUSTMENTS (AS AN EXAMPLE)

The foot brake, also termed the service brake, contracts on the brake drum. The **hand brake,** also termed the emergency brake, expands against inside of the brake drum. By studying Fig. 9, the functions of these brakes will be understood. Both brake bands are faced with brake linings.

The adjustment for clearance of the external brake band (**B**) is made at the nut (**C**) below the spring for clearance of the lower half of the brake band, and by nut (**D**) for the clearance of the upper half of the brake band.

The adjusting screws (**E**) and (**F**) are additional adjustments for procuring an even spacing or clearance all around the circumference of the drum. This clearance should be about 1/32″, or not over 1/16″.

The internal brake is operated by a cam (**H**) which expands a steel band lined with brake lining. The usual adjustment is made by shortening the brake rod at the turnbuckle.

The spring (**S**) serves two purposes: The adjustment nuts are locked by the spring and at the same time, it helps release the band when the pressure is taken off the brake lever.

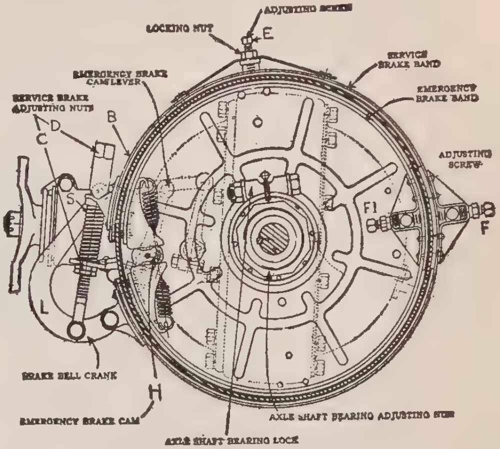

Fig. 9. The brake as used on the Studebaker "Light-Six" car. Note that a lever (**L**) termed a "**brake-bell crank,**" connects with the **external contracting band** (**B**). This lever (**L**) is connected with the foot-brake pedal through the clevises and brake rods.

THE TIMKEN BRAKE ADJUSTMENTS

The adjustments described in what follows are of the brakes as used on the Timken semi-floating or fixed hub type of axles, and on the full-floating axle as shown on pages 865, 866.

The **external** brake (Fig. 10) is the type used on both, but the **internal** brake is of two types, shown in Figs. 11 and 12. The one shown in Fig. 11 is the type used on the semi-floating, or fixed-hub axles, and the one shown in Fig. 12 is the "toggle"-operated expanding band type of internal brake used on the full-floating axles.

The **internal** brake shown in Fig. 14 is the "cam"-operated expanding band type of internal brake formerly used.

A later type of Timken brake is shown in Fig. 16.

External Brake Adjustments (Timken)

To adjust the external brakes, jack up both rear wheels, and put the brakes in the complete "off" position.

Adjust the stop screw (**B**) (Fig. 10) so as to allow the **lever** (**A**) to come down as far as possible and still have a clearance of about 1/16″ with the operating mechanism.

Now remove the cotter pin (**C**) and turn the adjusting screw (**D**) until the clearance between the brake lining and the drum at this point (rear) is not more than 1/32″. Be sure that the brake drum clears at all points; if necessary turn the adjusting screw out slightly. Replace the cotter pin.

Now adjust the **lower half of the band** by turning nuts (**E**) and (**F**) until about 1/32″ clearance is obtained at this point also.

After locking these nuts firmly, make a similar adjustment of the **upper half** by turning nut (**G**). Be sure that this nut is properly seated in the groove into which it fits, thus locking the adjustment.

When these adjustments are complete, there should be a maximum clearance between the brake lining and the drum of about 1/32″ at all points, but they should not be in contact at any place. Readjust until this condition is obtained.

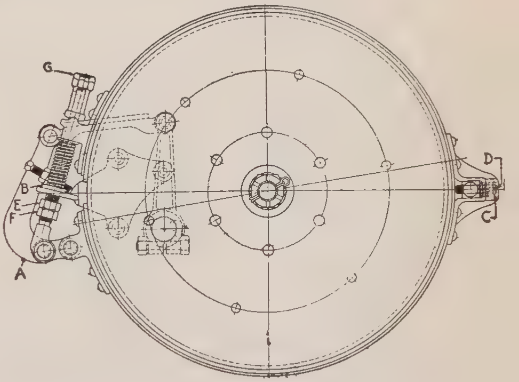

Fig. 10. External band brake (Timken).

Internal Brake Adjustments: Timken Toggle Type

In order to adjust the internal brake, it is necessary to remove the rear wheel, carrying with it the brake drum. Jack up both rear wheels, put the brakes in the complete "off" position, and remove the wheels.

To adjust the fixed-hub type of axle brake (see Fig. 11): First remove the cotter pin (**A**) and tighten up adjusting screw (**B**) until a maximum clearance of 1/32″ is obtained between the brake lining and the drum at this point. This clearance should be the least possible amount—only enough so that the drum will not rub at any point when revolved.

Having obtained the proper clearance, replace the cotter pin (**A**). Next remove the head pin (**D**) and disengage screw (**E**), freeing both ends of the brake band.

Adjust the four set screws (**F**) to give the least possible clearance between the brake lining and the drum—1/32″ should be the maximum.

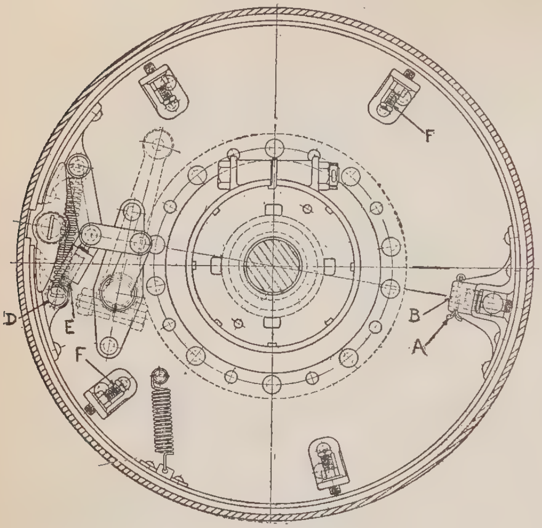

Fig. 11

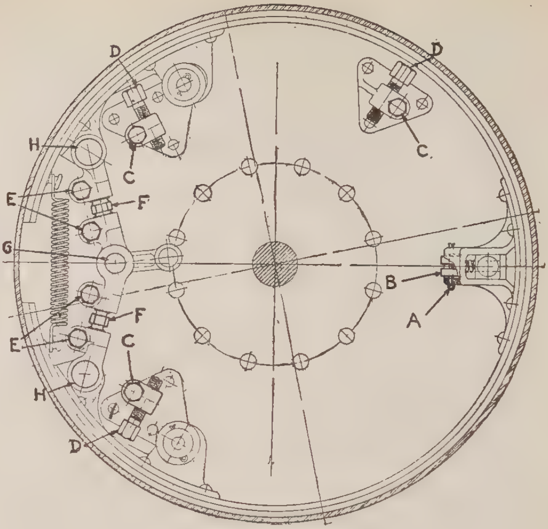

Fig. 12

Fig. 11. Internal toggle type of brake (Timken), as used on the fixed hub or semi-floating axle, as discussed on page 865.
Fig. 12. Internal toggle type of brake (Timken), as used on the full-floating type of axle, as discussed on page 865.

When this adjustment has been made, be certain that each set screw is firmly locked with the lock nut.

Now adjust the screw (E) to give not over 1/32″ clearance between the lining and the drum at the two ends of the band and replace the pin (D).

After making all these adjustments, there should be a maximum clearance all around the drum of 1/32″—if not, readjust until this result is obtained.

To adjust the internal brake on the full-floating type of axle, see Fig. 12.

Adjustment is made in a similar manner. Some of these axles are provided with a triangular plate in the brake drum which can be removed for adjusting the brake. In this case it is not necessary to take off the wheel.

Adjust the screw (B) to give the proper clearance at this point; obtain the correct clearance over the rest of the brake band by adjustment of screws (D) after loosening the clamp bolt (C).

After making these adjustments, be sure that the cotter pin (A) has been replaced and that the clamp bolt (C) has been tightened up firmly.

Now loosen the clamp bolts (E) and adjust screws (F) until the forward edge of head-pin (G) is in line with the rear edges of pins (HH). Tighten up bolts (E) and replace the wheel.

In replacing the wheel on the full-floating type of axle, be sure that you get a correct bearing adjustment as described on page 864 under "Wheel bearings."

Dummy Drum for Adjusting the Internal Brake

In garages or service stations when internal brake adjustments are frequently made, a dummy drum (Fig. 13) can be used to advantage. The same result can be obtained by a "cut-and-try" method, removing and replacing the wheel several times, but the use of a dummy will prove a great time saver.

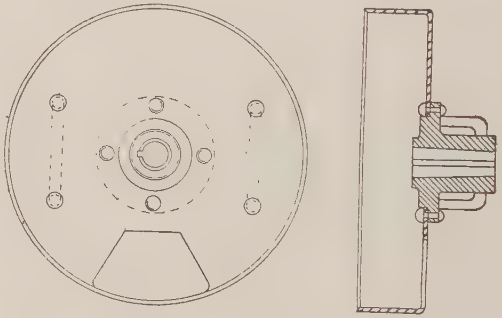

Fig. 13. Dummy drum which can be obtained of the Timken-Detroit Axle Co., Detroit, Mich.

Internal Brake Adjustments: Timken Cam Type

Adjustment of the Timken-cam type of internal brake: A cam type of internal brake has been used on several axles formerly produced (see Fig. 14).

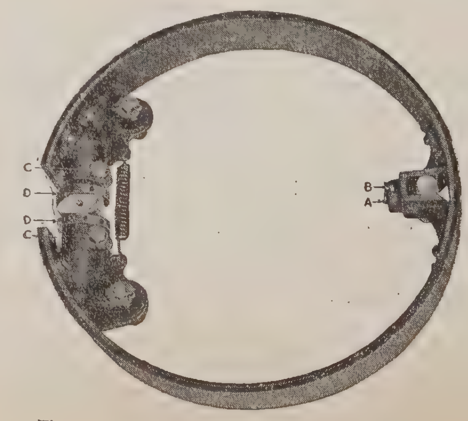

Fig. 14. Timken cam actuated internal brake.

To adjust this brake for slight wear of the brake-band lining, this can ordinarily be taken up satisfactorily without getting into the brake proper.

This is done by loosening nut (Q) (Fig. 15) and moving lever (J) forward one notch in ratchet (K), and then tightening nut (Q). Perhaps two notches forward may be required.

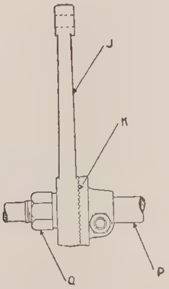

Fig 15

For more band-lining wear than can be taken up by this method, put jacks under the rear axles, being careful to have them press up against the housing proper (or, on some Timken axles, against the pads made for this purpose), but never against the truss rods. Raise both rear wheels off the ground.

Next, put all the brakes on both sides of the axle in a complete "off" position.

Now, if the adjustment is merely to take up for wear of the brake lining in service, it is necessary only to (1) remove the wheel which also removes the brake drum; (2) remove the cotter pin (B), give screw (A) two turns to the right (i.e., in a clockwise direction), and replace pin (B); (3) loosen screws (C,C) give cam plates (D,D) one half-turn outward (i.e., to the left or counter-clockwise), and tighten screws (C,C).

Put the wheel back on and try the brake in the "off" position for a bare yet sure clearance, so that it will not drag. Try it in the "on" position for holding power.

If greater clearance is required, remove the wheel and partially reverse the adjustments detailed just above.

If still more holding power is desired and there is some clearance yet to spare in the "off" position, remove the wheel and repeat the adjustments to a partial extent.

Timken Types "5510" and "5710" of Brake

Both the external and internal brakes on the 1922 series axles are the same as those made on the corresponding axles of the former series, except on the new series "5510" and "5710" for heavy cars.

On these axles the **internal** brake is of a new type, as shown in Fig. 16, and requires no adjustment beyond that which can be obtained in the brake-pull rods.

The adjustment of the external brake is similar to that explained on page 889.

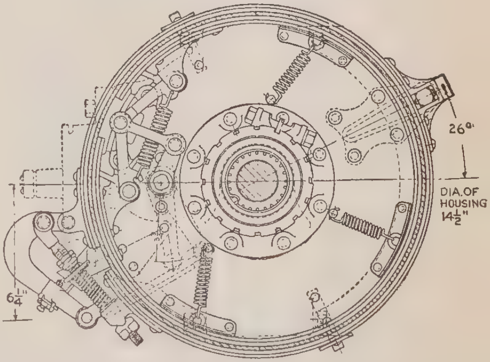

Fig. 16. Timken types "5510" and "5710" of brake—1922 series.

ADJUSTMENT OF BRAKES OF COLUMBIA REAR AXLE

External Brake Adjustment on Models "10000," "30000," "50000" and "51000" Columbia Rear-Axle Brakes

To adjust the external brakes on these models, jack up both rear wheels, and put the brakes in the complete "off" position with lever (A) back against stop (B).

Lever adjustment: Lever (A) must set back against stop (B)—lengthen pull rods if necessary to get this condition.

Rear clearance adjustment: Remove cotter pin (C) and lock (E), and turn adjusting screw (D) until the clearance between the brake lining and the drum at this point does not exceed 1/32″. Make sure that the drum clears at all points.

Lower half of band clearance adjustment: Replace lock (E) and cotter pin (C); next, adjust the lower half of the band by turning nuts (F) and (G) until the lining clears the drum evenly all around, not to exceed 1/32″; then lock nuts (F) and (G).

Adjust the upper half of the band by turning nut (H) until the lining clears the drum evenly all around, not to exceed 1/32″.

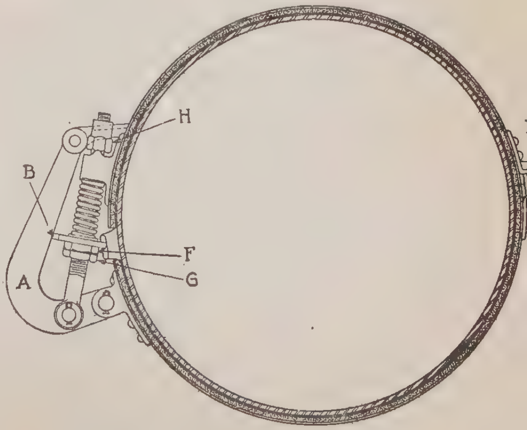

Fig. 17. External brake as used on the Columbia rear axles

Be sure that nut (H) is properly seated in the groove into which it fits, as this locks the adjustment.

When these adjustments are made, there should be a maximum clearance of 1/32″ between the brake lining and the drum at all points. The lining must not touch the drum at any place. Readjust until this condition is obtained, and test with a thickness gauge.

Internal Brake Adjustments on Models "50000," and "51000" Columbia Rear-Axle Brakes

To adjust the internal brakes on these models which are of the "toggle-acting type," and are provided with adjustment at four points proceed as follows:

As a time saver, and to get the best results in adjusting this type of brake, a **dummy drum should be used.** The openings in the drum permit a view of the parts to be adjusted, insuring a much closer and more accurate adjustment than could be obtained without its use.

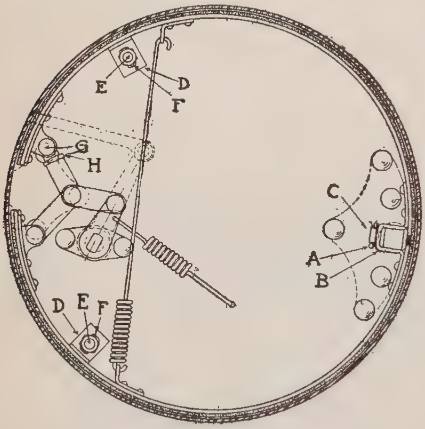

Fig. 18. Internal "toggle joint actuated" type of brake as used on the Columbia rear axles.

First, remove the rear wheels; then adjust the pull rods until the brake-shaft lever on the axle to which these rods connect is set back at same angle as external brake-tube levers when contracting lever (A) is back against stop (B) (see Fig. 17 and instructions for external brake adjustment above).

Next, remove cotter pin (A) and lock (B) (Fig. 18). Put on the dummy drum, bringing the opening in the drum directly over adjusting screw (C); turn adjusting screw (C) until the clearance between the brake lining and the drum at this point does not exceed 1/32″, or the least possible amount obtainable, so that the drum will not rub at any point when revolved. Having obtained the proper clearance, replace lock (B) and cotter pin (A).

Next, bring the openings in the drum directly over the internal brake supports (D). These supports have a small projection that fits into slots in the brake band. Be sure these are in place. Loosen the nuts on bolts (E) just enough to allow supports (D) to move freely. Adjust supports (D) so that the clearance between the brake lining and the drum does not exceed 1/32″, or the least possible amount that can be obtained, so that the drum will not rub the band at any point when the drum is revolved. In adjusting supports (D), use a bar as a lever for prying, working through the opening in the drum; with the bar resting on the drum-catch support, with the end of the bar at (F), move supports (D) up or down. This action moves the brake band until the proper clearance is obtained. Then hold the supports in place until the nuts on the outside of bolts (E) are drawn up tight, and remove the drum to see that it turns freely and that the clearance between the brake lining and the drum is the same all around. Clearance must not exceed 1/32″.

To get the proper clearance at the points, remove pin (G) and adjust screw (H) until a maximum clearance of 1/32″ is obtained; then replace pin (G).

After adjusting point (H), always check supports (D), making sure that this adjustment has not moved the band away from supports (D). If these supports do not set up tight to the band, readjust supports (D). After making all these adjustments there should be a maximum clearance all the way around the drum of 1/32″; if not, adjust until this result is obtained.

Important: Never adjust the pull rods without afterwards adjusting supports (D), as the adjusting of the pull rods pulls the band away from supports (D) causing rattles and also wear of the supports. To eliminate rattles, adjust supports (D) up tight to the band in release position.

In adjusting the brakes a thickness gauge should be used to measure the proper clearance between the brake lining and the drum. Dummy drums can be secured for models "10000," "30000," "50000," and "51000" from The Columbia Axle Co., Cleveland, Ohio. Thermoid brake lining 2½″ in width is used.

Internal Brake Adjustment on Models "10000" and "30000" Columbia Rear-Axle Brakes

The internal brakes on these models are the **"cam-operated type,"** and only one adjustment for "clearance" is provided. See Fig. 19.

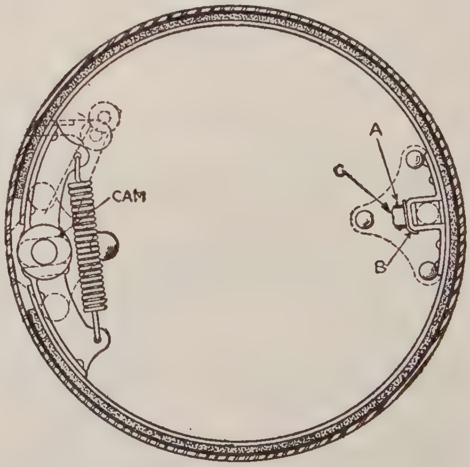

Fig. 19. Internal "cam-actuated" type brake, as used on Columbia rear axles.

To adjust, remove cotter pin (A) and lock (B), and turn the adjusting screw (C) until the clearance between the brake lining and the drum at this point does not exceed 1/32″.

Adjustment for wear, which is the only adjustment usually required, is made by shortening the pull rods from the cam lever forward to the chassis.

ADJUSTING DODGE BRAKES

The external brake is connected with the foot-brake pedal. Adjust the hexagon check-nuts on the lower part of the adjusting yoke (see Fig. 4, page 884) as well as the wing nut (**W**) at the top, in order that the band may be taken up as much at the bottom as at the top.

See that the "brake-supports" are adjusted so that the brake band takes hold evenly all the way around, and does not drag when released.

To adjust the internal brakes, take up on the front end of the pull rod.

Relining Brakes on Dodge

Material required for a Dodge brake relining job: 88″ lining 2¼″ x 3/16″ for the two external brakes; 71″ lining 2″ x 3/16″ for two internal brakes; 12 steel cotter pins 3/32″ x ¾″; 80 brass rivets 9/16″ long, ⅛″ diameter, ¼″ head.

Either 3/16″ or ¼″ brake lining can be used. On repair jobs ¼″ is often used.

Operation: (1) Jack up the rear wheels; (2) remove the wheel flanges; (3) remove the wheel-bearing adjusting nut; (4) remove the wheel and brake band; (5) wash the brake bands; (6) remove the old brake lining; (7) rivet the new lining bands; (8) replace the brake bands; (9) put the wheel on; (10) replace and adjust the wheel-bearing adjusting nut; (11) replace wheel flanges; (12) adjust brakes.

Note: It is now necessary to use a wheel puller to remove rear wheels on the later type of Dodge axle.

OVERHAULING BRAKES

There are three things which must be particularly noticed in taking care of brakes and putting them in condition:

1. There must be no grease on the shoes.
2. The fabric must be in the best of condition.
3. The brake linkage must apply the brakes when the pedal is depressed.

The grease which penetrates to the brake lining usually works its way from the differential, and can be stopped by renewing the washer in the wheel hub.

To remove grease, first remove the wheel, then inspect the brake lining and see if it comes under the condition mentioned in No. 1 or No. 2 in the list above.

If a coating of grease is over the surface of the fabric, there will be two methods of procedure. The first method for removing grease is by the application of gasoline. This removes the grease from the outer surface very well, but not from below the surface of the fabric. A blow-pipe torch can be used in this instance, which can be gently applied as shown in Fig. 20, this page, care being taken not to char the fabric.

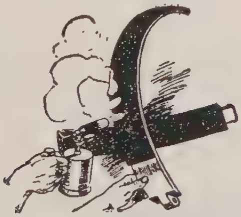

Fig. 20. Removing grease from under fabric brake lining on a two-piece internal expanding brake shoe.

After the heat has been directed against the surface of the brake for a short length of time, it will be noted that the grease will literally fry out of the fabric, leaving it upon the surface in the form of a black carbonaceous deposit. In this state it is readily removed by a cloth steeped in gasoline. The surface of the brake will now be in good condition if the lining has not been worn out.

If the brake lining is badly worn down, so far that the fabric lining is too thin to be of service, a new brake lining must be applied.

If the brake lining has worn down to the rivet heads, it should be renewed, unless the rivets can be sunk lower by a round-nosed punch, the other end of the rivet being placed over a small hole in a piece of metal on an anvil or vise. Then the rivets can be set up tighter.

Relining External Contracting Brake Bands

To reline the external brake: First, jack up the rear wheels. Disconnect the levers, etc., from the brake bands and remove the wheels and bands, being careful to keep all parts separate, so that they can be replaced with ease.

Second, wash all parts in gasoline or kerosene to remove the grease and dirt.

Third, remove the old brake lining, by placing the band in a vise and cut the rivets with a chisel (Fig. 21); then open up the bench vise about ½″, setting the bands so that the old rivets come over the opening one at a time. Drive them out with a nail set (Fig. 22). As the heads will most likely be worn off, it is easier to drive them from the lining side through to the band side. The old lining can then be easily removed from the band.

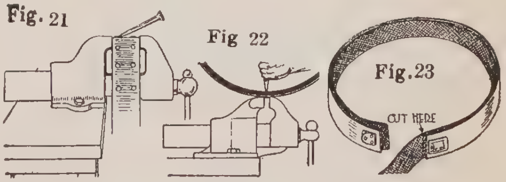

Fig. 21 Fig. 22 Fig. 23

Fig. 21. Method of cutting rivets on worn band.

Fig. 22. Punch the cut rivets out.

Fig. 23. Method of determining length of lining for an external contracting band type of brake.

Fourth, measuring brake lining:[1] It is best to secure the lining from the automobile dealer or manufacturer ready to apply, but if this is not possible, then proceed as follows: Place it **inside** the band (Fig. 23), holding it firmly against the band and cut the lining from ¼″ to ⅜″ **longer** than the band, depending upon the diameter of the band.

Fifth, rivet one end flush with band (Fig. 24-1) after having countersunk a hole in the lining for the rivet.

---

[1] Most accessory dealers possess data books of brake-lining measurements from early to late model cars. See also Index, under "Brake-Lining Sizes." The Raybestos Co., Bridgeport, Conn., supplies **brake service material** and supplies.

Sixth, place lining firmly in band all around, which should leave a projection of about 3/8" at other end (2, Fig. 24). **Seventh,** make a loop in middle (Fig. 24), so end (2) of lining will come flush with end of metal band, then countersink lining and rivet this end.

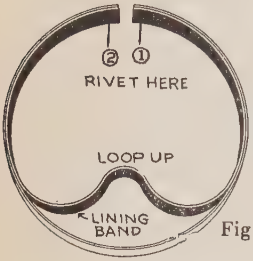

Fig. 24

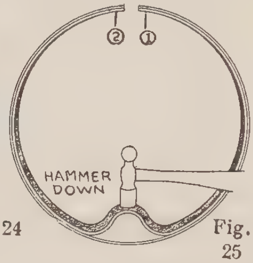

Fig. 25

Figs. 24, 25. Lining external contracting brake band.

Eighth, force lining straight against band with hammer (Fig. 25). **Ninth,** place band over a block of wood or vise and use holes in band as a template. **Drill holes** for the rivets. It is important that the holes be in the correct **position.** **Tenth,** countersink holes so that the rivet heads will be below surface of lining. Use a countersinking tool (Fig. 26).

A 3/8" metal drill can be used. Do not countersink too deep, but just enough to permit rivet head to be below lining surface. (The solid or tubular copper rivet is used in this example; see Fig. 31.)

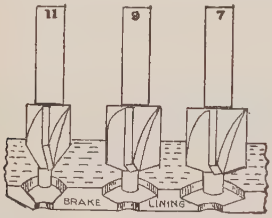

Fig. 26. **A brake lining counter-sink** for flat-head solid or tubular rivets 9/16", ½", and 13/32". This device will countersink holes in any style of brake or clutch lining. The shank is 5/16" in diameter, and works on a hand or power drill. (Stevens Co., 375 Broadway, New York.)

Eleventh, place copper rivets through lining so head of rivet will rest in countersunk hole in lining. See "Riveting Brake-Band Lining." **Twelfth,** round up with the brake drum and reassemble.

Relining Internal Expanding Brake Bands

Follow "First, Second, and Third" procedures under "Relining External Brake Bands." **Fourth,** place lining around band (Fig. 27) and cut lining length of band. **Fifth,** place lining on metal band (ends flush). Hold in place with a "C" screw clamp at each end; then mark holes from inside of band. **Sixth,** remove lining; drill and countersink holes. **Seventh,** place lining on band (Fig. 27) and start riveting at one end and follow around to the other end. **Eighth,** round band up with drum and reassemble.

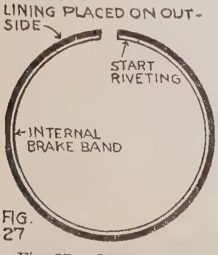

FIG. 27

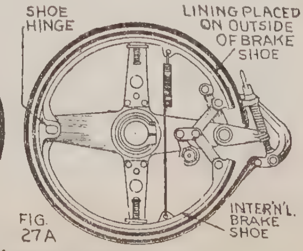

FIG. 27A

Fig. 27. Lining internal expanding brake band.
Fig. 27A. Lining internal expanding brake shoes.

Relining Internal Expanding Brake; Two-Piece Shoe Type

Procedure (see internal expanding brake shoes in Fig. 27A): Use brake lining longer than necessary for complete job. Rivet one end flush with one end of brake shoe. Insert free end of lining in vise. Rest other end of brake shoe against vise and press down, thus stretching brake lining tight over shoe band. Drill holes, countersink and rivet around the shoe, and cut off surplus brake lining. **If the brake is of the metal-to-metal** type, it is a matter of adjustment, no lining being used.

Riveting Brake Band Lining

Do not clinch the rivets against the brake drum. Drill and countersink the rivet head into the lining.

To place the rivets, see Fig. 27B. This shows a way of using a bolt held in a vise with the head of bolt resting on the arm of vise to give a solid foundation.

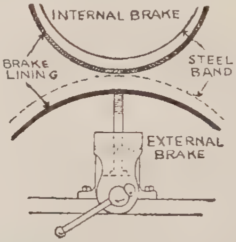

Fig. 27B. One method of riveting. Note that the illustration shows the internal brake curved up and the external brake curved down. The rivet head goes next to the fabric, and the riveting is always done on the band side.

Insert a rivet through the lining and band, as shown, the head of the rivet resting on the bolt. Draw rivet snug with a rivet set, or a short piece of small gas pipe. Two or three blows with a hammer will be enough to draw the rivet head and the lining tight and in place. Too much pounding will tend to draw the rivet deeper in the lining and perhaps weaken it to the point of breaking through.

To rivet: Holding the band in the same position, the projecting end of the rivet is peened down with the ball peen of hammer till a good head is formed and the rivet draws tight.

Brake Lining[1]

Most of the brakes now in use are fitted externally and internally with steel bands faced with a fabric lining. **There are several good brands of brake lining** on the market, for instance, Raybestos, Multibestos, Thermoid, etc.

Fig. 27C. Fabric brake lining. Fig. 28 Fig. 29 Fig. 30

The sizes are usually measured in thickness and width, and are sold at so much per foot.

The thicknesses run 3/32", 3/16", 1/4", and 5/16". The widths run from 1", 1¼", 1½", 1¾", on up to 6" wide. The Ford uses 1⅛"x5/32".

---

[1] See Index under "Brake-Lining Sizes," as used on various cars.

Brake Lining Rivets

The rivets are made of **solid copper** (Fig. 28), without burrs, or are made of **tubular brass** (Fig. 29) (hollow rivet), which are used on the Dodge and Maxwell cars, or are a **clinch or split rivet** (Fig. 30), as used on the Ford.

Solid Rivets and Split Rivets—How Used

When solid or tubular rivets are used, the head of the rivet is placed next to the brake lining fabric and is countersunk into it, and the rivet is bradded on the steel lining of the brake, as shown in Fig. 31.

Timken Detroit Axle Co. advises **copper rivets,** as they will not score the drum when the lining becomes worn.

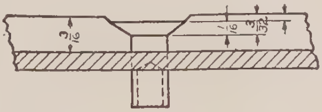

Fig. 31. Showing how the flat-head solid or tubular rivet is used with the head countersunk into the lining.

When split rivets are used, the head of the rivet is placed next to the steel band and the projecting ends of the rivets are turned into the brake lining or fabric as in Fig. 31A.

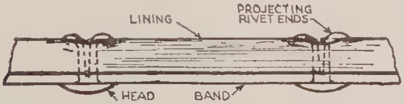

Fig. 31A. Showing how the split rivet is used with the head next to the steel band.

Many mechanics do not punch holes in the lining, but drive the split rivets through the lining. Place the lining and the band over a wooden block clamped in a vise, and **drive** the rivets through a hole in band and through the lining into the wood. Then put the rivet head on the bolt clamped in a vise, and turn over the projecting ends of the rivet into the lining, as shown in Fig. 31A.

The Raybestos Co., in its publication, "Silver Edge," advises **not to use split rivets,** the proper method being that of drilling, countersinking, and riveting, with the flat head of the rivet about 1/32″ below the surface of the lining (Fig. 31), **using a flat-head tubular or solid rivet** that will not split the lining and will hold until the lining is worn to half its original thickness.

There is only one efficient way to reline a brake and that is to **remove the band** so that you may be sure of what you are doing. The questionable practice of attempting to reline the brakes with split rivets without removing them from the drum is a rather poor gamble, because about every third rivet does not split. Both prongs turn the same way, enlarge the hole through the lining, and have no binding effect.

The **general condemnation of split rivets** arises from the fact that, as usually applied to a band that has been removed from the drum, the prongs are turned lengthwise of the lining, so that they parallel the warp threads. When the prongs are jammed into the lining they cut the cross-threads, or filling, which hold the warp threads together.

Experience has proved that split rivets, except for Ford cars, can never be substituted for tubular or solid rivets properly applied.

Brake lining tools and special machines for locating, drilling, countersinking, and riveting (also for punching the old rivets out) can be secured of the Raybestos Co., Bridgeport, Conn. **There are firms who specialize on brake adjusting, relining, and steering-gear work** exclusively.

THE ELECTRIC AND VACUUM BRAKE

Although the brakes under this heading are not in general use, they will be explained as a matter of information.

The Electric Brake

Construction: The Hartford braking motor (Fig. 32) is shown with reduction gearing. The armature shaft carries a worm gear which drives at a reduction of 100 to 1.

This worm gear in turn operates a drum through an internal gear at a reduction of 4 to 1, giving a total reduction of 400 to 1.

A steel brake pulling cable, which is wound on the drum, transmits the pull of the motor to the brake mechanism.

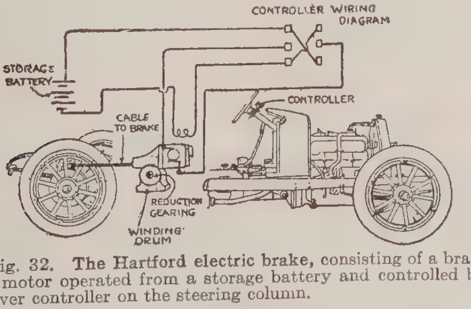

Fig. 32. **The Hartford electric brake,** consisting of a braking motor operated from a storage battery and controlled by a lever controller on the steering column.

The controller is moved by degrees, which applies the brake gradually; or suddenly, if moved to the extreme limit.

The point of decreased speed before coming to a full stop is illustrated by the fact that a car, moving at the rate of 50 miles an hour, or 73 1/3 feet a second, can within 35 feet, or in one half-second's time, be slowed down to 15 miles an hour or 22 feet a second, and can be brought to a dead stop within the next 10 feet.

The current required is 40 amperes for two-fifths of a second, at a pressure of 6 volts.

The Vacuum Brake

This brake is known as the Prest-O-Vacuum brake, and is shown connected with the rear brakes in Fig. 33.

Principle: By utilizing the suction in the intake manifold to exhaust the air from a cylinder (B) carrying a piston, the piston is forced to move, and in its motion applies the brakes through the usual braking system. The extent to which the brakes are applied depends, of course, upon the suction of the cylinder, and this is controlled by the driver through a throttle valve operated either by a pedal or a hand lever.

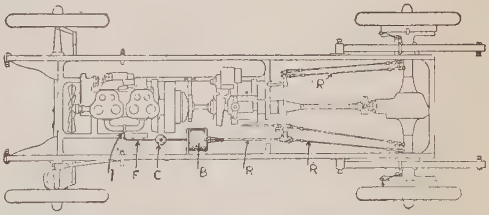

Fig. 33. The vacuum brake.

The general layout of the system when installed on a car is shown in Fig. 33. It will be noted that the forward end of the suction tube is attached to the intake manifold at its junction (I) with the carburetor pipe, this being the point of most constant suction. From here it leads to the throttle valve (C), located convenient to the driver's foot.

The construction and principle involved is similar to the air-brake cylinder used on railway trains, having a pressed-steel shell, a cast-steel head, and carrying a pressed-steel piston with leather packing. This piston has a diameter of 7″, an area of 38½ sq. in., and a stroke of 4″, the entire braking cylinder assembly weighing about 10 lbs.

The suction in the manifold (I) varies from 8 to 12 lbs. per sq. in. When the throttle valve (C) is opened wide, at least 10 lbs. per sq. in. suction is applied to the piston in the braking cylinder. Hence the area of the piston being 38½ sq. in., a suction, or, to be more exact, a pressure, of 10 times 38½ or 385 lbs., is applied to the piston.

The piston, therefore, is moved under a direct pull of 385 lbs., and this in turn is compounded through the toggle-joint connections to give a pull of 4,000 lbs. on the brake rods. This is an extreme example of what the system can do, as a pull of 4,000 lbs. is seldom required, unless on large trucks. It is evident that the pull applied to the brakes may be graded from 0 to 4,000 lbs. at the option of the driver, the pull depending only upon the opening of the throttle valve.

BRAKE LINING SIZES ON 1921 CARS[1]

Name and Model	Length	External Width	Thick-ness	Length	Internal Width	Thick-ness

INSTRUCTION No. 75

STEERING GEARS: Types; Care of; Adjusting; Lubricating and Overhauling FRONT AXLE: Alignment. FRONT WHEELS: Alignment; Adjusting Front-Wheel Bearings

TYPES OF STEERING GEARS[1]

The two methods of connecting a steering gear with the front axle of a car are the "fore-and-aft" method and the "cross-method," as explained on page 10.

The various types of steering gears are classified under six headings as follows, and as shown on pages 10 and 11.

1. Pinion and sector
2. Worm and sector
3. Worm and worm wheel
4. Planetary
5. Screw and nut
6. Screw and half-nut

Some of the leading makes of steering gears are illustrated on this and on the following pages, together with the method of adjusting.

Jacox Steering Gear

Type: Screw and half-nut type (Figs. 1 and 2); consists of a steering tube, to the lower end of which is attached a double-threaded screw (S). Turning the steering wheel moves the screw (S), which moves the two half-nuts (N). One of these nuts has a left-hand thread and the other a right-hand thread; therefore one half-nut (N) moves upward and the other down.

The two half-nuts (N) bear against two rollers (H) attached to a yoke (L) on a shaft (A), which projects outside of the housing and to which is attached a pitman arm (J) which is attached to the drag link, which in turn is connected to the steering-knuckle arm on the front axle.

Adjustment: If excessive backlash or lost motion develops, it can be taken up by loosening the clamp screw (B), and screwing down on the adjusting screw (D) which is screwed down directly on the thrust bearing (E), which forces down the double-threaded screw (S) and the sliding half-nuts (N) against the yoke rollers (H). After adjusting, lock the clamp bolt (B).

Lubrication: The gear is filled with heavy graphite grease when it leaves the factory. However, this should be thinned occasionally by inserting a little engine oil through the oil plug at the top of the gear housing. The telescoping tubing can be oiled occasionally at oil holes (OH) (Fig. 2).

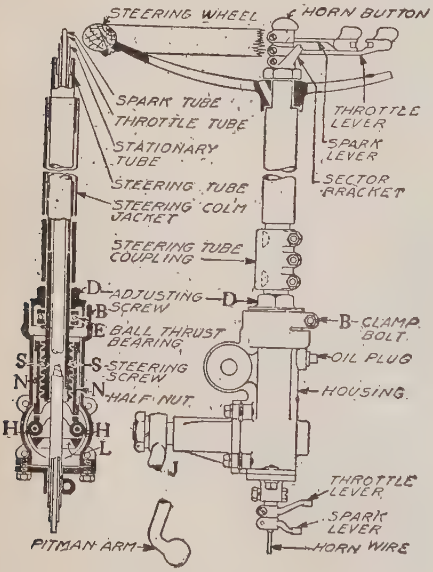

Fig. 1

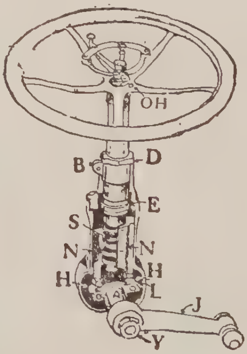

Fig. 2. Hard steering is not always due to adjustment. It may be due to lack of lubrication. The other members of the steering device, such as the drag-link connections, may also be dry. Likewise looseness may be due to the connections. Always keep nut (Y) drawn tight.

Assembling: If the steering gear is taken apart, and the method of steering is **"fore-and-aft,"** the left-hand nut (N) (Fig. 2) should be on top for left-hand steering, and the right nut should be on top for right-hand steering.

If the method of steering is the **"cross-steering"** method, the right-hand nut should be on left side for left-hand steering, but on the right side for right-hand steering.

---

[1] Address of steering gear manufacturers: "Jacox," Jackson, Church & Wilcox, Saginaw, Mich.; "Lavine," Lavine Gear Co., Racine, Wis.; "Warner," Warner Gear Co., Muncie, Ind.; "Ross," Ross Gear & Tool Co., La Fayette, Ind.; "Barnes," Barnes Gear Co., Oswego, N.Y.; "Gemmer," Gemmer Mfg. Co., Detroit, Mich.

Warner Steering Gear

Type: Worm (W) and worm-wheel (H) (Fig. 3).

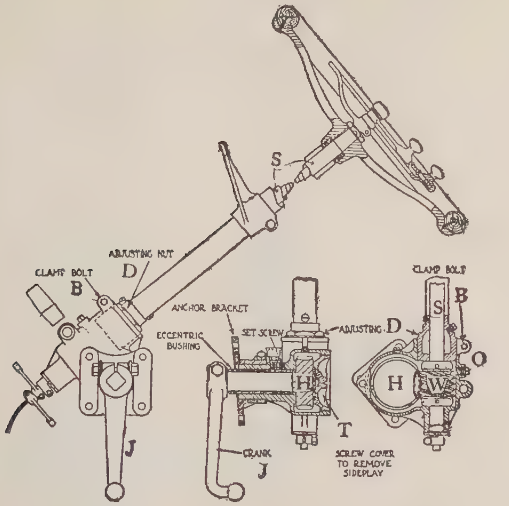

Fig. 3

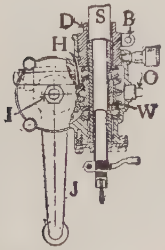
Adjustment: There are two adjustments. The adjusting nut (D) on top of the steering device can be adjusted by loosening clamp bolt (B) to take any up-and-down motion found in the wheel. The worm (W) and worm wheel (H) can be brought into closer contact by adjusting the eccentric bushing (T).

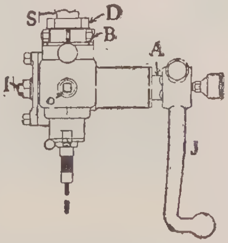
Lubrication: Pack with grease through plug (O). Inject oil occasionally.

Gemmer Steering Gear

Type: Worm (W) and worm wheel (H) (Figs. 4, 5, 6).

Adjustment: The end play in the worm-wheel shaft (A) is taken up by loosening lock nut (L) (Fig. 5) and taking up on adjusting nut (I).





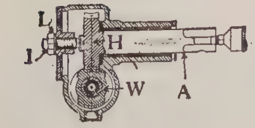


Fig. 4 (upper)
Fig. 5 (lower)

Fig. 6

The second adjustment is made by loosening clamp bolt (B) (Figs. 4 and 6) and tightening adjustment collar (D).

Ordinarily these two adjustments will remove any wear. However, if the wear is excessive and these adjustments will not remove the trouble, the arm (J) should be removed and the steering wheel turned around so that cross-shaft (A) will have turned one quarter-turn. In this position place arm (J) back, and it will be found that a new surface will be given to the gears.

Lubrication: Pack with grease. Oil can be injected occasionally to keep the grease from hardening.

The Lavine Steering Gear

Type: Screw and half-nuts.

Action: Nuts (N) are divided, and operate on right and left-hand threads cut in a worm or double-threaded screw (S). When steering wheel is turned, one nut moves up, the other down, causing (O) to operate arm (J).

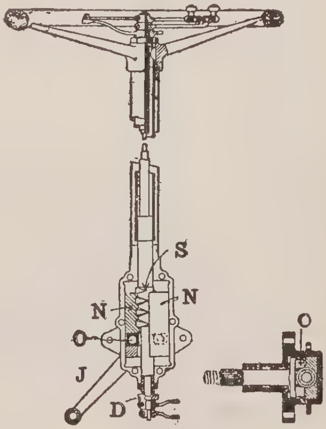

Fig. 7

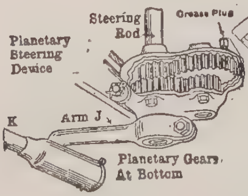
Adjustment is by nut (D) at the bottom.

Lubrication: Grease.

The "Planetary" and "Pinion and Sector" Types of Steering Gears

The planetary type of steering gear (Fig. 8) differs from other types in that there are reduction gears at the bottom of the steering device. This type is used on the Chevrolet "490" and the Overland "4." The "cross-type" steering method is used.

The planetary type is also used on the Ford, but the gears are at the top of the steering column instead of at the bottom, as shown on page 11, Fig. 9; see also Index under "Ford steering gear."



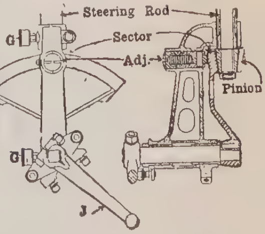


Fig. 8 Fig. 9

Fig. 8. Planetary type of steering gear with the gears at the bottom of the steering device.

Fig. 9. The pinion and sector type of steering gear as used on the Reo.

Adjustment of the planetary type of steering gear: There is no adjustment except to see that all nuts are tight.

Lubrication: Pack with grease.

The "pinion and sector" type of steering gear is shown in Fig. 9, and is that of the steering device used on the Reo model "F" truck, but it serves to explain the principle, as used on other Reo cars.

Adjustment of pinions and sector endwise may be controlled by the adjusting screw. This pinion may be moved up or down by unclamping the locking bolt (not shown) near the bottom of the steering device, allowing the whole steering column to move up or down to give the right engagement. Do not disturb the adjusting screw when making this adjustment.

Lubrication: Inject grease.

Steering Gears Used on Trucks

The steering gears as used on trucks differ but little from those used on passenger cars.

A popular type of truck steering gear is shown in Figs. 10 and 11.

Observe in Fig. 10 the **fore-and-aft method of steering** is shown. This means that the rod (drag rod) which connects from the arm J (Fig. 10) to the steering-knuckle arm has a direct forward-and-backward or aft motion, which turns the steering knuckle as shown in Fig. 19, page 902.

Observe in Figs. 11 and 12, the **cross method of steering** is shown. This means that the drag rod **D** (Fig. 12) is placed ahead of the tie rod (B) and a motion crosswise of the car is imparted to the steering knuckle arms by movement of arm J (Fig. 11).

The **type of steering device** shown in Fig. 10 is the screw-and-nut principle, and the action is explained under the illustration.

The **type of steering device** shown in Fig. 11 is the differential screw principle, and the action is explained under the illustration.

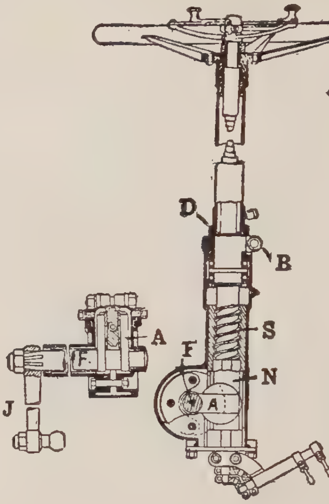

Fig. 10

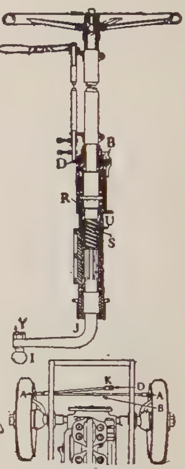

Fig. 11 (upper)
Fig. 12 (lower)

Fig. 10. **Ross "fore-and-aft" steering device for trucks. Type:** screw and nut. **Action:** movement of the steering wheel turns screw (S). This causes nut (N) to travel up or down, which moves (A) (F) and (J). **Adjustment:** loosen clamp bolt (B) and tighten down (D).

Fig. 11. **Ross "cross-type" steering device for trucks.** Note that ball (I) on arm (J) fits into the end of the drag rod (D) at (K) (Fig. 12). **Type:** differential screw. **Action:** arm (J) is caused to turn by a differential action of one screw of fine pitch operating into another screw of coarse pitch. **Adjustment:** loosen (B) and tighten (D). **Lubrication:** oil injected at top.

Fig. 12. Note that the connections are all in front of the axle, and it is thus termed the "cross-steering" method.

EXAMPLES OF ADJUSTING STEERING GEARS

As an example, the "worm-and-worm wheel," or "worm-and-gear" (as it is often termed), type of steering device, as used on the Studebaker "Light Six" is shown below (Fig. 13).

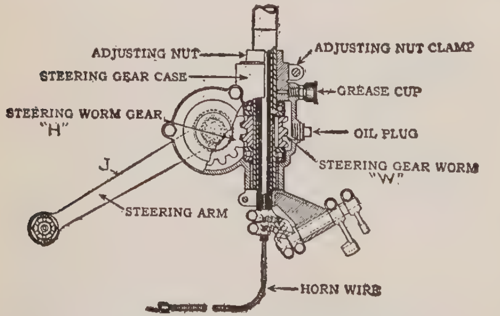

Fig. 13. The **Studebaker "Light Six"** steering gear. **Adjustment:** Jack up the front axle so that the steering device will turn freely. Make adjustment with the steering wheel turned to the extreme right, as if about to turn a sharp corner. There is less wear at this position than in the straight-ahead position, and a tight adjustment in the straight-ahead position would probably be a binding adjustment in the angle position.

In this extreme position work the steering wheel up and down. If the steering column moves up or down, loosen the adjusting-nut clamping bolt, and slowly turn down the adjusting nut until all end play is eliminated; then tighten the clamp bolt.

If there is still backlash, it is an indication that the teeth on the worm (W) and worm wheel (H) are worn. **To adjust:** Remove the steering arm (J). Turn the steering wheel until the steering worm gear (H) has rotated one-quarter around, and replace arm (J) and tighten it. This will permit the engaging of entirely new sets of teeth on the worm wheel and the worm gear.

Lubrication: Usually when a steering gear begins to steer hard, it is due to lack of lubrication. The grease cup is used to lubricate the worm-shaft bearing, and heavy oil is injected at the oil plug.

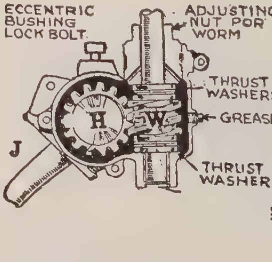

Fig. 14

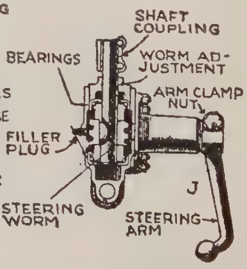

Fig. 15

Fig. 14. **Dodge: Type:** "Worm-and-worm wheel." Both made of hardened steel. **Adjustment:** To remove end play in worm shaft, loosen the coupling or shaft connection (not shown) on the steering column, also the clamping bolt at the top of the steering case. Then screw down the adjusting nut until the play is removed, but not too tight. Tighten the parts which were loosened.

To take up end play between worm (W) and worm wheel (H), remove the eccentric-bushing locking bolt. Then turn the octagonal end of the eccentric bushing, which projects through the frame, until (H) is brought in close contact with (W). Be sure to replace the eccentric-bushing locking bolt, so that it sets between the teeth on the inner end of the eccentric bushing. After long usage the steering lever arm (J) can be disconnected and (H) can be rotated 90° or one quarter-turn, and new teeth are then brought into play. Any end play found in the worm-wheel shaft can be taken up by an adjustment on the side of the steering device (not shown).

Lubrication: Pack cup grease in the steering-gear case at the grease plug, with a grease gun. Turn a grease cup above (H) (not shown) every 100 miles.

Fig. 15. Maxwell "25": Type: "Worm-and-worm" wheel; has two adjustments.

If an excessive amount of end play or lost motion exists, remove the two upper bolts in the steering-gear shaft coupling, and pull the steering wheel and shaft upwards. Then unscrew the steering-arm clamp nut and remove the steering arm with the worm-wheel shaft. The steering-gear worm adjusting-plug clamp screw should then be loosened, and while turning the steering gear with a hand on the coupling about a quarter-turn to the right and left, tighten the plug until the play is taken up.

If there is still lost motion in the steering wheel, remove the steering arm and turn the wheel until the steering-arm clamp has rotated a quarter-turn and replace the steering arm, thus giving the gear and worm a new bearing surface. **Lubrication:** Soft cup grease through the filler plug.

Removing, Disassembling, Adjusting, and Lubricating a Steering Gear (Mitchell "F" as an Example)

The steering gear is of the worm-and-gear type, a complete gear being provided to allow for wear between the worm and the gear. It is irreversible in operation, while ease of steering is obtained by the provision of ball bearings to absorb the thrust.

Removing the steering gear from the car: The throttle and spark connections should be removed from the bottom of the steering column, and the wheel and tube are then removed The side arms should be taken off by removing the clamp screw and pulling the arm off the end of the shaft.

Loosen the screw which supports the steering gear in the bracket riveted to the frame, and remove the entire gear by sliding it in toward the engine free of the bracket, when it can be lifted out of the car.

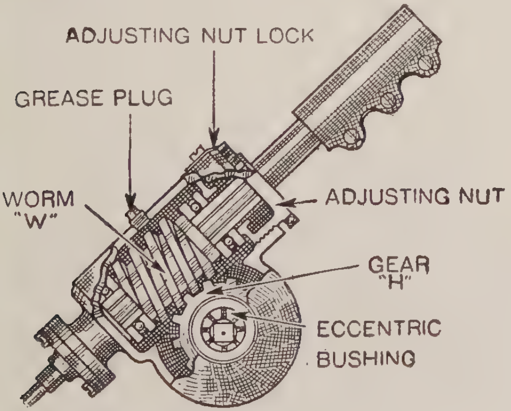

Fig. 16. Mitchell steering gear.

To disassemble the steering gear, remove the steering adjusting nut lock and unscrew the adjusting nut. Remove the cover on the inner side of the steering-gear housing, when the gear with its shaft can be drawn out of the housing. The worm with its ball bearings can then be removed from the housing and the steering gear is completely disassembled.

In adjusting the steering gear it is important first to locate the looseness or play. Do this by having someone move the wheel back and forth, watching meantime to see if the column itself moves up and down, indicating end play in the worm. This can be overcome by tightening the adjusting nut at the top of the housing. If close observation shows end play on the gear shaft, this can be overcome by tightening the gear adjusting screw on the cover.

If there appears to be **play between the gear and the worm,** the steering gear should be removed from the car and the eccentric bushing in which the gear shaft is supported should be moved around until the gear is in proper mesh with the worm. When the bushing has been moved around to the point where all adjustment has been taken up, a new part of the gear can be brought into mesh with the worm by revolving the steering tube until the gear has made one quarter-revolution. A new slot will have to be filed in the square end of the shaft to accommodate the side-arm clamp screw. In making this adjustment, the eccentric bushing should be moved back to give all the adjustment possible with the gear properly meshed with the worm.

If play is found to exist where the side arm goes on the shaft, it can easily be taken out by tightening up the clamp screw. Play sometimes develops **in the drag-link** connections either at the steering gear or at the front axle, and this can be taken out by tightening up the adjusting plugs in the ends of the drag-link connections.

Lubricating the steering gear: About once every season, or every 5,000 miles, the plug on the steering-gear housing should be removed and the housing packed with cup grease. The grease cup on the steering-gear housing should be filled with cup grease and given two or three turns every week or every 500 miles. The **spark-and-throttle-lever rods** in the bottom of the housing should be lubricated with a few drops of oil every 300 miles. The **drag-link connections** at the front axle and at the steering gear should be packed with grease once a season, or every 5,000 miles.

The Marmon Steering Gear

Type: Worm-and-worm wheel (Fig. 17).

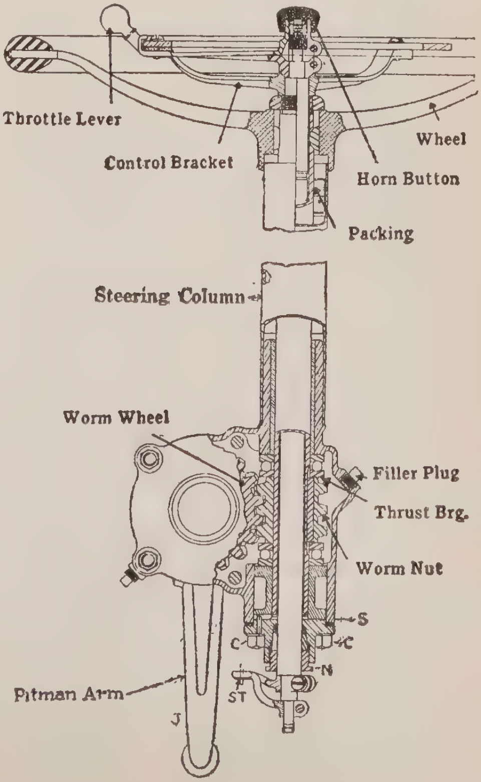

Fig. 17. Marmon steering gear.

The steering column contains five concentric tubes, with respective connections for the four controls at the wheel. Through the center runs the horn wire, surrounded in order by tubes for the throttle, spark, friction ring (stationary), steering wheel, and outer shell. On the lower end of the steering shaft is a worm, provided with thrust bearings, which turns the worm gear operating the steering-crank shaft. If end play develops in the steering shaft, it may be adjusted.

The steering gear may be removed from the frame and disassembled for cleaning and lubricating, but if no change in its operation is detected, refilling of the oil chamber every 1,000 to 3,000 miles is the only necessary attention.

Adjustment: When enough wear has taken place to necessitate taking up some of the lost motion, this may be done by removing one or two of the shims (S) under the plate at the bottom of steering gear.

To do this, disconnect the spark and throttle control arms (S) and (T) at the bottom of the gear and slide them off. Then remove the nut (N) which is around the column and which fits into the bottom plate. Next, remove the four cap screws (C) holding this plate, and it may be taken off without difficulty.

STEERING GEAR TROUBLES, TESTS, AND REMEDIES

The play in the steering gear itself can be taken up by the various adjustments provided.

The up-and-down play of the wheel is taken up by loosening the clamp screw on top of the frame bracket and turning the adjusting nut down. This action forces the shoulder on the column closer to the thrust bearing, as shown in Fig. 18.

Most gears have an eccentric bushing on the side to take up the **play between the worm and wheel,** or sector, as the case may be. There are holes or slots in the eccentric bushing for turning it after the clamping device has been loosened up. If this does not take up the play, there is still **another remedy for the worm and wheel type.**

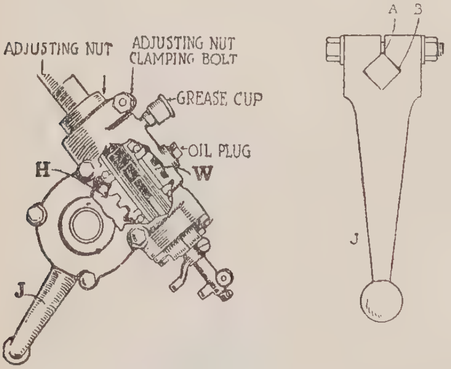

Fig. 18. Method of bringing a new surface of the worm and wheel into engagement to take up the play after all other adjustments fail.

Remove the steering gear by disconnecting all the spark and throttle controls, dash brackets, etc. Then take off the steering arm, and turn the wheel so that the square shaft to which the arm was attached will make a quarter-turn. In other words, the corner (A) will be replaced by (B). Then the arm is clamped back.

This operation brings a new surface of the worm and wheel into engagement, and takes up the play. The eccentric bushing should be turned back, so that it can be used to take up the play in the usual manner, after the steering arm has been changed.

Repack the steering gear with grease, and clean out the oil cups, refilling with clean lubricant. When making adjustments on the steering gear always have the wheels locked over, either to the right or left, as far as they will go.

Loose Steering Connections and Their Relation to the Front Axle

Lost motion in the steering mechanism or connections: The extreme amount of play in a steering wheel should **not exceed a 2″ movement** of the steering wheel.

On the preceding pages it was explained how "up-and-down motion" and "play in the steering gears" could be taken up. If these adjustments fail to relieve the play, then the trouble must be **in the connections from the steering device to the steering connections of the front axle.** The illustration (Fig. 19) shows the connections of the steering device with the front axle and the points where play could exist.

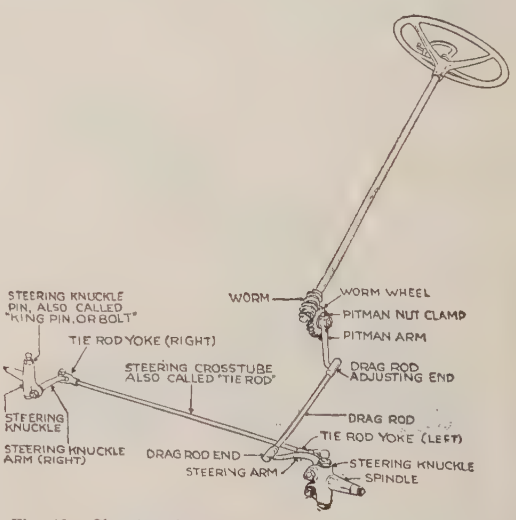

Fig. 19. Showing the principal connections from the steering device to the front axle.

It will be observed that if the play is not in the worm-and-worm wheel, it could be in any of the points from the pitman arm nut clamp to the steering knuckle pin, or it may be due to loose bearings in the front wheels.

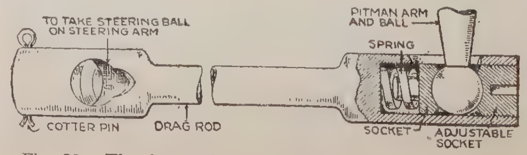

Fig. 20. The drag rod, also called "drag link," "steering-gear thrust rod," etc.

The drag rod or link (Fig. 20) connects the steering ball with the steering arm of the steering knuckle. It should be taken off and the inside cleaned out.

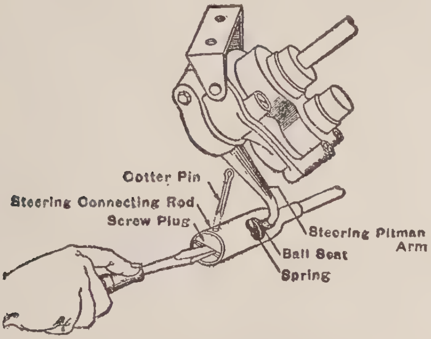

Fig. 21. Method of adjusting pitman arm ball.

Adjustment for this is made by screwing the slotted nut either in or out, and then replacing the cotter pin. Repack the joints with fresh grease, and, if possible, put on a leather boot.

If there is considerable play in the steering knuckles, the bushings should be renewed, and in some cases the steering-knuckle pin itself must be replaced. Always cover the surface well with oil when replacing, as when new parts are fitted there is little space between the walls, and it takes the oil some time to get there.

The steering ball is the ball on the end of the steering arm on the steering knuckle to which the drag-rod connection fits. There is a great thrust imposed upon this ball at all times when the car is in motion, and the nut securing it to the connections should be drawn up occasionally and locked.

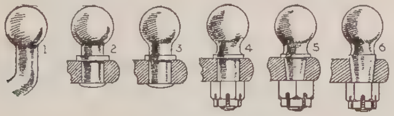

Fig. 22. An evolution of improvements made by the Timken Co. in the steering ball is shown above. The original method is shown in (1), which was integral with the arm. The ball (4) was later produced, and this could be replaced, but it was found that wear would occur in time; therefore a tapered ball with a shoulder was produced as in (5). But this did not provide for "take up," as the take up would draw the shoulder and not the taper; therefore the improved ball without the shoulder (6), and with a tapered shank, permits drawing the ball tight in its seat. Thus there is no limit to the amount of adjustment possible.

Hard or Difficult Steering

Hard or difficult steering may arise from a number of causes as follows:

1. Too tight an adjustment of the steering gears.
2. Lack of lubrication in the steering device, drag link, yoke ends, or steering-knuckle pin.
3. Lack of lubrication or tightness in the connections at the yoke ends of the axle, as well as at the tie rod and steering-knuckle pin bearings.
4. Wheels out of alignment.
5. Tires not properly inflated.
6. Wobbly wheels.

To Test for Steering Troubles

1. Jack up the front wheels.
2. Disconnect the drag link and try the gear thus disconnected.
3. Examine the drag-link and tie-rod connections, and the steering-knuckle spindles.
4. If this inspection does not locate the trouble, loosen the toe-board bracket and see if the steering column is in alignment.
5. See if the steering gear is fastened securely to the frame.

If, on inspection, nothing is found to indicate excessive tightness of the parts, and the steering operates freely when the car is jacked up, yet operates hard when the car is running on the road (with the tires properly inflated), it is evident that the front wheels are out of alignment.

Note. When the car is standing, it is very difficult to turn the steering wheel; do not therefore judge the tightness of the steering gear or its connections except when the front of the car is jacked up and the front wheels are clear, or when the car is in motion.

Never take a steering gear apart except as a last resort.

The lubrication of the steering gear is explained under the different examples given in the pages preceding. In addition, all parts of the steering connections should be kept lubricated, as the grease cups on the tops of the steering-knuckle pins and the steering cross-rod pins should be given two or three turns every week, or each 500 miles.

The steering column on most steering devices is a tube 1¾″ in external diameter.

The steering wheel is usually 18″ in diameter, except on the very light cars.

ALIGNMENT OF THE AXLES AND WHEELS

The word "alignment" or "alinement" means to "line up," that is, to line up the two wheels, or the axles, or the steering knuckles, or the frame, or the springs, or, in fact, any part of the car which should be in alignment with the other like part.

For example, suppose the one side of the front axle has shifted farther ahead than the other side; this throws the front wheels out of alignment on the side that is shifted, and the result is harder steering as well as wear on the side of the tire, as the wheel which is out of line is at all times being drawn sidewise.

Likewise a bent or twisted front axle will cause excessive vibration, especially in the steering, because there are certain angles at which a front axle should be set, and each side should be in alignment. If either is out of alignment, the result is that the part out of alignment is not working in harmony with the other part.

Wheels and axles that are out of alignment produce:

1. Vibration.
2. Excessive wear on tires.
3. Wobbly wheels, in some instances.

Parts which should be lined up are:

1. Front axle.
2. Front axle with rear axle.
3. Springs with axles.
4. Front wheels.
5. Front wheels "toed-in" and "cambered."
6. Front axle and steering knuckle "castered."

Each of these parts, if not properly aligned, will produce one or all of the following:

1. Vibration.
2. Wear on tires.
3. Hard steering.
4. Wobbly wheels.

Alignment of Front Axle

The front axle, if bent or twisted, will cause the wheels to be out of alignment.

In order to check a front axle for a twist or bend at the steering knuckle or at the axle end yoke, one method is to line up the center of each steering-knuckle spindle hole with the other, as shown in Figs. 23 and 24 from **(A)** to **(B)**. This line should be central with the top of the axle and the spindle holes.

If one point is higher than the other, or if the spring seats are out of line, or if the axle is bent or twisted, it should be bent cold if possible; otherwise heat it at the point where it is out of line and straighten it with a press, but do not heat the axle more than a dark red.

If the steering-knuckle yokes are bent, they can be twisted back into place by means of a rod through the yoke holes, thus twisting the yoke back to normal.

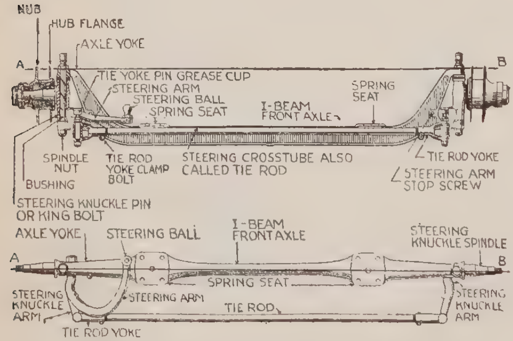

Fig. 23 (upper)
Fig. 24 (lower)

Figs. 23 and 24. Testing for alignment of the steering-knuckle spindles with the front axle.

If play develops between the steering knuckle and the front axle yoke and tightening of the nut does not relieve the play, then it is a case of renewing the bushing, or reaming out the old one and putting in an oversize steering-knuckle pin.

Alignment of the Front Axle with the Rear Axle

Measure the distance on one side of the front axle at the spring seat, at the center of the front axle, to the center of the rear axle, as at **(E)** (Fig. 25).

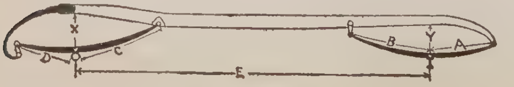

Fig. 25

Then measure the same on the other side. These distances should be equal. If they are not, one of the front wheels, or one of the rear wheels is out of line, thus affecting the steering as well as producing tire wear.

The spring clips can be loosened and the axle slightly moved, if axle proves to have been shifted. If the axle is bent, it should be straightened.

Lining up Springs with the Axle

Measure the distances (Fig. 25) from the horneye of the spring to the center of the axle as shown at **(A)**, **(B)**, **(C)**, and **(D)**, also **(X)** and **(Y)**. The distances should be the same on each side of the car. Measure with a stiff straightedge of some sort, not a tape line.

Alignment of Wheels

This subject is of more importance than one would imagine. For instance, if the wheels are not properly "lined up," there will be wear on the tire, and steering will not be easy. If a car has been subjected to severe jolting or has struck a curb, the wheels may have been thrown out of alignment or the back or front axle may have been moved sideways.

In lining up the front wheels there are four factors to be considered:

1. Trueing up the front wheels.
2. Toeing in the front wheels.
3. Camber of the front wheels.
4. Caster of the steering knuckle.

Trueing up the Front Wheels

In considering the first factor, "trueing up the front wheels," many points are to be taken into account. For instance, **wheels which are not properly trued up are:**

1. Unbalanced;
2. Wobbly.

The fact that the wheels are unbalanced causes the wheels to become wobbly.

The front wheels of the car should be carefully balanced, so that, when the wheel is jacked up and spun, the wheel will come to rest with the valve stem at the bottom.

Factors which cause an unbalanced wheel are:

1. Rim out of true, vertically and laterally, due to unevenness in drawing up the tire bolts or rim lugs, or due to the rim having shifted on the felloe of the wheel, or having been placed out of line on the felloe originally.
2. Heavy blow-out patches in the tire.
3. The wheel itself being out of line.

Should the wheels be badly out of balance, owing to the uneven section of the cover or other part of the tire, a steering "wobble" may be set up at high speed in the steering wheel. This, of course, should be corrected by careful balancing.

FACTORS WHICH PRODUCE WOBBLY WHEELS, HARD STEERING, VIBRATION, AND TIRE WEAR

The principal factors which tend to produce wobbly wheels, hard steering, vibration, and tire wear are enumerated as follows:

1. Wheel bearings worn or loose.
2. Worn steering-knuckle pins or bushings.
3. Steering-knuckle pin nut loose.
4. Steering-gear connections loose, such as the drag rod, steering ball, tie rod, and other connections.
5. Wheels out of alignment.
6. Wheels out of balance.
7. Loose spokes at the hub or felloe.
8. Tire rim out of line on the wheel.
9. A sprung wheel, usually due to skidding force.
10. A bent steering knuckle or yoke end.
11. Front springs out of line, and also the steering ball and steering arm connections on the steering knuckle, which should be in line with the pitman arm on the steering device.

A method of testing the front-wheel bearings to see if they are loose is shown in Fig. 26. In testing for lost motion in front-wheel bearings, a wedge-shaped block or the like should be jammed between the spindle and the axle end, as shown at (**A**), otherwise lost motion in the spindle or knuckle might be taken for looseness in the wheel bearing. After taking this precaution, try to move the wheel as indicated by the dotted lines, and any lost motion in the bearings can be readily felt.

If a wheel is suspected of being out of true, it may be tested as shown in Fig. 27. With one hand resting on a block to steady it, and holding a rule, or the like, close to the wheel rim, the wheel is revolved very slowly; if it is out of true, the space between the end of rule and the wheel rim will vary.

If the trouble is simply due to the rim having shifted on the felloe, it may be rectified as indicated in Fig. 27 (center illustration).

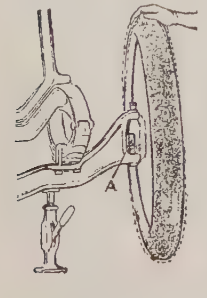

Fig. 26

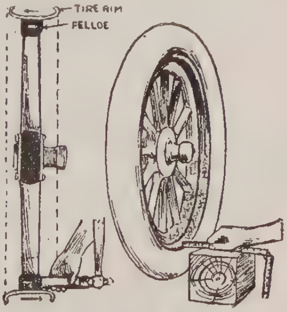

Fig. 27

Fig. 26. Testing for loose front-wheel bearings.

Fig. 27. Testing for a wheel out of true, which causes it to become unbalanced and thus to produce wobbling.

Sprung axle or spindles will either throw the wheels too far out at the bottom, as shown in Fig. 28, or the steering knuckle will be bent either in or out, which will produce wobbling. The point to determine is whether the wheel itself is out of true, by testing as shown in Fig. 27, or if the steering knuckle or axle is out of true by testing as shown in Figs. 23 and 24 (page 904).

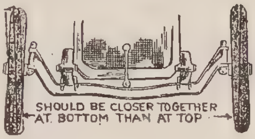

Fig. 28

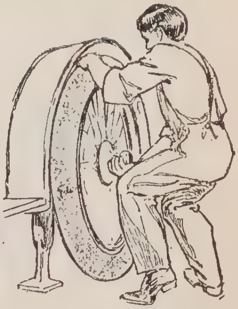

Fig. 29

Fig. 28. Wobbly wheels can be due to a sprung axle yoke or a sprung steering knuckle. Usually, the tendency to wobble is caused by side pressure on the wheels, called "skidding force," due to **skidding** against a car track or curb.

Fig. 29. Testing the rear-wheel bearings for play. Wobbly rear wheels are caused by their being **loose,** or rear axle ends **bent** due to **skidding** against curb or from car tracks.

Testing rear-wheel bearings: Lost motion in a rear-wheel bearing is best tested for by taking hold of the tire with one hand to steady the body, then working the wheel up and down with the other hand, assisted by the knee and lower portion of one leg (Fig. 29). When the right hand is placed on the hub, the right leg is often more conveniently used than the left, as shown in the illustration.

Keep spring clips tight: It is well to notice the spring clips occasionally, especially when the car is new. In fact, it is a good idea to tighten the bolts holding the spring clips occasionally. A loose spring clip will often cause a **disalignment.**

Why tires wear unevenly: Very often, when a front tire has a worn place around the tread, it is due to disalignment. The reason why a right rear tire wears faster than others is the fact that the crown of the road is oval, and also that as most of the driving is done on the right side, the weight is thrown more on that side.

Tighten the hub caps: Occasionally hub caps are lost through carelessness in replacing them after lubricant has been applied. While they should be set up snugly, undue force should not be used, as the threads of the brass member may become stripped. An excellent plan is to screw the caps up tightly, and then to tap the wrench a light blow with the hammer. Sometimes too much lubricant is used, and when tightening the cap, the grease gives one the impression that the cap is snug.

On wire wheels it is very necessary that the hub cap be drawn very tight, otherwise a noise and probable damage will result. See also page 601.

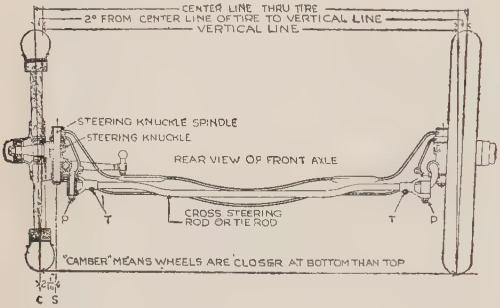
Adjustable stop screws on front axles: Adjustable screw stops (**C**) (Fig. 31, page 906) are provided in the body of the I-beam front axle against which, bosses forged integral with the steering-knuckle arms strike, to limit the cramping angle of the wheels; the amount of this cramping angle is determined by the interference of the tire with the chassis. The stops should be adjusted so that the tire does not come nearer than 1″ to any part of the frame.

CAMBER, TOE-IN AND CASTER; MEANING OF

These terms are often used in the instruction books of the various automobile manufacturers, but their meaning is vague. The following explanations will make them clear.

"Camber" of the Front Wheels

The front steering-knuckle spindles of a front axle are "cambered" about 2°, that is, the front wheels are closer together at the bottom or ground than they are at the highest point directly above.



CENTER LINE THRU TIRE

C S

Fig. 30. **"Camber"** of front wheels of the Columbia front axle. "Camber" means that the wheels are closer together at the bottom, due to the steering-knuckle spindle being placed at an angle instead of being perfectly vertical; thus the wheel itself is inclined 2°.

By observing the illustration (Fig. 30), which is a view taken when looking toward the front when seated in the car, it will be noted that a center line drawn through the center of the wheel is 2° from the vertical line.

This camber is given to the steering knuckles and spindle when they are machined, by tilting the steering knuckle. If the camber has been lost, due to a heavy shock on the wheels or axle, it can be recovered by bending the front axle between the spring seat and the steering-knuckle yoke. It is best to bend cold if possible. If the axle is heated, do not heat quite red.

The idea of cambering is to make the center line of the spindle bolt coincide, as near as it is practical, with the center of contact of the tire with the ground (C) to (S).

The purpose is to bring the point of contact of the tires with the road more nearly under the spindle pins, or king bolts, thus permitting the car to be steered more easily. Wheels have a tendency to spread apart at the bottom and to come together at top, when speeding.

On the **Ford,** the front wheels are cambered about 3°, or about 1 9/16″, that is, the distance between the front wheels at the top is greater than at the bottom. If a plumb line was dropped through the spindle, it should strike the ground at (S) (Fig. 30), or about 2 1/16″ from the pivot point of the wheel (C). This of course varies on different cars.

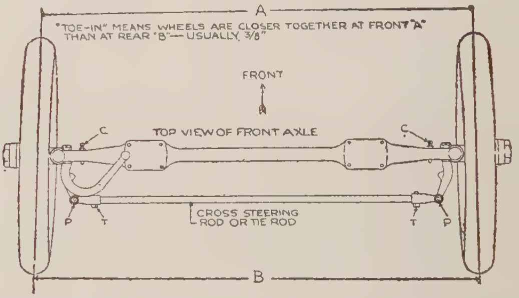
"Toe-in" of the Front Wheels

To offset the wearing action on the tires by the "camber," and to produce more even wear on them, the wheels are slightly "toed-in" at the front. An additional reason for this is, that when the car is running at high speeds, the wheels have a tendency to "toe-out." If toed-in too much, or not enough, the treads of the tires will grind.

The term "gather of the front wheels" is also sometimes used instead of "toe-in."

The cross-steering rod is so adjusted, that the distance between the front of the wheels (**A**) is from ¼″ to ⅜″ less than at the rear of the wheels (**B**) (Fig. 31), when measured in front of the tires about half-way up or in line with the horizontal center of the hubs. Usually the measurement is taken from inside of the felloe of one wheel to the other.

Do not compare "toe-in" with "camber," as "camber" means that the wheels are set in at the bottom.



A
"TOE-IN" MEANS WHEELS ARE CLOSER TOGETHER AT FRONT "A" THAN AT REAR "B"— USUALLY 3/8"

P
B

Fig. 31. **"Toe-in"** of the front wheels, meaning that the front wheels are closer together at (**A**) than at (**B**). The purpose of the adjustable stop screws (C) is explained on page 905.

The "toe-in" can be adjusted by adjusting the length of the tie rod from one steering-knuckle arm to the other, by removing the tie-rod yoke pin (**P**) (Fig. 31), loosening one or both clamp bolts (**T**), and screwing in or out until the wheels are given the proper adjustment. This adjustment should be made with the wheels on the ground. If inspection shows that the axle or spindles are bent, it will be necessary to have those parts straightened or replaced before correct alignment can be secured.

The average "toe-in" is ⅜″. On the Studebaker, Dodge, and many other cars this is the extent of the "toe-in." On the Ford, it is about ¼″.

As the steering knuckles become loosened from wear, the toe-in will become affected.

To check the toe-in: One method is shown in Fig. 33. Jack up the front axle. Make a center line on each tire as the wheels revolve. Then measure the distance from one line to the other. A straight stick with uprights can be used as shown in Fig. 33. The measurement should be made at points about where the tops of the upright are shown in the illustration, and this distance should be about ¼″ to ⅜″ less in front than at the rear, as at (A) (Figs. 31 and 32). Another method (and one that is more accurate) is shown in Fig. 34.

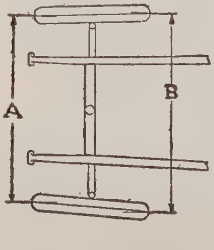

Fig. 32

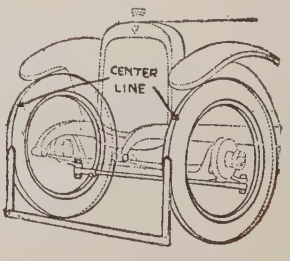

Fig. 33

Fig. 32. Another explanation (in addition to that given in Fig. 31) of "toe-in" of the front wheels.

Fig. 33. One method of checking "toe-in."

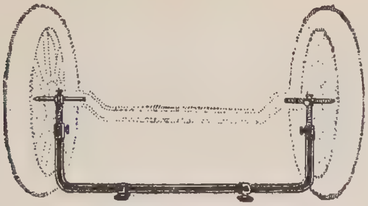

Fig. 34. This illustration shows an automobile **running-gear aligner,** which has a graduated scale and will make exact measurements on the felloe of the wheel, front and rear (instead of from center to center of the tire), at the exact horizontal center of the wheel. (Mfd. by the Mechanical Utilities Corpn., 1348 N. Clark St., Chicago, Ill.)

"Caster" of the Front-Axle Yoke and Steering Knuckles

This subject will require some explanation. We quote from the Timken manual on the subject as follows:

"**Caster steering effect:** You have noticed the casters on a bureau or bed. The little wheel touches the floor at a point to the rear of the caster's vertical axis.

"Because of this the wheel **trails,** and does not tend to change the direction of motion of the bed. Steering the bed in any direction is done with scarcely any effort.

"The principle of caster steering was introduced into Timken Detroit front axles some years ago, but by a construction somewhat different and more effective than that of a bed caster.

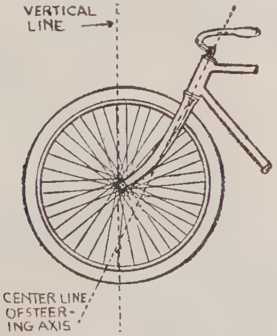

Fig. 35. The steering axis meets the ground in advance of the point of contact of the wheel. This is termed **"caster action."** This is why the handle bar will come back to position when released, and why one can pedal a bicycle with "hands off."

If one strikes a rut or hole with a "caster action," the jar is not nearly as great as if there were no "caster action," or if the frame were vertical.

The caster principle is one that has long been used in the front wheel of a bicycle. The axle is mounted so that it tilts slightly forward at the bottom. As in a bicycle, straight lines passing through the steering heads, or the pins of the steering knuckles, meet the ground a little in advance of the points of contact with the front wheels, so that each wheel really **trails** behind its steering axis.

"That is why the bicyclist can steer without using his hands.

"This particular method of effecting caster steering brings another and a very great advantage to the driver of a car.

"It would require considerable technical discussion to explain what can easily be seen by examining a bicycle. Turning the wheels to the right or left actually raises the body of the car slightly; thus the weight of the vehicle tends to bring the wheels back to the straight fore-and-aft position.

"This gives added security, for, if the steering gear should break or escape your control, the very weight of the car will tend to keep it on its course.

"The safety of Timken-Detroit construction received a remarkable demonstration by a prominent American racing car on the Speedway at Indianapolis.

"The cross-rod connecting the two steering knuckles in the front axle was removed. Thus steering could be effected through the control of only one wheel; the other front wheel was absolutely independent of control.

"With the two steering knuckles thus disconnected, the car was run several times around the Speedway at forty miles an hour."

This "caster" effect is given to the steering knuckle at the factory, and it varies, with different manufacturers, **from 2° to 14°, depending** on the type of car.

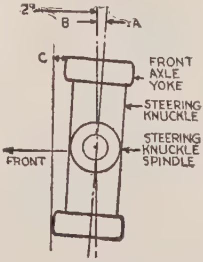

Fig. 36

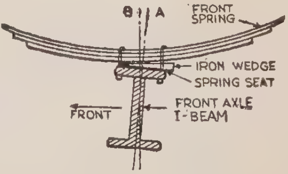

Fig. 37

Fig. 36. The illustration is supposed to represent the end view of a front axle looking at the end of the steering knuckle. Line (**A**) is a center line through the center of the knuckle and axle end, which represents the **"caster"** or angle at which the steering knuckle is inclined from the vertical line (**B**), which is about 2°. The distance at line (**C**) is about 3/16" or ¼".

Fig. 37. An exaggerated illustration showing how to **wedge** between the front spring and the spring seat **to give a "cant" or "caster"** effect to the steering-knuckle spindle on the front axle.

By observing Fig. 36, it will be noticed that the steering knuckle is inclined slightly, at the top, away from the direction of travel. The center of the steering knuckle (**A**) is about 2° off the vertical (**B**).

Thus the front wheels are purposely placed 2° out of perpendicular (or "castered"), in order to bring the point of contact between tire and road more directly under the steering spindle, thus insuring easier steering and less vibration when striking ruts, holes, etc., in the road.

A serious disalignment, perpendicularly, is occasioned only after a very severe shock, and in such a case it is advisable to repair or replace, as soon as possible the front axle or steering knuckle which has been injured to such an extent as to spring it badly.

If the axle is not sprung and is in line, as in Figs. 23 and 24 (page 904), but is tilted forward at the top, instead of backward, it can be temporarily given the caster effect by wedging the front springs between the spring and spring seat, as shown in Fig. 37, which will give a slight cant to the front axle. The wedge can be placed at the front or rear of the spring to give the desired effect.

REMOVING, CLEANING, AND ADJUSTING FRONT WHEEL BEARINGS; ALSO STEERING KNUCKLE PINS

All front-wheel bearings are of the roller or the ball type. The adjustments are given on next page, and full instructions are also given just how to take-up on steering-knuckle pin if loose or worn.

Removing, Cleaning and Adjusting Front Wheel Roller Bearings

As an example, the Timken will be used (Fig. 38). Front wheel bearings in ordinary service should be removed, cleaned, greased, and readjusted at least twice a year. If the service is unusually severe, the condition of the lubricant and the bearing adjustment should be inspected every two or three months.

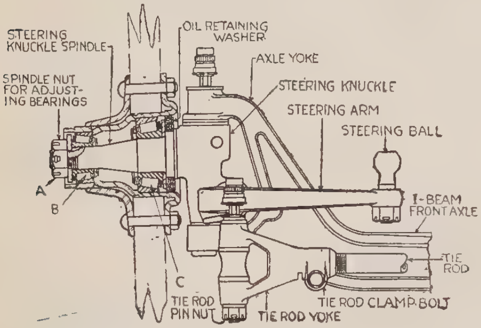

Fig. 38. The Timken-Detroit front axle steering knuckle of the Elliott type.

To remove the bearings, take off the hub cap and jack the wheel up clear of the ground. Wipe the grease from the end of the spindle and take off the **castellated nut (A)** (Fig. 38) after pulling out the cotter pin which locks it.

Now, kneeling directly in front of the wheel, grasp the rim with both hands and pull directly toward you, being careful not to let the outer bearing slip from the hub and fall to the floor, as this may bend or damage the cage so that the bearing will not render perfect service when replaced.

The outer bearing (B) having been removed, lift the wheel off the spindle, exposing the inner bearing.

With a stiff brush and gasoline or kerosene, clean all old grease from the bearings, spindle, and inside of the hub. It is not necessary to remove the inner bearing (C) from the spindle to clean it, although it can be removed if desired.

Occasionally both bearings should be removed, placed in a solution of washing soda and water, and brought to a boil. This cleans off any grease from behind the rollers which may not have been removed by the brush and gasoline.

The bearings having been thoroughly cleaned and dried, replace the larger, or inner, bearing on the spindle, covering it well with good clean grease free from acid, grit, or any solid matter. Care should be taken to have no grit or dirt on the paddle. Pack the inside of the hub between the two bearing cups, and cover the outer bearing with grease.

Adjusting front-wheel bearings: Now replace the wheel and, holding it firmly in position, slide the smaller or outer bearing on the spindle, pressing it firmly into the hub.

Slide on the keyed lock washer and screw the adjusting nut tightly up against it, so that the wheel binds, at the same time revolving the wheel to insure all working surfaces on the bearings coming in contact.

Now **back off** the adjusting nut just enough to allow the wheel to rotate freely, but without noticeable end play. Lock the nut at this point with the cotter pin.

Be sure your bearing adjustment is right before locking it—**the wheel should be loose enough to oscillate,** that is, when spun, it should come to a stop and then start to turn back in the opposite direction, but not loose enough to have any amount of shake.

When your adjustment is correct, cover the end of the spindle with grease and replace the hub cap, screwing it up tightly.

Adjustment of steering-knuckle bearing: Timken heavy-type passenger-car front axles, and some front axles for cars of medium weight, are fitted with a Timken roller bearing in the steering knuckle head (Fig. 38).

To adjust this bearing tighten up on the nut on the bottom of the knuckle pin after removing the cotter pin. This forces the bushing on the lower boss of the yoke up against the steering knuckle, which in turn forces the bearing up into the cup for a proper seat.

Do not fail to lubricate this bearing thoroughly with a good quality of cup grease through the cup on the top of the knuckle pin.

Removing, Cleaning, and Adjusting Front-Wheel Ball Bearings (Chevrolet "490" as an Example)

The front wheel bearings used on Chevrolet cars are of the cup-and-cone type, and are very easily adjusted. See Fig. 39.

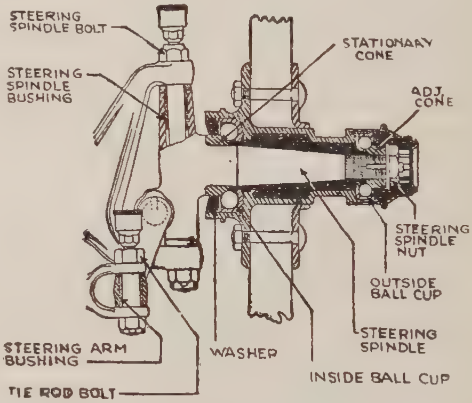

Fig. 39

To keep the bearings clean and well lubricated is an absolute necessity if you are to secure maximum efficiency. Once a month the front wheels should be removed and the bearings thoroughly washed in gasoline or kerosene.

To remove the wheel, unscrew the hub cap, spindle nut, and adjusting cone. (See note below.) The wheel can then be slid off the spindle. The adjusting cones screw on the spindle and can be removed with a wrench, gripping the milled faces. The **hub caps** have right-hand threads, unless wire wheels are used.

The front wheels should fit the steering spindle snugly without end play.

To adjust the bearings, spin the wheel and at the same time screw the adjusting cone up until it is tight enough to stop the rotation of the wheel; then unscrew the adjusting cone just enough to allow the wheel to spin.

Note: The **lock nut and adjusting cone** on the right-hand wheel (as viewed when one is seated in the car) has left-hand threads. To unscrew, turn to the right. The lock nut on the left-hand wheel has right-hand threads. To remove, turn to the left. When the lock nuts are removed, the wheel can be pulled off very easily, as the cone merely slides on the spindle.

Before replacing the wheel, examine the felt washer. If it is damaged, replace it after prying out the retaining washer. Press the cone in as far as possible and slide on the retaining washer. Then turn the cone until the lug on the washer fits into the recess on the back of the cone to prevent its turning. Tighten up the lock nut until the wheel has no perceptible side play on the spindle, but still revolves very freely; then replace the cotter pin and spread it and then screw the hub cap in place.

To lubricate the bearings, remove the hub cap and pack it full of cup grease, and replace. If the bearing is dry, repeat this operation two or three times.

If grease runs out, between the hub of the front wheel and the steering knuckle, the cause is either too much grease or a defective felt washer.

Adjustment of Front-Wheel Bearings and Front-Axle Steering Knuckle (Mitchell Model "F" as an Example)

There are two adjustments in connection with the front axle, namely, the wheel bearings, and the steering-knuckle ball bearing.

Should play develop between the steering knuckle and the axle, it may be taken up by loosening the nut at the bottom of the pivot pin and tightening the pin by screwing it down. It should be tightened just enough to remove the play and not enough to bind the bearing. With the adjustment made, the nut should be replaced on the bottom of the pin and locked with a cotter pin.

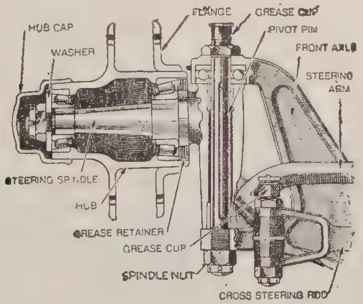

Fig. 40

In reassembling the wheels on the steering knuckles, or in taking up play, the bearings should be carefully cleaned, the hub packed with grease, and the wheel mounted on the spindle with the bearings in place. The washer should then be mounted on the end of the steering knuckle and the nut drawn up. The wheels should be rotated by hand while the nut is being drawn up, and the nut tightened until the wheel binds. Turn the nut back until the cotter-pin hole in the spindle registers with the next slot in the nut. Rap the wheel outward to free the bearings, and see if the wheel spins freely, when the nut should be locked in place with a cotter pin.

The correct adjustment is had when the wheel revolves freely with just a perceptible shake in the bearings.

Grease should be packed inside the hub cap, and the hub cap mounted.

Testing for Play in the Wheel Bearings

Play in the rear or front wheels can be detected by jacking up the car, grasping the rim, and working the wheel laterally (Fig. 26, page 905).

If the wheel shows looseness, the adjustment nut should be tightened. This nut is located within the hub cap, and whatever its shape may be, it is made so that a slight turn makes a considerable change in adjustment. Do not have the wheels too tight, but turn the nut until the wobble disappears.

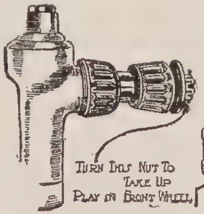

Fig. 41

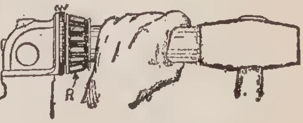

Fig. 42

Fig. 41. Taking up play in a front wheel having roller bearings.

Fig. 42. **A good method of getting the bearing into position** is to slip a short length of pipe over the spindle, against the inner shell of the bearing, and to drive the bearing to its proper place by hammering on the pipe.

In case of ball-bearing wheels, it would be well to take out all the balls and examine them for wear. If any signs of wear are found, remove and replace the worn balls at once. The ball races should be carefully cleaned with gasoline and freed from the slightest suspicion of grit. The same attention as regards cleaning should be given the bearings.

If a "click" is heard when turning the front wheels with ball bearings, look for a broken or cracked ball, and remove it at once, otherwise it will ruin the entire bearing.

Do not fail to see that the felt washer or grease-retainer washer is in place, so that grease will not work out between inner part of the hub and the bearing, when replacing.

To Adjust Steering Knuckle

Steering yoke and knuckle: Wear between the steering yoke and knuckle can be taken up by a thin shim put under the bottom of the steering knuckle if it is worn to such an extent that the adjustment does not take up the wear.

Steering-knuckle pin and bushings: Steering knuckle pins and bushings are usually assembled with a clearance of .005″. This clearance permits a perceptible looseness of the pins in the bushings, but with a closer fit than this, steering becomes stiff.

An Example of Rebushing a Front-Axle King-Pin Bearing

For this example we shall use the front-axle assembly of the Traffic truck. Note the **lower and upper bronze bushing** in the axle yoke which is the bearing surface for the king-pin or steering-knuckle pin.

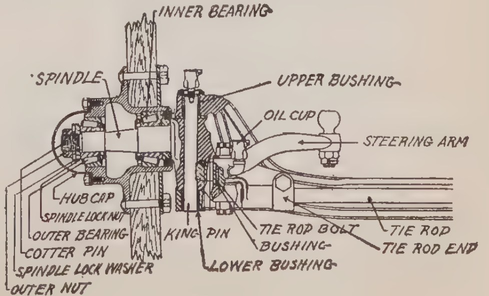

Fig. 43

After most trucks have been in service for a considerable period of time, certain parts of the front axle will become worn to such an extent as to cause "lost mostion" or looseness in steering. This wear depends almost entirely upon the lubrication the various parts receive.

In designing the Traffic truck these points were taken into consideration, and therefore bronze bushings are provided in all such parts as are most subjected to wear. Such bushings will be found at the upper and lower ends of the axle yoke in which the king-pin revolves, and in the tie-rod ends.

There is nothing difficult about replacing the bushings, as the work may be done with the aid of such tools as the average truck owner has in his possession.

To replace the axle bushings it will be necessary first to remove the king-pins and steering spindles. This may be done by raising the front axle until the weight of the truck is removed from the front wheels, removing the steering arms and driving out the steering-spindle king-pins. The bushings may now be driven out with a flat end punch slightly smaller than their outer diameter. The tie-rod end-bushings may be driven out in a similar manner.

The new bushing is now driven in, taking care that it goes in perfectly straight so as not to affect the "line-up" with the other parts. As the bushing will shrink when being pressed in, it is usually necessary to bore out its inner wall slightly so as to make it the exact diameter of the king-pin or bolt it is to receive. This may be done with a special reaming tool, care being taken that it does not wobble or chatter when being turned through the bushing, as this will destroy the bearing surface.

The new part should not bind in the bushing, as this will prevent lubrication, causing the bushing to "freeze" or seize the king-pin or bolt.

TYPES OF FRONT-AXLE STEERING KNUCKLES

Types of Front Axles

The principle of steering an automobile, as explained on page 10, is termed the **Ackerman** principle.

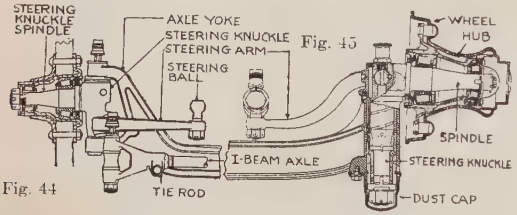

Fig. 44

Fig. 45

The type of **front-axle steering knuckle** in general use is the **Elliott** (Fig. 44).

Another type, the **Lemoine,** used on the Marmon, is shown in Fig. 45.

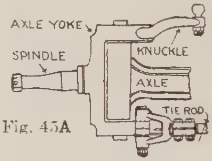

Fig. 45A

In the **reversed Elliott type** (Fig. 45A), the yoke is mounted on the steering knuckle spindle, while the steering knuckle is mounted on the axle. (Used to a limited extent on some large vehicles, such as busses, which permit a very low center of gravity.)

ADJUSTMENTS OF TIMKEN REAR AXLE DRIVE PINION AND BEARINGS

The rear-axle **drive pinion and bearing adjustments** (Figs 46, 47, 48) are on later types of Timken axles than those shown on pages 865, 867.

There are three conditions which make adjustment of drive pinion, differential gears, and bearings necessary: (1) noise; (2) excessive backlash in gears; (3) loose pinion or differential bearings.

Noise is the most common condition—see instructions on pages 865, 867. Be sure the drive-pinion shaft bearings and differential bearings are properly adjusted.

Adjustment of Timken drive-pinion shaft bearing (Fig. 46): Remove cap screws (O) and (X) which hold the bearing cage (L). After removing cage, add or remove shims (M) until properly adjusted, which is about .003" loose, or the thickness of thinnest shim.

Adjustment of drive pinion gear (Fig. 46) **to eliminate noise and backlash,** is made by loosening cap screws (O) and turning (B).

Adjustment of differential bearings is made by tightening up on adjusting rings (J) and (K) as explained on page 865.

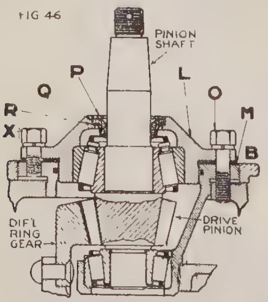

Fig. 46. Timken Model 5014, rear-axle drive pinion adjustment. Note oil seal (Q). Adjustment of **bearings,** by removing shims (M); adjustment of **mesh of drive pinion** and ring gear, by turning (B).

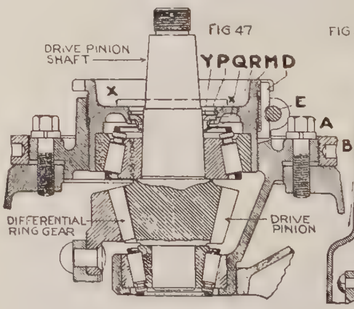
Adjustment of Timken drive pinion for backlash and elimination of noise (Fig. 47): Loosen cap screws (A) and turn adjusting ring (B) about 2" to the left. Tighten (A) and run axle to determine whether noise has increased or lessened. If lessened, continue adjustment by turning (B) to left until quietest point is found. If noise is increased, then adjust (B) to right to obtain quietest running position. Tighten (A).

Adjustment of drive pinion shaft bearing (Fig. 47): Remove lock bolt (E) and lock (D), and turn adjusting cap (M).

Adjustment of differential bearings is made by tightening up on adjusting rings (J) and (K), as explained on page 865.



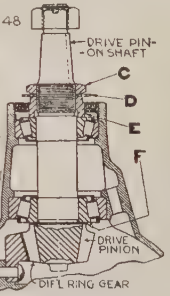


Fig. 47. Timken Models 5114, 5140, rear-axle drive pinion. Note oil seal (Q). **Bearing** adjustment, by turning (M); mesh of **drive pinion** and ring gear, by turning (B).

Fig. 48. Timken Model 0500, rear-axle drive pinion. **Bearing** adjustment, by turning (E); mesh of drive pinion and ring gear, by removing or adding shims (F).

Oil seal: In Figs. 46 and 47 there is a hydraulic cup leather (Q) oil seal used on drive-pinion shaft. The seals need no attention, as a special tension spring (Y) keeps the leather cup tight. After long use it may be necessary to replace (Q). If so, remove lock wire (P) and outer tension spring (Y). This releases the tension on the cup leather (Q) which can be removed. To remove axle-shaft oil seal, it is first necessary to pull out axle shaft from housing. This oil seal is also used on fixed hub types of axle shafts, as on page 883.

Adjustment of Timken drive pinion shaft bearings (Fig. 48): First straighten lock washer (D). Loosen lock nut (C). Tighten adjustment nut (E) until shaft turns freely without noticeable end-play. Tighten (C) and peen over (D).

Adjustment of drive pinion for backlash to eliminate noise (Fig. 48): Move drive pinion in toward ring gear by adding shims (F). To move drive pinion in opposite direction, remove shims (F) as required.

Adjustment of differential bearings is made by tightening up on adjusting ring (J) and (K), similar to explanation on page 865.

INSTRUCTION No. 76

COMMERCIAL CARS: Trucks; Types and Construction; Transmissions; Truck Engines; Governors; Truck Chains; Dump Bodies and Hoists; Trailers; Truck Axles; Worm-Gear Ratio; Taxicabs

Commercial cars include those cars principally used for commercial purposes, such as trucks and taxicabs.

It is interesting to note that the automobile truck and delivery-wagon manufacturers have increased at a very rapid rate, even greater in proportion than the manufacturers of the passenger car.

There were 10,449,785 passenger cars and trucks registered in 1921: a gain of 1,517,327 over 1920, or 16.9 per cent. Thus the importance of the automotive industry and its potential needs is plain.

TRUCKS: GENERAL EXPLANATIONS

Probably the subject of trucks will interest many of our readers, as it is fast taking the place of horse-drawn vehicles. There is not much to be treated under this head, however, as the truck, as a whole, involves precisely the same principle as the pleasure car—with the exception of minor details of construction which will be taken up in their respective order.

Therefore for one to master the truck construction and operation, he has but to refer to the subjects of **engines, carburetion, ignition, lubrication, operating a car, etc.,** discussed elsewhere in these pages.

Truck Motive Power

Motive power used for trucks is derived from:

1. Gasoline engines (used most).
2. Gasoline engines and electric motors.
3. Electric motors.
4. Steam.

Truck Engines

The general principles of the gasoline engines, as generally employed on trucks, are identically the same as those used on pleasure cars; the ignition, carburetion, clutch, and all parts, with minor exceptions, such as governor and starter, and the drive principle, are identically the same. Therefore, if the reader will master these subjects, he will then understand the construction of a truck.

Four-cylinder engines are used mostly on trucks. Some manufacturers use the two-cylinder-opposed type of engine, but not the six, eight, or twelve. See page 936 for a typical truck engine.

The four-cylinder engine is more efficient for truck and tractor use than a six or twelve-cylinder engine. The four has less parts, is simpler to care for, and as its speed is less than that of a pleasure car, the four-cylinder engine is the adopted type for trucks and tractors. See also pages 937, 38, 39.

The main difference between a passenger-car engine and a truck engine is explained below.

Passenger-car engines must be constructed as lightly as possible consistent with strength, so that the total weight of the car can be kept at a minimum. It is rarely ever called upon for its maximum power at any speed, and only a small percentage of developed power is required under normal driving conditions. The result is that the resistance offered the power impulses is small in proportion to the developed power of the motor. Therefore in design, the weight and strength of the reciprocating parts are in proportion to the resistance offered the power impulses in average service. Consequently the engine is lightly constructed throughout, accelerates quickly, and attains a high speed.

Truck engines are called upon for a larger percentage of their developed power at practically all times. Therefore the moving parts are more generous in size, and are designed to withstand greater strains. The engine must operate for long periods of time under a great many unfavorable conditions, such as heat and dust. This calls for more adequate cooling facilities and generous water radiating surface.

Ignition must be positive and simple, and as the speed is limited, and because of the governor action on the carburetion mixture to the cylinders, the magneto is the adopted type of ignition for most trucks.

Starting is usually by hand crank in connection with the "impulse" starter. See also pages 281, 286.

Governor: A great number of trucks use governors. **Gasoline feed** is usually gravity principle.

Truck Drive Methods

The driving methods are:

1. Double-chain drive.
2. Propeller-shaft drive (used most).
3. Two-wheel drive.
4. Four-wheel drive.

The double-chain drive has the advantage of a solid or "dead" rear axle, but has the disadvantage of a chain, which causes considerable wear and jerky action.

The worm-driven rear axle with a propeller-shaft drive method is considered the best. A "live" axle is used, but constructed in such a manner that it is as substantial as a "dead" axle.

The maximum speed of the average truck is 9 m.p.h. for heavy duty, and 25 m.p.h. for light duty trucks.

Types of Trucks

Trucks are classified as to their carrying capacity, and are usually rated as ½-ton, ¾-ton, 1-ton, 1½-ton, 2-ton, 2½-ton, 3½-ton, and 5-ton capacity. Those in greatest use are of 1 and 2-ton capacity.

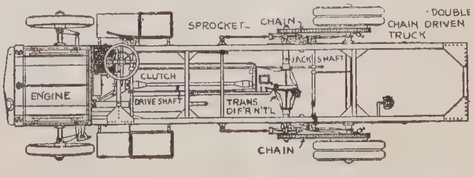

Fig. 1. Top or plan view of a truck chassis using a **double-chain drive.** Note that the rear axle is a "dead" type of axle, and the differential is mounted on the jack-shaft (see pages 6 and 15). The engine is a four-cylinder engine. In fact, most truck engines are four-cylinder (see pages 937, 38, 39).

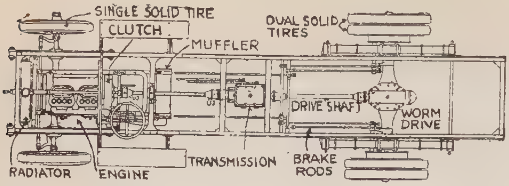

Fig. 2. Top or plan view of a truck chassis using a **propeller-shaft and worm-gear drive.** Note that the rear axle is a "live" type of rear axle. The differential is mounted on the axle shafts.

We shall classify commercial cars in three divisions: motor delivery, trucks, and taxicabs.

When the ½, ¾, 1 and 1½-ton trucks are fitted with pneumatic tires, they are called "motor delivery" or "speed wagons," etc.

How to select a car for commercial use is treated elsewhere. See page 640.

The motor delivery is usually an automobile of the passenger-car class, with a special delivery body, as illustrated in Fig. 3. Inasmuch as this type of car was treated in previous instructions, it will not be further dealt with here.

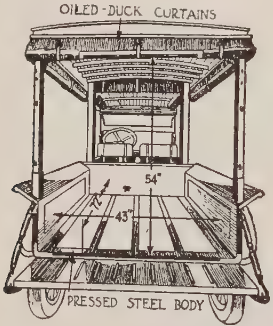

Fig. 3. Dodge light delivery.

The specifications of a light motor delivery are similar to those of the standard passenger car, except that various parts have been strengthened.

The gasoline tank is beneath the driver's seat, and the steering wheel has been set at a higher angle to give a greater loading space.

Maximum load	1,000 to 1,500 lbs.
Tires	33" x 4"
Loading space	72" x 43"
Wheelbase	114"
Clutch	dry plate
Gear ratio	4 to 1
Body	steel, 54"high

The truck is constructed along the same lines, except that the chassis, engine, axle, and all parts are heavier, and the chain or worm drive is usually employed.

Truck Gear Shifts and Gear Ratio

The gear shift is usually the S. A. E. standard three-speed (page 29) for **light-duty** trucks, such as 1-ton capacity and under, and the S. A. E. standard four-speed truck gear shift (Fig. 4) for **heavy-duty** trucks of 2-ton capacity and over.

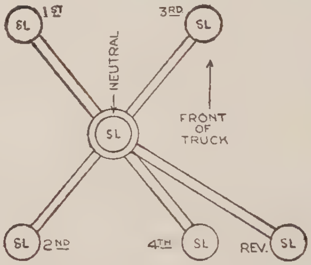

Fig. 4. Standard 4-speed S.A.E. truck-gear shift position.

Gear ratio: Three speeds forward are usually provided on **light-duty** or high-speed trucks under 2-ton capacity. Many of the manufacturers are adding a 4-speed transmission, however.

Heavy-duty trucks of 2-ton capacity and over, are usually equipped with a 4-speed transmission, the ratio of the fourth speed being 1, or **direct drive** from the engine to the rear axle. On some trucks, the fourth speed is higher than the direct drive.

Details of Three Models

Capacity, lbs.	2,000	4,000	7,000
Price	$1,575	$2,200	$3,000
Wheelbase, in.	128	148	168
Tires, front	34x3	36x4	36x5
Tires, rear	34x4	36x6	40x5
Bore	3½	4⅛	4½
Stroke	5	5¼	5½
Horse power	19.61	27.20	32.40
Speed, r.p.m.	1,700	1,300	1,200
Speed, m.p.h.	22	17	9 to 14
Gear, ratio in high gear	7¾-1	8½-1	10¼-1
Final drive	Worm	Worm	Worm

Operating a Truck

It would be merely a repetition to go into details here regarding the operation of a truck, because it involves identically the same principles as explained in connection with the operation of a pleasure car.

Trailers: See Index.

FORD ONE-TON TRUCK

The engine, with its ignition and carburetion, cooling and lubrication systems, is the same as the model "T" (see Ford instruction).

The clutch is the standard Ford multiple disk in oil, delivering the drive to a two-speed planetary gearset in unit with the engine. From here the final drive is by means of a propeller shaft and **overhead worm,** instead of a bevel pinion gear.

From the worm the drive transmission passes through the bevel-gear differential and semi-floating rear axle to the rear wheels.

The Ford truck is rated at 1-ton capacity and has 30" x 3½" pneumatic tires in front and 32" x 4½" in the rear. It can be specially equipped with solid tires on the rear wheels.

The wheel base is 123" instead of 100". **Weight of the truck chassis,** with solid tires in rear, 1,395 lbs.; with demountable rims for pneumatic tires, 1,340 lbs.

The springs are of the same principle as those used in the Ford passenger car, excepting that they are made heavier in the rear to withstand a great load. This is a transverse type, having an arch in the center.

The wheels are of the wood artillery type. **Brakes, steering gear, control system,** etc., are the same as on the model "T."

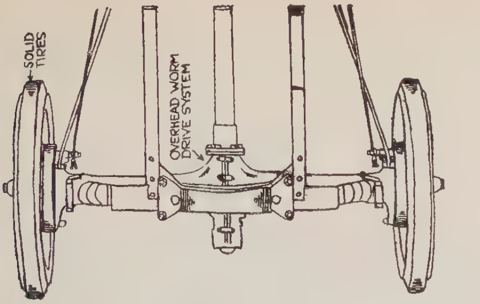

Fig. 5. The Ford worm gear rear axle and heavier springs are the features in which the Ford truck differs chiefly from the Ford passenger car. Pneumatic tires are standard equipment. Solid tires can be obtained specially.

The principal changes are in the rear worm drive, and heavier rear spring and tire equipment.

Tail and side lights are oil or electric. The frame is larger and heavier.

To obtain details of construction, adjustments, etc., other than of the rear axle, see the Ford instruction.

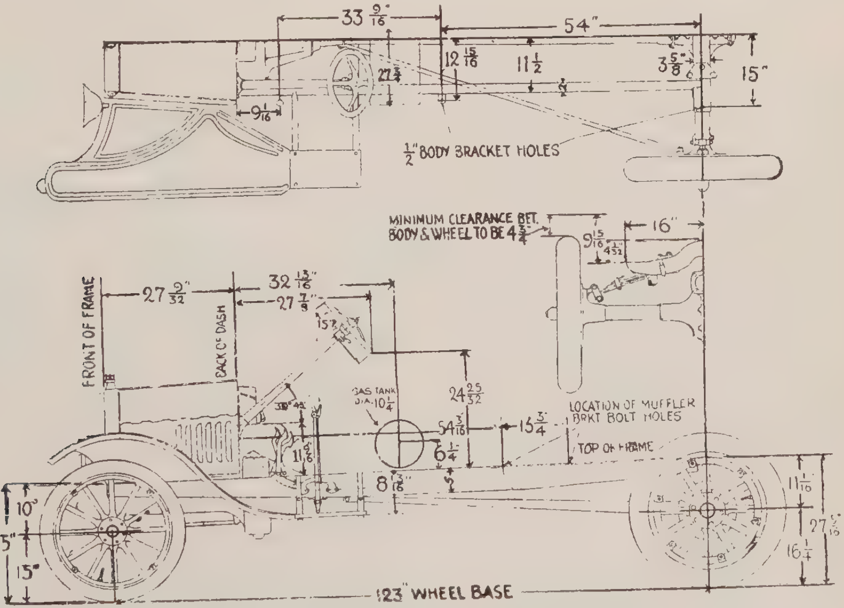

Fig. 6. Dimensions of the Ford truck chassis, from which one can estimate the dimensions for suitable bodies for various purposes.

The Ford truck chassis includes a hood for the motor, front fenders, stepping boards, headlights, tail light, horn, and a set of tools. The starting and lighting system is optional.

The Ford truck may be purchased either with standard or special gearing. The standard gearing gives the truck a maximum of power. The special gearing increases the speed of the truck from five to seven miles an hour, converting it into a fast delivery car.

The rear axle reduction of the worm and gear of the standard gearing is 7¼ to 1 on high gear. The worm gear has 29 teeth, and the worm has 4 threads cut on it; consequently the ratio is 29÷4=7.25. On low gear the total gear reduction is 19.9 to 1, and on reverse 29 to 1. See page 956; "How to compute worm-gear ratio" and also page 8 for the meaning of "Gear ratio."

The rear axle reduction of the worm and gear of the special gearing is 5 1/6 to 1 on high; 14 to 1 on low; and 21 to 1 on reverse speed.

This rear axle is of the "plain live type" construction, because the inner bearings are on the axle shaft and the axle shaft supports the differential.

Ford Truck Specifications Condensed

Engine: Four-cylinder; cylinders cast in block; bore, 3¾"; stroke, 4"; horsepower, 20.

Frame: Heavy pressed steel.

Transmission: Special Ford planetary type; multiple steel disk clutch operating in oil.

Gear ratio: Choice of standard gearing (7¼ to 1) or special gearing (5 1/6 to 1).

Final drive: Worm-gear type.

Starter: Ford starting and lighting system—optional.

Wheel base: 124 inches.

Wheel equipment: Demountable rims, pneumatic tires front 30" x 3½", rear 32" x 4½". (Solid tires for rear wheels optional.)

Capacity: One ton. Price $380. (Elect. starter, etc., $70 extra.)

Speed: With standard gearing, a speed of not more than 15 m.p.h. is recommended, and with the special gearing, a speed of not more than 22 m.p.h. is recommended.

Disassembling Rear Axle and Differential (Ford Truck)

First, remove the entire rear system from the car, which is done as follows:

1. Jack up the frame of the truck to raise the rear. If a hoist is available, it will serve the purpose very well.
2. Disconnect the universal (see Ford instruction).
3. Disconnect the front end of the radius rods.
4. Disconnect the brake rods.

   If the rear spring shackles are now disassembled, thereby freeing the rear system from the frame, the entire rear system may be rolled from the truck.

5. Raise the rear system and support the axle housing near each end. A pair of carpenter's horses will be handy for supports.

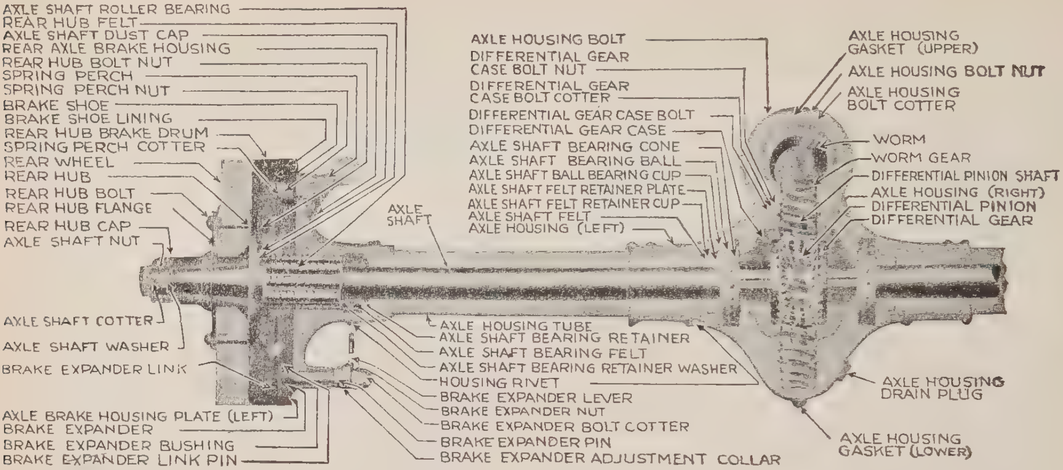

Fig. 7. Ford truck rear axle—longitudinal view.

6. Unscrew the drive-shaft tube-flange screws.
7. Remove the rear-axle housing cap.
8. Take out the bolts which join the two halves of the axle housing.
9. Remove the rear wheels, after which the two halves of the axle housing may be pulled apart, thereby exposing the differential to view.

The differential gear case may now be disassembled.

To remove the worm, proceed as follows:

1. Take out the drive shaft to worm coupling pins.
2. Remove the front-worm roller bearing with its retainer and felt. These can be slipped over the coupling.
3. Now drive the coupling from the drive shaft after which the worm should be forced from the coupling.
4. Unscrew the worm-thrust bearing-retainer nut, after which the retaining washer, thrust bearing, and rear-worm roller bearing can be taken off.

The differential gears fit on splines cut on the axle shaft. They are held in place by means of two half-rings which fit into a groove cut in axle shaft.

To remove, force them toward the wheel end of shaft, and drive out the two half-rings. Then force the gear off the differential end of the shaft.

Reassembling

In reassembling the system, take care to replace parts correctly and to use new paper liners.

Lubrication of the rear axle is accomplished by the use of a good semi-fluid oil, and it is only necessary to see that an adequate supply is in the axle housing. A new truck should have its axle lubricant changed after 500 miles, again after 1,000 miles, and thereafter whenever the condition of the lubricant demands it. Two grease cups insure the lubrication of the axle-shaft roller bearings. These cups should be filled with cup grease and should be given one complete turn every 100 miles.

After reassembling a rear axle, the truck should be jacked up; the differential should be filled with oil, and then run for 10 minutes to allow the lubricant to reach all parts.

Adjustments: As on the Ford passenger car, there are no adjustments on the rear axle. When the parts are worn they are replaced, the parts costing less than the repair.

G.M.C. MODEL "K41" TWO-TON TRUCK

Specifications

This model is built in two lengths: type "A," 146″ wheel base; type "B," 158″ wheel base.

Load capacity: 4,000 pounds, with additional maximum allowance of 1,500 pounds for body equipment.

Engine: G.M.C. design and manufacture; four-cylinder "L" head, water cooled; bore 4″; stroke 5½″.

Horse power: By S.A.E. formula, 25.6; actual horse power at governed speed, 37.

Cylinder and crank case: Cast in unit; cylinders, removable sleeve type.

Lubrication: Positive pressure system from gear pump, forcing oil with constant pressure to all bearings of engine; chassis lubrication by pressure-gun system.

Governor: Fly-ball type of special manufacture.

Carburetor and fuel supply: G.M.C. two-jet type of carburetor with special heated intake manifold; fuel by gravity from sheet-steel tank of 20½ gallons capacity.

Cooling: Combination pump-driven and thermo-siphon; pump capacity approximately 20 gallons per minute.

Radiator: Continuous fin, tubular, built-up type; capacity 7½ gallons.

Ignition: High-tension magneto with impulse-starter coupling.

Clutch: Multiple-disk dry-plate type of special manufacture.

Transmission: G.M.C. selective two-range transmission, each range having four forward speeds and one reverse; in unit with the engine; provisions for tire pump and power takeoff.

Rear axle: Worm drive, full floating, with gear ratio of 7.25 to 1; drive through radius rods from rear axle to frame.

Frame: Pressed open-hearth steel, heat treated.

Brakes: Service and emergency, both internal expanding; interchangeable brake rods, meaning that when the foot-brake linings become worn, the pedal may be connected to the hand-brake linings, which are usually in good condition, because the hand brake is not used as much as the foot brake. The hand-brake lever is then connected with the old foot-brake linings which are sufficient to hold the truck, as the hand brake is only used to lock the truck when stopped.

Wheels: Metal, hollow-spoke type.

Tires: Solid, 36″x4″ front; 36″x7″ rear. Pneumatic, non-skid cords, 36″x6″ front and 40″x8″ rear, supplied at extra cost.

Maximum body length: A, 11½ ft.; B, 13½ ft.

Road Clearance: Rear axle, 9½″, solid tires; 12″ pneumatic tires.

Turning radius: Type "A," 28½ ft.; type "B," 31 ft.

Weight of chassis: Type "A," 5,245 pounds; type "B," 5,285 pounds.

Controls: Left-hand steering and center control; spark and throttle levers located on segment with connections outside of steering column; foot throttle operated by driver's right foot; ignition and light switches, oil gauge, ammeter, and choker throttle located in instrument case on dash.

Equipment: Electric headlamps mounted on radiator side members, electric tail lamp, generator and storage battery, horn, tool kit, and jack.

Fig. 9. **Top and side view of G.M.C. 2-ton truck chassis,** equipped with solid tires, giving the principal dimensions. The load capacity is 4,000 lbs. In addition to the body for which 1,500 lbs. is allowed. When the load of 4,000 lbs. is removed, the frame will rise 3″.

The main features in which the G.M.C truck differs from other trucks is in the **two-range transmission** and the **engine cylinders fitted with sleeves.**

Engine

Engine: 4-cylinder "L-"type; detachable head. Removable cast-iron cylinder sleeves (or barrels) pressed into the cylinder block are used. These sleeves can be removed when worn and new ones substituted. Thus if a cylinder is scored, or if the cylinder wall is damaged, it is not necessary to re-bore; pull out the sleeve and substitute a new one.

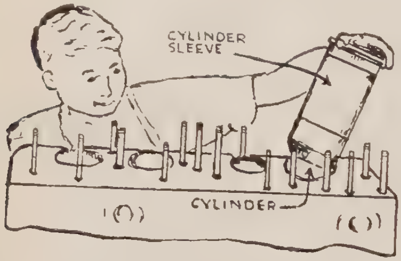

Fig. 10. Illustrating a "cylinder-sleeve" removed from the cylinder block. The piston moves in this sleeve.

To remove the sleeves, the cylinder head is removed and the oil pan is removed so as to remove the piston and connecting rod. The sleeve is withdrawn and replaced by a special assembly tool (Figs. 11 and 12), explained as follows:

To Remove Cylinder Sleeve

To remove the sleeve, first take off the cylinder head and oil pan, and withdraw the piston and connecting-rod assembly from the cylinder to be replaced.

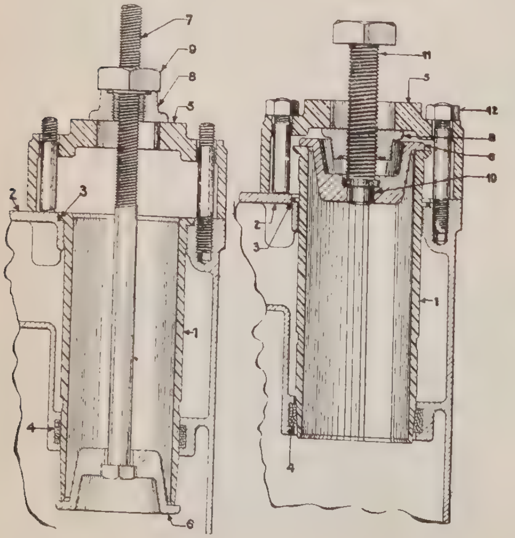

Fig. 11 Fig. 12

Fig. 11. Removing the cylinder sleeve.

Fig. 12. Replacing the cylinder sleeve.

Refer to Fig. 11 for an assembly of the tool in place for withdrawing the damaged sleeve. First, insert the long bolt (7) in the bottom plate (6) and place this in the sleeve (1) as shown by illustration. Put the upper part (5) over the cylinder so that its edges clear the top of the sleeve, as shown, and slip the spacer nut (8) over the bolt and, by turning the nut (9), pull the bottom plate (6) up to the position shown. Part (5) is used on all three sizes of G.M.C. engines, and has been so designed that there is a position on each cylinder where it will clear the studs so that it is not necessary to remove the cylinder-head studs.

Make sure that the bottom plate (6) is well centered on the bottom end of the sleeve, and then tighten the nut (9) until there is a good strain on it. Then strike the top of the bolt (7) a good sharp blow with a hammer, which should break the sleeve loose from its seat, and then, by turning the nut (9), pull the sleeve up until the top end of it comes in contact with part (5). Then remove the tool plate, etc., and by prying under the bottom edge of the flange on the top of the sleeve at two opposite points it will be possible to pull it the rest of the way out.

To Replace Cylinder Sleeve

Before replacing the sleeve, clean out the old gasket (3) in the corner of the recess at the top of the cylinder block for the flange of the sleeve, and put in a new gasket (Fig. 12). Also, remove the cork gasket (4) from the groove in the cylinder and clean the groove out thoroughly and put in a new cork ring, taking care not to break it when putting it in. If the cork is soaked in warm water, it will be easier to handle it.

To insert a new sleeve first paint lightly the entire outside of it with a mixture of red lead and machine oil. Then push it down into place as far as it will go by hand, and tap it down with a lead hammer or wooden block until the replacing tool can be put on as shown in Figs. 12 and 13.

Plate (6) should be inserted in the sleeve as shown, and in its center should be dropped plug (10). Slip the bolt (11) through part (5) as shown, and screw on the nut (8) so that the bolt is just flush with the bottom of the nut. Then place part (5) over the top of the sleeve in such a position that two opposite cylinder-head studs will project through the holes in part (5) so that the cylinder-head nuts can be put on to hold part (5) down on the cylinder head. Tighten up the cylinder-head stud nuts (12) and then screw down bolt (11) (Figs. 12, 13) and push the

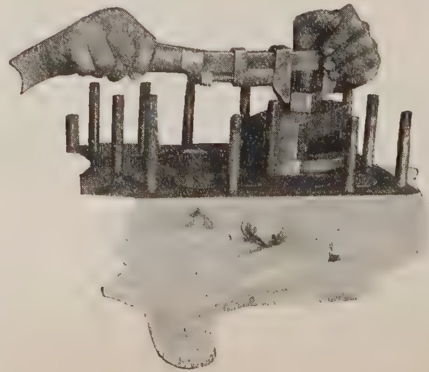

Fig. 13

sleeve down in place. The process of pushing down can be assisted by tapping the top of bolt (11) with a lead hammer from time to time as it is screwed down. Make sure that the top of the sleeve flange goes down until flush with the top of the cylinder head, so that the cylinder-head gasket can be properly seated.

G.M.C. Manifold and Jackets

Exhaust gas from the manifold is employed to heat the in-going fuel and air. Fig. 14 shows a section through the center of the intake and exhaust manifolds, governor-throttle body, and carburetor.

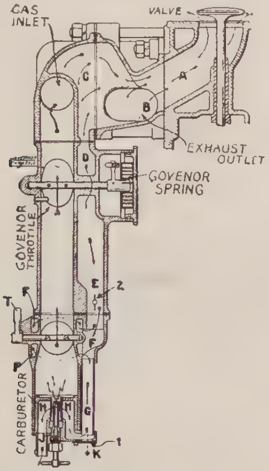

Fig. 14. G. M. C. combined inlet and exhaust manifold.

Principle: Exhaust gas leaving the cylinders at (**A**) enters the exhaust manifold where the major portion of it goes out through (**B**) to the muffler. Some portion of it, however, takes the course indicated by the arrows and strikes the wall of the intake manifold at (**C**). Some of the gas goes down back of the governor-throttle body as indicated at (**D**), and passes on through (**E**) to the heat jacket (**F, F, F**) surrounding the upper part of the carburetor.

From this point, it goes down through the tube (**G**) and circulates through the space around the low-speed jet at (**H**) and passes out into the atmosphere at (**J**).

Adjustment: In very warm weather it may be found that this system provides too much heat, and that an excessive amount of heat reduces the power considerably.

In order to control the amount of heat used, two adjustments are provided. The first of these is the shutter (1). When open, it allows the exhaust gas to escape at (**K**) instead of circulating through (**H**) and going out at (**J**). This prevents preheating of the fuel and of the in-going air at the low-speed jet.

Should there still be too much heat with the shutter (1) open, the damper (2) may be partially or entirely closed. As will be seen from the drawing, this damper may be used to close off the passage from the throttle-body jacket (**E**) into the carburetor jacket (**F**).

This damper is provided with a lock nut on the outside to hold it in any position desired. The (**T**) handle on the damper is parallel to the butterfly valve on the inside, so that the position of the handle on the outside indicates the position of the valve inside.

Electric System

The Remy generator with third-brush regulation and thermostat control with cut-out on the top of the generator is used. See page 362 for explanation of this type of generator.

Ignition: The ignition is by means of an Eisemann high-tension magneto entirely independent of the electric system. An **impulse starter** is used. The timing order is 1, 3, 4, 2. The breaker gap on the magneto is .012.

To check the ignition timing: Turn the engine over by hand until No. 1 piston is at the top of its compression stroke. In this position, the setting mark (see page 269; "Eisemann magneto type G4") on the rotating distributor disk should be just under the set-screw pointer at the top of the magneto frame. If it is not in this position, the timing is incorrect and the coupling should be re-set.

To re-set the coupling, leave the engine on top of dead center of No. 1, as described above, and loosen the two clamping screws on the forward end of the impulse coupling. When these screws have been loosened, turn the magneto **backward** until the setting mark (**R**) (Fig. 2, page 269) is under the setting point. Then retighten the clamping screws on the magneto coupling. When tightening the adjusting screw, make sure that the loose intermediate insulating disk of the coupling is not pinched endwise. It should have 1/50″ end play.

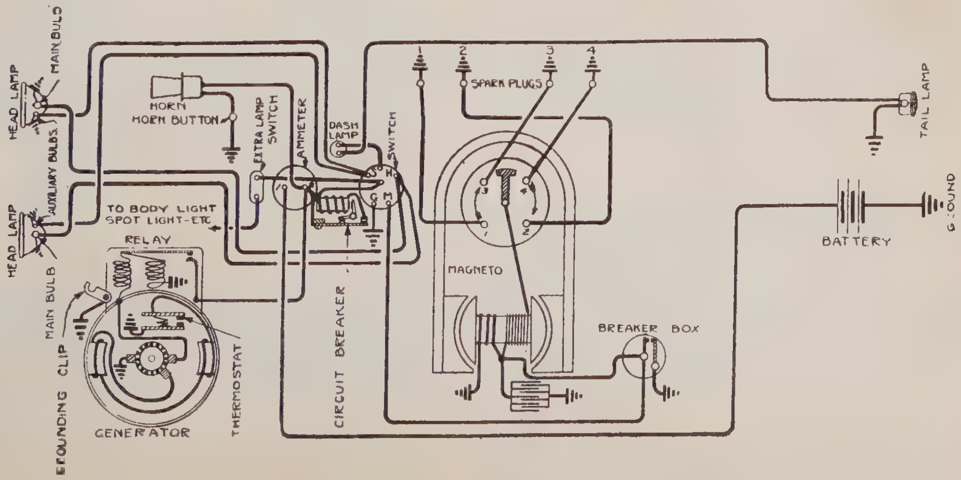

Fig. 15. Wiring diagram of G. M. C. truck.

G.M.C. Two-Range Truck Transmission

When a truck is operating under difficult road conditions, it is desirable to have a large gear reduction. When a truck is operating under good road conditions, it is desirable to have a small gear reduction.

In practical trucking, it is often necessary to operate the same truck part of the time under good road conditions, and part of the time under poor road conditions. Consequently it would be desirable to have a truck with two different transmissions, either of which could be used at the driver's option.

In order to accomplish this result, it is only necessary to take a standard transmission and have an extra pair of gears between the main shaft and the counter shaft. This is called the **two-range transmission.**

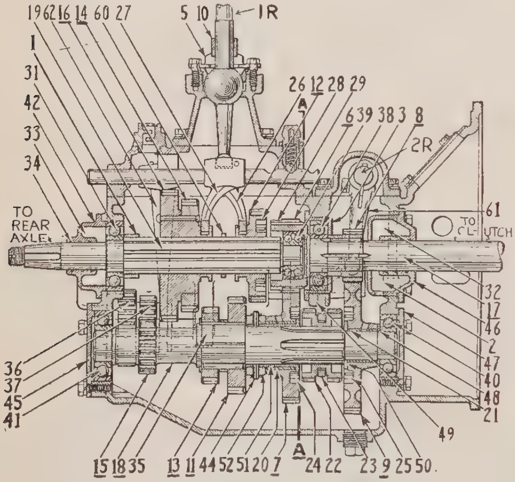

Fig. 16. G.M.C. Two-range transmission.

A sectional view of the transmission is shown in Fig. 16. To the left of the lines (**A** and **A**) the transmission is the same as a standard 4-speed transmission. However the gear (7), instead of being fastened solid on the countershaft, is permitted to rotate freely upon it except when it is engaged by the sliding clutch (22). To the standard transmission, the gears (8) and (9) have been added. The gear (9) is free to rotate on the countershaft unless engaged by the clutch (22).

Thus it is seen that the transmission can be operated either through the gears (6) and (7) or through the gears (8) and (9), simply by moving the clutch (22). This clutch is operated by a **range lever** which can be moved by the driver.

Gear Ratios

The various gear ratios obtainable will now be taken up. In Figs. 17 to 24, the two-range transmission for 2-ton trucks is shown diagrammatically. The numbers of the gears refer to the number of teeth on the gear. Thus gear 12 has 12 teeth; gear 33 has 33 teeth, etc. The dotted arrow shows the course of the power transmission. **The rear axle** of the 2-ton G.M.C. truck has a ratio of 7.25.

Transmission in Low Range

Let us put the range lever in low position. This will engage gear 33 (Fig. 17) (shown as gear 9 in Fig. 16) with the countershaft.

If the gear-shift lever is put in first speed, the transmission will be in the position shown in Fig. 17.

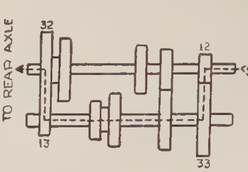

Fig. 17. Low—first.

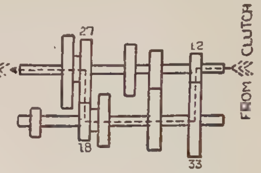

Fig. 18. Low—second.

The gear ratio effected will be:

1st speed: 7.25 (rear axle) x $\frac{33}{12}$ x $\frac{32}{13}$ = 49.08.

Shifting the gear lever to second speed, we get the position shown in Fig. 18. Here the ratio is:

2d speed: 7.25 x $\frac{33}{12}$ x $\frac{27}{18}$ = 29.91.

Shifting to third speed, we get the position shown in Fig. 19, with the ratio:

3d speed: 7.25 x $\frac{33}{12}$ x $\frac{22}{23}$ = 19.07.

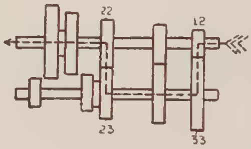

Fig. 19

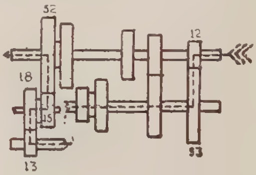

Fig. 20

Fig. 19. Low—third.
Fig. 20. Low—reverse.

Shifting to fourth speed, the power is transmitted directly through the main shaft, the countershaft playing no part. Since there is no reduction within the transmission, the total reduction is 7.25.

4th speed = 7.25.

By shifting to reverse, we introduce a double idler gear (18) and (15) (Fig. 20) between gears 13 and 32. The ratio here is:

Reverse: 7.25 x $\frac{33}{12}$ x $\frac{18}{13}$ x $\frac{32}{15}$ = 58.89.

Transmission in High Range

Let us now put the range lever in high position, thus disengaging gear 33 from the countershaft and engaging gear 28 (Fig. 21) (shown as gear 7 in Fig. 16) with the countershaft.

With the gear-shift lever in first speed (Fig. 21) the ratio will be:

1st speed: (Fig. 21) 7.25 x $\frac{28}{17}$ x $\frac{32}{13}$ = 29.39.

With the gear-shift lever in second speed (Fig. 22), the ratio will be:

2d speed (Fig. 22): 7.25 x $\frac{28}{17}$ x $\frac{27}{18}$ = 17.91.

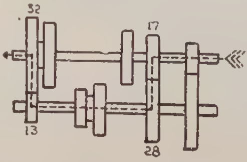

Fig. 21

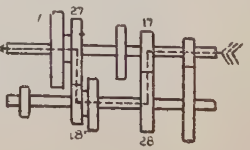

Fig. 22

Fig. 21. High—first.
Fig. 22. High—second.

With the gear-shift lever in third speed (Fig. 23), the ratio will be:

3d speed: (Fig. 23) $7.25 \times \frac{28}{17} \times \frac{22}{23} = 11.42.$

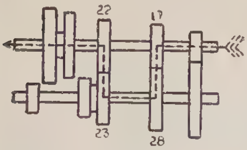

Fig. 23

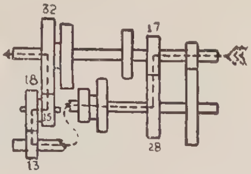

Fig. 24

Fig. 23. High—third.
Fig. 24. High—reverse.

In 4th speed we have the direct drive again, and consequently the ratio is 7.25.

In reverse (Fig. 24) the ratio is:

Reverse: $7.25 \times \frac{28}{17} \times \frac{18}{13} \times \frac{32}{15} = 35.27.$

Summing up the ratios, we have:

Speed	Ratio	
	High Range	Low Range
1st	29.39	49.08
2nd	17.91	29.91
3d	11.42	19.07
4th	7.25	7.25
Rev.	35.27	58.89

In moving a heavy load, a good method would be to start in low range, 1st speed; shift to 2d speed; shift to 3d speed; move the range lever to high range; shift to 4th speed.

G.M.C. Rear-Axle Adjustments

A general assembly of the rear axle showing the driving mechanism is illustrated in Fig. 25. Power is supplied by the propeller shaft to turn the worm which is shown above, having teeth in contact with the worm wheel.

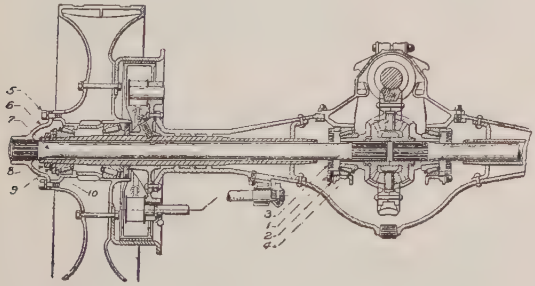

Fig. 25. G.M.C. 2-ton truck rear axle.

The worm wheel is mounted on the differential, and the hubs of the latter turn on roller bearings. This entire assembly of the worm, worm wheel, and the differential, is **a separate assembly in the differential carrier, and may be removed** as a unit by first pulling out the axle drive shafts and then removing the bolts which attach it to the top of the axle housing.

The axle driving shafts (7) are splined on the inner ends, and fit in corresponding splines in the hubs of the differential. The outer ends of these shafts transmit power to the wheels by means of steel flanges (6) splined and shrunk on the ends, which flanges are attached to the wheels by means of studs (5) in the end of the hub.

All gears run in an oil bath, the worm wheel acting as a carrier or pump which picks up the oil and carries it to the worm, which, because of the high speed at which it runs, throws some of it off on the worm housing from where it runs down through troughs to the front and rear worm bearings. From the outer ends of these bearings oil returns through the bearings. The differential housing should be kept filled with oil up to the level of the filler plug on the back of the housing.

The differential is of the bevel-gear type, using four pinions and two bevel gears, all of which are hardened.

The axle shafts are of the **full-floating type** made of chrome nickel steel heat-treated, and have no work other than to transmit power to the rear wheels.

The wheel bearings are carried on a heavy heat-treated nickel steel tube pressed in the axle housing and securely locked in place by the screw shown in Fig. 25.

Adjustment of Worm Shaft Bearings

Since Timken taper roller bearings are used, it is possible and necessary to have them properly adjusted. They should at all times allow a slight play between the worm and worm wheel, especially when the axle is cold, in order to allow for the expansion which occurs as a result of warming up when in operation.

The amount of this play may be determined by turning the propeller shaft by hand. If turning this shaft indicates too much or too little backlash, the bearings should be readjusted by means of the cup (V) Fig. 26. First, loosen the clamp bolt (**D**). Next, remove the lock (**B**), and then turn the adjusting cup (**V**), which has a right-hand thread, to the right until any end play in the shaft is entirely removed.

It is now necessary to readjust to get the proper amount of play to allow for heat expansion. To do this, back out the adjusting cup (**V**) three notches, or one quarter-turn, which is equal to .016″ end play. Replace the lock and bolt in their position.

Should oil leak out around the end of the worm shaft, the stuffing-box packing at this point may be tightened by screwing in the packing gland (**H**). **Caution:** Don't try to stop oil leaks by tightening adjusting bearing cup (**V**).

Adjustment of Differential Bearings

To adjust the differential bearings it is necessary to **remove the complete carrier assembly** from the axle.

To do this, first disconnect the universal joint from its flange on the worm shaft. Next, take off the hub stud nuts and remove both axle driving shafts (Fig. 25). When the bolts have been taken out of the carrier flange, the carrier assembly may be lifted out of the housing. Make all adjustments on the left-hand bearing only. (Fig. 25). **Do not touch the right-hand differential bearing,** as this will disturb the proper meshing of the worm and gear. (In determining Right and Left, always face the direction in which the car travels forward.)

Loosen the cap bolts (F) (Fig. 26). Remove the cap screw (1) and the lock (2) (Fig. 25). Turn the bearing adjuster (3) to the right, which will push the bearing cup (4) tighter against the bearing, thus removing end play. In making this adjustment, care should be exercised not to draw these bearings too tight, as it is necessary here also to allow for heat expansion resulting from warming up.

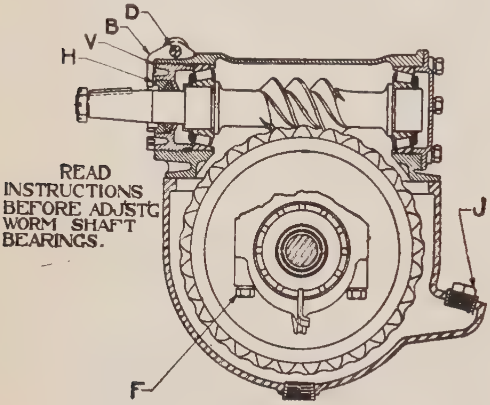

Fig. 26

When the adjuster (3) has been screwed up to take out all end play, it should be backed off so that there is a barely appreciable amount of end play, and should then be locked in this position.

It will be found, especially during warm weather, that the differential worm housing will become quite warm, but this is to be expected since considerable power is transmitted through these gears and bearings and, consequently, temperatures up to 180° are to be expected.

Adjustment of Rear-Wheel Bearings

The rear-wheel bearings can be adjusted by **jacking up the wheels until they are free from the floor.** By using a bar between the floor and the bottom of the wheel, it can be determined whether the wheel has any play or not. (These wheels are so heavy that it is difficult to determine this without the use of a bar.)

The wheel bearings should be so adjusted that there is a barely perceptible shake in the bearing.

If it is found that the bearings require readjustment, first take off the driving flange nuts (5) (Fig. 25) and remove the driving flange (6) together with the axle shaft (7). Next, using the special wrench in the tool kit, remove the nut (8), and then take off the washer (9). Again using the special wrench, tighten up the nut (10) until the required adjustment of the bearing is obtained. Then replace the washer (9), and tighten up the lock nut (8) solidly.

It is a good practice to examine the wheel bearings in the hubs at least every 6,000 miles, at which time the hubs and bearings should be thoroughly washed out and refilled with the proper lubricant, which is a light grease free from acid. Additional grease may be introduced at any time by removing the axle shafts.

G.M.C. ONE-TON TRUCK MODEL "K-16"

Specifications

Load capacity: 2,000 lbs., with additional maximum allowance of 900 lbs. for body equipment.

Road speed: 25 miles per hour.

Engine: G.M.C. design and manufacture; four-cylinder "L"-head, water cooled; bore 3½", stroke 5½".

Horse power: By S.A.E. formula, 19.6; actual horse power at governed speed, 32.5.

Cylinder and crank case: Cast in unit; cylinders, removable sleeve type.

Lubrication: Positive-pressure system from gear pump, forcing oil with constant pressure to all bearings of engine; chassis lubrication by pressure-gun system.

Governor: Fly-ball type of their own manufacture.

Carburetor and fuel supply: G.M.C. two-jet type of carburetor with special heated intake manifold; fuel feed from sheet-steel tank of 12½ gallons capacity.

Cooling: Combination pump-driven and thermo-siphon; pump capacity approximately 15 gallons per minute.

Radiator: Continuous fin, tubular type with core and steel separate; capacity 5⅛ gallons.

Ignition: High-tension magneto.

Clutch: Multiple-disk dry-plate type of their own manufacture.

Transmission: G.M.C. selective type, three speeds forward and one reverse; in unit with engine; provisions for tire pump and power takeoff.

Rear axle: Three-quarter floating bevel pinion drive with six-to-one gear ratio; drive through radius rods from rear axle to frame.

Frame: Pressed steel, reinforced.

Brakes: Two sets, external contracting for service, internal expanding for emergency; **interchangeable brake rods** (see "Brakes," page 915).

Wheels: Steel felloe with twelve interlocking wooden spokes.

Tires: 34" x 5" non-skid cord all around.

Wheel base: 132".

Road clearance: Rear axle 8¾".

Turning radius: 23 ft.

Weight of chassis: 3,250 lbs.

Controls: Left-hand steering and center control; spark and throttle levers located on segment with connections outside of steering column; foot throttle operated by driver's right foot; road speed controlled by governor; lights and ignition switches, ammeter, oil gauge, and choker lever located in instrument case on dash.

Equipment: Electric starting and lighting system of special design and manufacture, tool kit, horn, jack, and extra rim.

The most popular light-duty truck of the G.M.C. line is the one-ton model. The engine is identical in design (though smaller in construction) with the two-ton model. The transmission has three speeds ahead and one reverse, the gear-shift positions being S.A.E. standard (page 29). The rear axle is of the three-quarter floating type and has bevel-gear drive.

To Remove Axle Shafts

1. Remove the six nuts (6) (Fig. 27).

2. Pull the shaft with the flange out of the wheel. This may be done without jacking up the truck.

To Remove Rear Wheel

1. Remove the axle shafts as described above.

2. Straighten the bent-over ears on the lock of nut (7) (Fig. 27).

3. Unscrew nut (7); it has a left-hand thread on the right wheel and a right-hand thread on the left wheel.

4. Pull the wheel off.

When replacing the wheel, special care should be taken to see that the felts and retainers are in the proper position. Nut (7) should be drawn up tight against the bearing, as this bearing is non-adjustable. Bend over the ears of the lock to prevent nut (7) from turning.

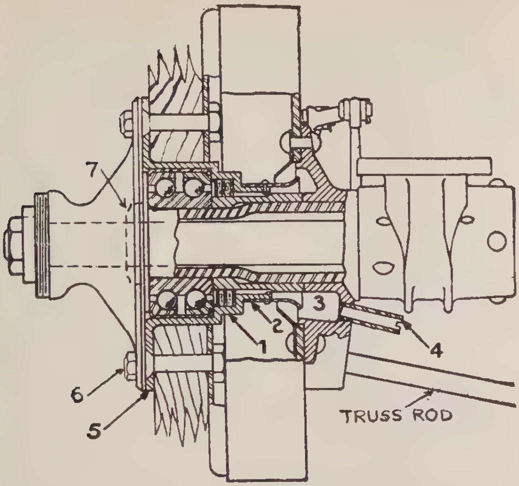

Fig. 27. Section of rear wheel of G.M.C. one-ton truck.

1. Felt washer retainer.
2. Oil shedder.
3. Grease recess.
4. Drain pipe.
5. Paper gasket.
6. Hub flange nut.
7. Wheel bearing nut.

A paper gasket at (5) and felt washers and retainers for them at (1) should prevent leakage of the wheel-bearing lubricant. Any grease which may leak past at (1) will be carried out by the oil shedder (2) into the recess (3) in the brake spider, from where it should drip on the ground from the end of the drain pipe (4). It should be impossible for any wheel-bearing leakage to get on either the internal or external brakes.

To Remove the Rear System from the Truck

1. Jack up the frame, thus taking the load off the springs.

2. Unbolt the spring clips from the rear-axle housing.

3. Block up the propeller shaft near the rear universal joint.

4. Disconnect the brake rods from the rear axle.

5. Disconnect the driving flange (9) (Fig. 28) from the rear universal joint.

6. Pull the entire rear system from the truck.

To Remove Driving Pinion Assembly

1. Remove the rear system as described above.

2. Remove the axle shafts and rear wheels as described above.

3. Remove the clevis pin from the front end of the left-hand internal brake rocker (inside the brake shoe), and then take off the truss rod (Fig. 27) nut behind it.

4. Replace the axle shafts in order to keep the differential bearings (1) and (2) (Fig. 28) from dropping out of place. If the bearings should drop down, they may be replaced by inserting a rod through the axle housing and raising them into place, so that the rear-axle shaft will slip through them.

5. Remove the two cap screws and four nuts which hold the pinion housing (3) (Fig. 28) to the differential housing.

6. Remove the bolts (4) which hold together differential housings (5) and (6).

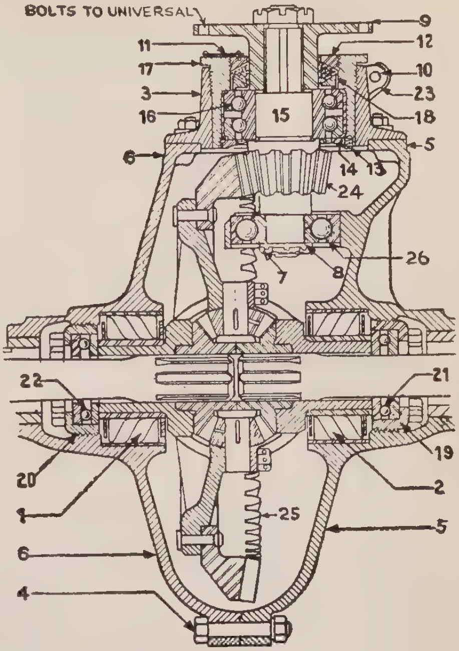

Fig. 28. Differential assembly of G.M.C. one-ton truck.

(1) Differential bearing, left.
(2) Differential bearing, right.
(3) Pinion housing
(4) Differential housing bolt.
(5) Differential housing, right half.
(6) Differential housing, left half.
(7) Rear pinion bearing nut.
(8) Pinion bearing nut lock.
(9) Driving flange.
(10) Bearing clamp bolt.
(11) Packing-nut spring lock.
(12) Pinion-shaft packing nut.
(13) Front-bearing lock nut screw.
(14) Front-bearing lock nut.
(15) Pinion shaft.
(16) Front bearing.
(17) Adjusting cage.
(18) Inner packing ring.
(19) Differential thrust-bearing adjusting nut, right.
(20) Differential thrust-bearing adjusting nut, left.
(21) Differential thrust bearing, right.
(22) Differential thrust bearing, left.
(23) Adjusting cage lock.
(24) Pinion.
(25) Ring gear.
(26) Rear pinion bearing.

7. Jar the housings apart with a lead hammer, and keep the differential assembly **to the left** while spreading the two halves of the housing. Do not attempt to remove the driving pinion until the ring gear is at least ½" to the left of the face of the right-hand housing (5).

8. At this point, remove the pinion-housing assembly (3) with all its parts.

To Disassemble the Pinion Assembly

1. Hold the assembly in a vise by clamping the driving flange (9) (Fig. 28).

2. Turn down the ears on the rear-bearing nut lock (8), and remove nut (7).

3. Remove the cotter pin and nut that hold the driving flange (9).

4. Hold the assembly in the vise by the housing flange (3).

5. Remove the driving flange (9).

6. Loosen the bearing clamp bolt (10).

7. Remove the spring lock (11) from the pinion-shaft packing nut (12).

8. Remove the front-bearing lock nut screw (13) (the small screw at the rear of the bearing cage).

9. Remove the front-bearing lock nut (14) with a small punch and hammer.

10. Use a hardwood block and hammer to drive the pinion shaft (15) and bearing (16) to the rear out of the cage (17).

If the adjusting cage (17) **is to be removed from the housing,** both should be punch-marked and the number of exposed threads noted, so that it may be returned to the same position.

The inner packing ring (18) for the pinion shaft is tap-fit in the cage. To remove it, use a hardwood block and drive from the inside of the cage.

Both bearings are press-fit on the shaft. When removing, be sure the strain comes on the inner race of the bearing.

Use a new nut lock (7), if available, when reassembling the rear bearing. If the old lock is used, break off all ears that were used previously.

In replacing the drive flange (9) fit nut (12) and the packing round it first, and insert the packing and flange together. **The pinion is integral with the shaft.**

To Remove Differential Assembly

1. Remove the drive-pinion assembly, as mentioned above.

2. Remove both axle shafts, as described above.

3. Spread the axle housing entirely apart and remove the differential assembly. **Do not disturb the differential thrust-bearing adjusting nuts** (19) **and** (20) **unless necessary** (Fig. 28).

4. Remove the Hyatt bearings (1) and (2) and the thrust bearings (21) and (22).

5. Insert the drive shafts in the axle housing when the thrust bearings are replaced, to prevent them from dropping out of position. If the thrust bearings drop out of position while assembling, they may be lifted into position by inserting a rod through the center of the housing.

When replacing a ring gear, care should be taken to see that the rivet heads are not over ⅛″ high on either side of the gear. Rivets should be driven hot.

To Adjust Bevel Gears

1. Place the differential assembly in the left differential housing (6) (Fig. 28), guiding the thrust bearing (22) into place by means of an iron rod.

2. Bolt the entire pinion assembly (3) to the left differential housing (6), thus holding the differential in place.

3. Remove bearing-clamp bolt (10) and adjusting cage lock (23).

4. Turn adjusting cage (17) to adjust pinion (24), so that the face of the pinion is flush with the face of ring gear (25).

5. Remove the plate in the differential housing above the thrust-bearing adjusting nut (20).

6. Unlock the adjusting nut (20).

7. Through the plate in the housing, turn adjusting nut (20) until the ring gear meshes properly with the pinion.

8. The mechanic should be able to spin the ring gear freely, and there should be a clearance of about .002″ in the "high spots." Do not allow too much backlash (play).

9. Lock adjusting nut (20).

10. Lock adjusting cage (17) with lock (23) and bearing-clamp bolt (10).

11. Remove pinion assembly (3) from differential housing (6).

12. Place pinion assembly (3) in the right half of the differential housing (5), inserting rear-pinion bearing (26) into its recess.

13. Assemble the right half of the differential housing (5) to the left half (6), guiding the thrust bearing (21) into position by means of an iron rod.

14. Draw up the adjusting nut (19) tightly.

15. Bolt the pinion housing (3) to the differential housing.

16. Back off the adjusting nut (19) until the differential assembly turns freely.

Note. For correct gear-tooth contacts, read pages 869, 874.

To prevent leakage, the pinion shaft is provided with a stuffing box into which screws the nut (12) which is locked in place by the snap ring (11). A special Mogul packing is provided for this purpose. The packing nut (12) should not be drawn in tighter than just sufficient to prevent leakage. **Do not attempt to prevent leakage by tightening adjusting cage** (17).

SPECIFICATIONS OF 1 1/2 AND 2-TON AUTOCARS

Types "XXI-F" and "XXI-G"[1]

Axles: Front, I-beam steel; rear, "Autocar" full-floating, double-reduction gear drive, compound bevel and spur gear, wheel and axle bearings, tapered roller type.

Bodies: Standard bodies always available; blueprints of special body designs furnished upon request.

Brakes: On rear wheels; service brake external, emergency internal.

Capacity: 11,000 lbs. over all—chassis, body, and load.

Carburetor: Plain tube, automatic float feed.

Clutch: "Autocar" triple dry-plate clutch.

Color: Chassis, "Autocar" red; body, optional.

Control: Steering gear and hand levers at right side; throttle control in steering wheel and accelerator pedal; clutch and service brake in foot pedals.

Cooling system: Vertical tube radiator, centrifugal water pump.

Equipment: Gas headlights and tank; three oil lamps; horn; kit of tools.

Frame: Reinforced pressed steel.

Gasoline capacity: 11 gallons.

Ignition: High-tension magneto—fixed spark.

Engine: Horizontal opposed, 4¾″ bore by 4½″ stroke; crank shaft mounted on annular ball bearings.

---

[1] The only difference between types "XXI-F" and "XXI-G" is that the former has a 97″ wheel base, and the latter a 120″ wheel base.

Engine lubrication: Splash; gear-driven, force-feed lubricator of 1-gallon capacity, delivering oil through sight feed to the crank case.

Springs: Front, semi-elliptic; rear, platform springs.

Tires: Solid; front, 34″ x 4″; rear, 34″ x 5″, or pneumatic, 34″ x 5″ front and rear.

Transmission: Sliding-gear type; three speeds forward, one reverse; direct drive on high speed; tapered roller bearings.

Tread: 58″.

Wheel base: Type "XXI-F," 97″; type "XXI-G," 120″.

Wheels: Wood, artillery type.

The variety of bodies adapted to the Autocar chassis is indicated by the fact that Autocars are doing the hauling for concerns in all lines of business.

This truck differs from other trucks in the type of engine and the **double reduction of gears** in the rear axle.

Engine

The Autocar "F" and "G" engine (Fig. 30) is of the two-cylinder opposed type, 4¾″ bore (diameter of cylinder) by 4½″ stroke (length of piston travel). It is cooled by water, circulated by a pump through water jackets and radiators. A fan behind the radiator assists in cooling the water.

The crank case is divided horizontally into two parts: the upper part contains the timing gears and gears for driving the magneto and lubricator; the lower part holds the crank shaft and cam shaft. To this lower part are bolted the cylinders. For access to the crank shaft, the magneto, lubricator, and upper part of the crank case can be removed.

The connecting-rod bearings are lubricated by two dippers on each connecting-rod cap dipping into the oil in the crank case. The cylinders, pistons, and timing gears are lubricated by splash from the crank shaft. To maintain the proper level of oil, the automatic lubricator pumps oil into the crank case when the engine is running.

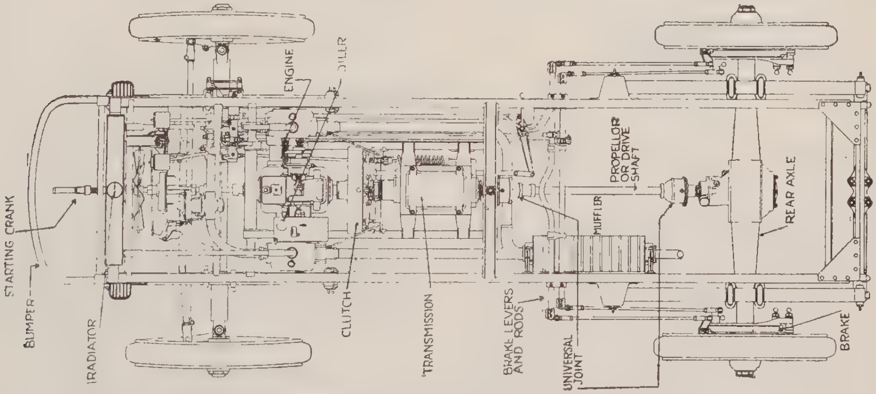

Fig. 29. Top view of Autocar chassis.

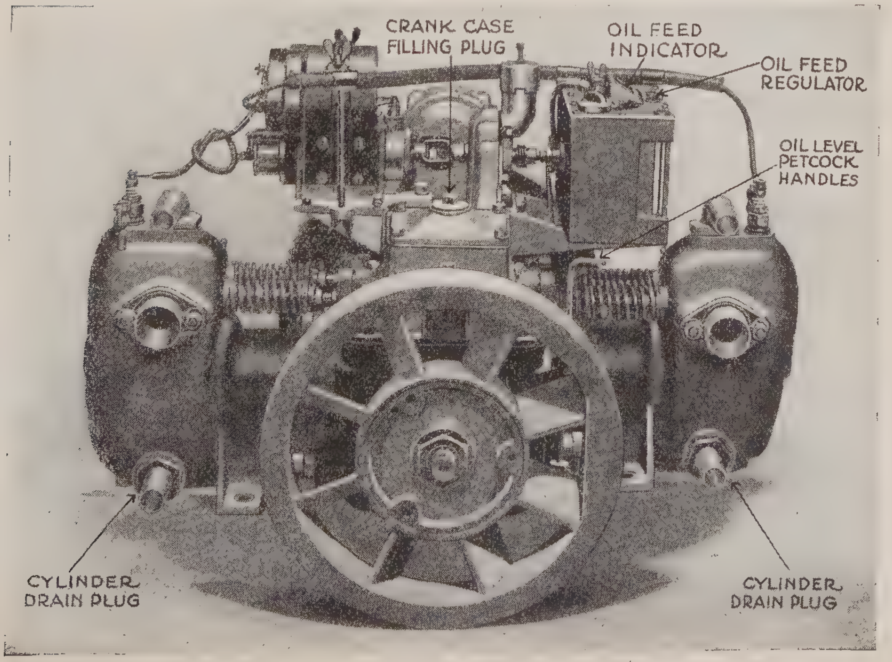

Fig. 30. Side view of the Autocar "F" and "G" engine.

Timing of Magneto (Types "F" and "G")

When either setting the valves or timing the magneto on the "F" engine, it is important to use the marks on the face of the front flywheel as reference points. This arrangement is shown in the illustration (Fig. 31).

Before setting the magneto, open both cylinder priming cocks and turn the flywheel in the running direction until the inlet valve (front valve) of the cylinder under the magneto, which is No. 1 cylinder, opens and closes; continue turning in the same direction until the line on the flywheel, marked (**A**) (Fig. 31) is directly under the flywheel pointer. This position must be exact. Loosen the nut on the magneto coupling and yoke studs, as well as the small screws on the magneto bracket that hold the base of the instrument in place. Place a small chisel or screwdriver between the magneto coupling and lock nut and tap gently to loosen the coupling, so that the armature may be turned freely.

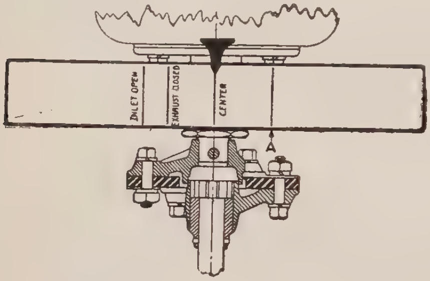

Fig. 31. Magneto ignition timing on the Autocar.

Remove the breaker-box cover and distributor disk, turn the armature in the running direction, using the small magneto wrench on the breaker screw, until the platinum points start to break or separate. Be sure that the distributor brush is on No. 1 contact, which is the one nearer the gasoline tank. Hold firmly in this position with the small magneto wrench, and tighten the coupling nut with the wrench provided for this purpose.

Verify the adjustment by turning the engine backward slightly and then slowly forward, so that the line on the flywheel, marked (**A**) in the illustration again coincides with the pointer. If when in this position the platinum points are starting to open and the distributor is on No. 1 contact, the timing with respect to the ignition is correct.

Replace the distributor-breaker cover and attach the wires. The short wire connects the No. 1 cylinder with the No. 1 contact point on the distributor, and the long wire, the No. 2 cylinder with the No. 2 contact point on the distributor.

Push the magneto back to the coupling, being sure to see that it is located in the center of the magneto bracket. Tighten the screws on the bracket at the magneto base and lock with the lock nuts. Tighten the yoke bolts and apply the ground wire to the breaker-box cover.

Cam-Shaft Setting (Types "F" and "G")

When replacement of a crank-shaft gear, cam-shaft gear, or crank shaft in either repair work or rebuilding is required, it is recommended that the following procedure be followed in determining the correct setting of the cam shaft with respect to the crank shaft.

The rear cam-shaft bearing being assembled in place, turn the crank shaft until the crank pins are exactly on outer dead center. Check this condition by measuring from the finished edge of the case to each of the crank pins. Allow the cam shaft to enter the rear bearing a short distance, and turn until the inlet cam begins to act on No. 1 cylinder. In this position turn the cam shaft until the acting face of the inlet cam is at right angles to the finished surface of the crank case. A small steel square should be used to find the correct position.

Having obtained this adjustment, allow the cam-shaft gear to mesh with the crank-shaft gear. It may be necessary to rotate the crank shaft slightly in the **running** direction in order to permit this meshing to take place. The front cam-shaft bearing may then be assembled and locked in position.

It is necessary to provide perceptible backlash between the cam-shaft gear and the crank-shaft gear, otherwise rapid wear and a noisy condition will result. If a slight shake cannot be detected by the hand, place a .0025" shim between the cam-shaft bearings and the crank case. There must also be end play from .005" to .015" between the shoulders of the cam shaft and the cam-shaft bearings. If such is not the case, correct the difficulty by backing off the cam-shaft gear slightly, or filing the ends of the cam-shaft bearings as circumstances may require.

When the setting is completed, it is considered good practice to mark the gears at points of contact for future reference.

Valve Setting (Types "F" and "G")

In replacing a front flywheel, installing a new cam-shaft gear, crank-shaft gear, or crank shaft, it is necessary to mark on the flywheel those positions which must be used in connection with valve setting and magneto timing. These points are "Center," "Exhaust Closed," "Inlet Open," and a line used in making the spark adjustment.

To determine the "Center" position, remove the cylinder-head plug, and insert through the cylinder-head hole a small steel scale, allowing it to rest against the head of the piston. Rotate the crank shaft, observing the travel of the steel scale, and when dead center is passed continue to turn until some convenient scale graduation appears opposite the face of the plug counter-bore, which is used as a reference point.

Note this position on the flywheel rim by making a temporary mark at the point indicated by the flywheel pointer. Turn the flywheel in the opposite direction until dead center is again passed and the scale returns to the graduation previously noted. The corresponding point on the flywheel rim is to be marked as before. Half-way between the two marks on the flywheel scribe a line and mark it "Center."

Measure ahead on the rim two inches from "Center," and scribe another line. This latter is used as a reference point in magneto setting.

With the cam shaft properly set and the crank case upper section assembled in position, turn the flywheel until both valve plungers of No. 1 cylinder have completed their inward travel. Adjust the valve-plunger foot screws to the same clearance for both inlet and exhaust valves, .015" to .025" being a conveniently obtainable interval.

Turn the flywheel until the cam shaft is acting on both the No. 1 cylinder cams, the inlet being just ready to open and the exhaust just closing. Using from one to two thicknesses of newspaper between the adjusting screws of the cam plungers and the valve stems on No. 1 side, find the two points, by rotating the flywheel through a slight angle, at which these shims may be just pulled out, and mark the corresponding positions temporarily on the rim of the flywheel, referring of course to the flywheel pointer. From the mid-point of these marks measure 5/16" to each side, and lay off temporary lines.

The line on the right must not be more than 2 5/16" nor less than 1 5/16" from the "Center" line, these limits being required owing to the necessary tolerance allowed in manufacture of the parts. Should the limits be exceeded, shift the cam-shaft gear one tooth in the direction which will correct the difficulty. Assuming that the point so reached fulfills these conditions, scribe a line through it, and the other point 5/8" distant to the left. Mark the one on the left "Inlet Open" and the other "Exhaust Closed."

It is now necessary to set all valve-plunger foot screws to the clearance required under operating conditions. Rotate the flywheel until the cams engage the plungers on the cylinder being adjusted, and the flywheel pointer is midway between the "Inlet Open" and "Exhaust Closed" line. Adjust the valve-plunger foot screws for .005" clearance between the head of the screw and the end of the valve stem, this being the amount adopted by the factory as standard.

Note. When this work is being done with the engine in the car, use two levers on the crank webs and check with a scriber in the spark-plug holes.

Rear Axle and Gearing

The rear axle contains a double set of gears (Fig. 32). A bevel pinion (**P**) connected with the end of the drive shaft (**S**) meshes with a bevel gear (**B**) on a short jack shaft, and thus drives the latter. This in turn drives the differential assembly through a pair of **spur gears** (**SG1**) and (**SG2**)

The inner ends of the two driving axles (**A**) are mounted in this differential assembly and transmit the drive from it to the wheels.

The jack shaft is mounted on adjustable taper roller bearings, and by removing the rear cover it can be examined without dismantling the axle proper. The bevel pinion is mounted in a cage and can be removed by unscrewing the cap screws in the flange of the cage.

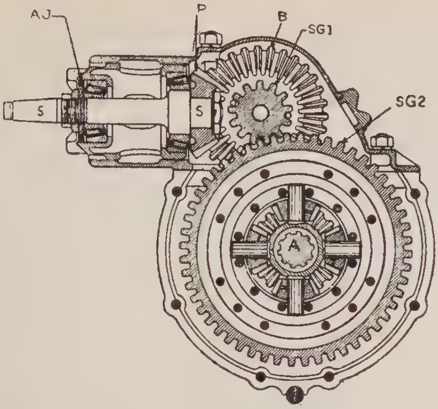

Fig. 32. Autocar double set of gears in rear axle. Termed "double reduction drive to differential."

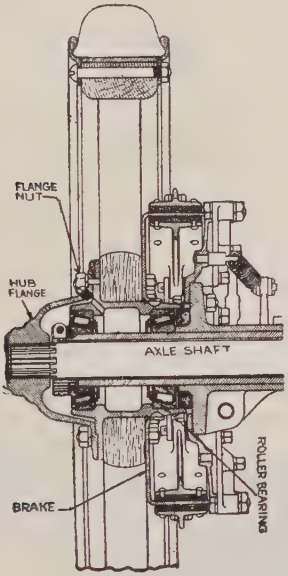

Fig. 33. Rear wheel and axle shaft of the Autocar.

The driving axle shafts (Fig 33) **can be removed** by unscrewing the flange nuts holding the axle or hub flange to the wheel, and pulling out the axle and flange as a unit.

Pinion-shaft adjustment is made by adding or removing paper gaskets between the gear cover and the pinion-shaft housing. Looseness in the pinion shaft can be adjusted at (**AJ**) (Fig. 32).

Transmission

The Autocar 1½ and 2-ton trucks are equipped with a progressive type of transmission (Fig. 34).

In the transmission there are three shafts: The **clutch shaft** (**A**), which extends through the front of the case, on the outer end of which the clutch is mounted; the **main shaft** (**B**), projecting through the rear of the case in line with the clutch shaft, and through which the power is transmitted to the driving shaft, and then to the rear axle; and lastly, the **counter shaft** (**C**), located directly below the main shaft.

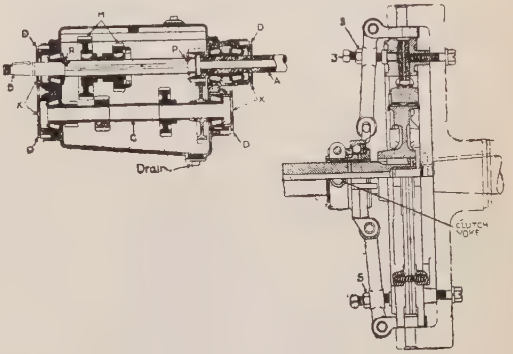

Fig. 34. Autocar progressive-type **transmission** to the left, and Autocar **clutch** to the right.

Clutch

The clutch is of the "Autocar" triple plate type. It consists of two cast-iron plates, faced with asbestos fabric, carried on four keys in the flywheel, and one steel plate between them mounted in slots milled in the spider on the clutch-shaft end. These plates, when clamped together by means of the eight springs contained in the removable plate bolted to the face of the flywheel, produce the friction for driving, power being transmitted through the steel plate through the spider mounted on the end of the clutch shaft.

The clutch is released by the trunnion block or clutch yoke, operated by the clutch pedal, acting against four arms carried on the floating ring, and bearing against the four keys in the flywheel. This block is provided with ample ball-thrust bearings to compensate for the pressure of the clutch spring.

Adjustment of the clutch is made at set screw (3) after loosening lock nut (5).

INTERNATIONAL ONE-TON TRUCK, MODEL "21" (FORMERLY MODEL "H")

This truck is one of six different sizes manufactured by the International Harvester Co. of Chicago, Ill., and is probably the most popular model or size.

Specifications

Maximum capacity: 2,000 lbs.

Wheel base: 115″, regular; 128″, special.

Frame: Pressed-steel channel, extra strong, 5″ deep, with 5 cross-members and two braces at rear.

Engine: Four-cylinder, cast en-block L-head type; engine and transmission mounted on sub-frame suspended from three points on main frame.

Bearings: Three crank-shaft bearings: rear, 1¾″ x 4⅛″; center, 1¾″ x 2¼″; front, 1¾″ x 3¼″.

Lubrication: Forced lubrication by pump to main bearings with overflow to troughs into which the lower ends of the connecting rods dip, making a splash system to the cylinders and crank shaft. Submerged type of plunger pump.

Ignition: High-tension Bosch, magneto on cross-shaft in front of engine.

Cooling: Water-cooled; centrifugal pump; large vertical tube radiator and fan; pump on cross-shaft in front of engine; total cooling system capacity is 4¼ gals.

Governor: Fly-ball centrifugal type; limits speed to 21.8 m.p.h.

Clutch: Dry-plate multiple disk; asbestos lined.

Transmission: Sliding gear, selective type; direct on high.

Gear reduction: Engine to rear wheels, 6.86 to 1 on high.

Axles: Front, I-beam heat-treated steel drop-forging; rear, heat-treated steel drop-forging for carrying the load and live axle for transmitting the power.

Internal gear drive: Tubular propeller shaft with universal joints at each end; power transmitted through differential and drive shafts to pinions meshing with internal gear on each rear wheel.

Control: Left-hand drive, spark and throttle levers on steering wheel, foot accelerator, service brake, and clutch operated by foot pedals; gear change and emergency brake levers in the center of driving compartment.

Brakes: Service and emergency; internal expanding, self-adjusting.

Springs: Half-elliptic, front, 2¼" x 41¼"; rear, 2½" x 54", with quarter-elliptic auxiliary springs 2¼" x 30½".

Wheels: Artillery type, 36" diameter, with 3½" front and 3½" rear pressed-on solid tires.

Fuel capacity: 17-gallon tank on dash.

Regular equipment: Front fenders, oil tail lamp, horn, tools, two gas headlamps, and Prest-O-Lite tank.

Special equipment: Supplied at additional cost: open express body; front section and seat; open and enclosed cabs; full-length top; side, front, and rear screens for full-length top; electric lighting and starting outfit; power tire pump; hub odometer; oil dash lamps; windshield; skid chains; pneumatic tires and oversize solid tires; suitable bodies can be secured for every hauling purpose.

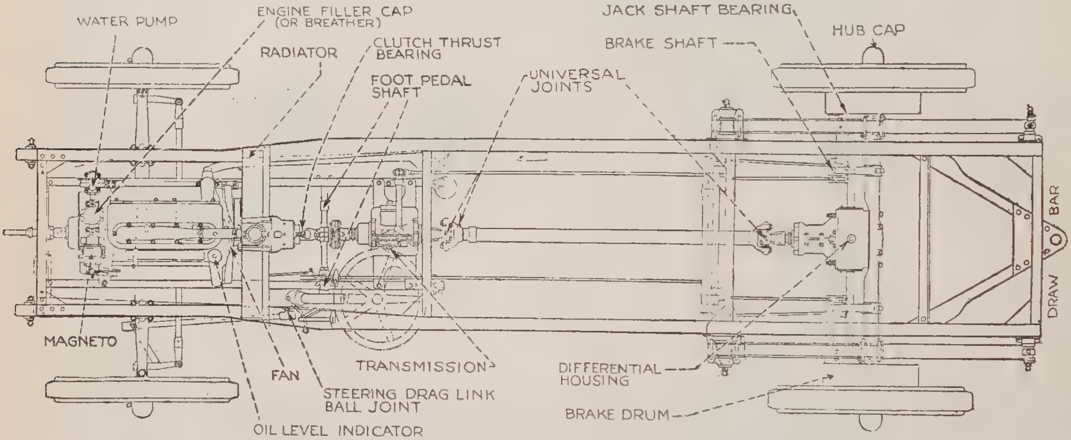

Fig. 35. Top view of International one-ton truck chassis.

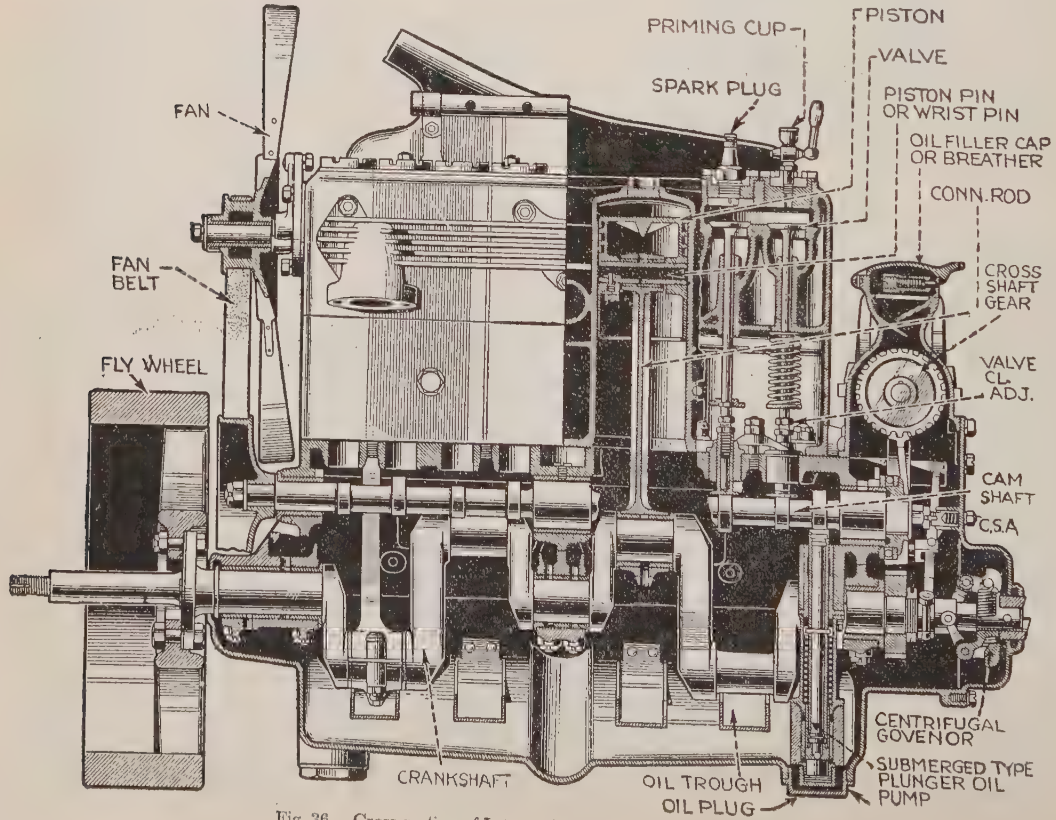

Fig. 36. Cross-section of International one-ton truck engine.

Engine

The engine is of the L-head type; bore, 3½″, stroke, 5¼″; firing order, 1, 2, 4, 3.

The fan is mounted on the rear of the engine block. The wrist pins are keyed to the pistons, the connecting rods being fitted with phosphor-bronze bushings at the piston end. The connecting-rod bearings are of tin babbitt and are fitted with shims to permit adjustment.

To remove pistons and connecting rods:

1. Remove the crank-case bolts and drop the crank case.
2. Remove the connecting-rod bearing caps.
3. Remove the connecting rods with the pistons from underneath the engine.

A submerged plunger type of **oil pump** in the right front corner is driven by a cam on the cam shaft and draws oil through a gauze strainer, delivering (through a tube cast in the crank case) to each of the troughs into which the connecting rods dip as the crank shaft revolves. The crank-shaft bearings have large oil pockets above them which receive oil splashed up by the connecting rods. The pistons are also oiled by splash.

By unscrewing the cap below the pump, the screen can be taken out for cleaning.

The centrifugal governor is carried at the front end of the crank shaft and acts directly upon a sliding sleeve, which moves one end of a pivoted lever, to the other end of which is attached a rod working in a tubular casing and operating the governor throttle. A spring working with the rod, and accessible through a cover directly under the magneto, allows of slight adjustments of speed. The seals locking the screws will disclose any unauthorized tampering with these parts.

Cam-shaft end-thrust play can be taken up with the cam-shaft end-thrust adjustment screw (C.S.A.) (Fig. 36). A similar adjustment is also shown on the model "L4" Continental engine (Fig. 55, page 937).

Fuel System

A 17-gallon gasoline tank is mounted on the dash and feeds by gravity to the carburetor. Underneath the tank is a **combination strainer and reserve valve,** as shown in Fig. 37.

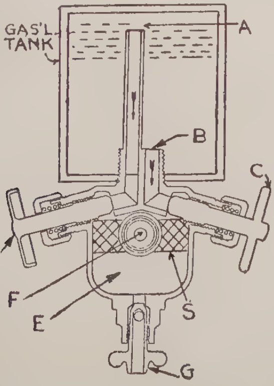

Fig. 37. Combination gasoline strainer and reserve valve on one-ton International truck.

When the engine is to be started, the valve (**D**) (Fig. 37) is opened, thus allowing the gasoline to enter at (**A**), pass through strainer (**S**), and through outlet (**F**) to the carburetor. When the level in the tank reaches point (**A**), the flow of gasoline to the carburetor will cease and the engine will stop, thus notifying the driver that he has only about two gallons of gasoline left. The valve (**C**) is then opened, permitting the gasoline to enter at the lower level (**B**), and consequently using the remaining two gallons. Matter which does not pass through the strainer will collect in sediment chamber (**E**), and can be emptied through the needle drain valve (**G**).

Ensign Carburetor

The Ensign type "D" 1¼″ carburetor is used, and operates as follows: the fuel enters and passes upward through screen (**B**) (Fig. 38) and downward through the float-controlled needle valve (**D**), into the float chamber.

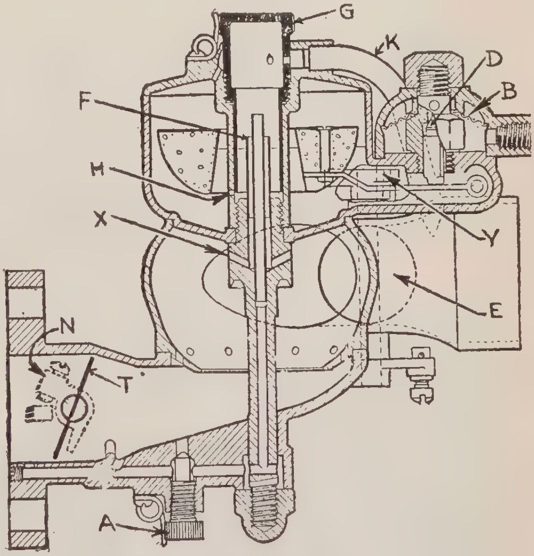

Fig. 38. Ensign carburetor as used on International truck.

A, Idling adjustment screw.
B, Strainer screen.
D, Float needle valve.
E, Starting shutter.
F, Suction tube.
G, Fuel adjustment sleeve.
H, Fuel orifice.
K, Compensating air tube.
N, Throttle stop.
T, Throttle.
Y, Stop finger.
X, Suction outlet.

The float maintains the fuel level 1/32″ below the top of the suction tube (**F**), which opens through holes (**X**) at its lower end into the centrifugal chamber. The suction tube is surrounded by a larger tube, into which the fuel enters through small fuel hole (**H**). The effective opening of this hole is controlled by a gas-adjusting tube (**G**), shown in solid black, which can be screwed up and down by its knurled head. This tube performs the function of the usual gas-adjusting needle valve. A compensating air tube (**K**) is connected to the interior of the gas-adjusting tube through an automatic valve which lifts when the air speed through the carburetor becomes high enough, and lowers the vacuum in the gas-adjusting tube, preventing the formation of too rich a mixture.

Adjustment is made at the factory. If tampered with and the engine does not start to operate properly, readjust as follows:

Before starting, be certain that the idling adjustment screw (**A**) on the bottom of the throttle tube is closed; that is, that it is turned clockwise (to the right) to seat. Turn the fuel adjusting sleeve (**G**) clockwise to the closed position, then open two (2) turns counter-clockwise, which will give a full opening to the fuel orifice (**H**). Be sure that starting shutter (**E**) is open with stop finger (**Y**) against the stop lug when "control" is down.

To start the engine, close the starting shutter by pulling up the "control," and open the throttle one-quarter to one-half. After the engine starts, push down the control about half-way. The handling of this starting shutter is largely dependent on temperature. As soon as the engine warms up slightly, push the "control" all the way down, warm the engine up, running slightly above idling speed until the mixing chamber of the carburetor is warm, then open the throttle to about one-third engine speed (this must be done with retarded spark).

Now thin the mixture by turning sleeve (**G**) clockwise until the best engine speed is obtained with this throttle setting. Slow down the engine and adjust the screw in the throttle stop (**N**) for idling position, then adjust the idling mixture by opening the adjustment screw (**A**) counter-clockwise to a point where the engine idles evenly and without loading up. Too thin an idling mixture will result in a "flat spot," or hesitation when accelerating. The top of the **cork float** is set 7/16" below the top of the bowl, and should not be changed.

Clutch

The clutch is of the dry-plate disk type as shown in Fig. 39. Pressure is applied through the action of three springs (**A**) (Fig. 39), which can be adjusted by the spring screw nuts (**B**). Care should be taken to keep them adjusted evenly.

Fig. 39. Dry-plate disk clutch used on International one-ton truck.

Adjusting: As the asbestos facings wear down, the clutch pedal will work back and finally hang up against the floor boards, preventing the clutch from engaging. It can be returned to the proper position by screwing the clutch-shaft tube (**C**) (Fig. 39) out of the clutch-pedal adjuster (**D**) the necessary amount. See that the clutch-pedal adjuster lock screw (**E**) enters the slot and is wired fast.

Clutch brake: The flange on the end of the clutch shaft is provided with an asbestos facing with which a flange on the clutch adjuster (**D**) can be made to engage by pressing the clutch pedal clear down. As the clutch adjuster does not revolve, it serves as a brake on the clutch. Do not bring this brake into action when coasting; simply press the clutch pedal lightly, just enough to disengage the clutch.

The clutch spider has oil-soaked wood bushings which should not need lubrication, although oil will not injure them. The declutching mechanism is provided with a grease cup which should be given a turn or two every day.

To remove clutch: Take off the spring adjusting nuts (**B**) loosen clamp collar (**F**), slip the clutch pressure spider (**K**) back, removing the starter sprocket spider, if used. Take nut (**G**) off the clutch spider stud. At the other end of the shaft remove the joint ring (**M**) and back out the clutch shifter pivot screws (**H**). The entire center section can now be dropped out, after which the removal of a cotter pin in the collar permits the detachment of the clutch spider and disks.

Transmission

The transmission has three speeds forward and one reverse. The gear shift is standard S.A.E.

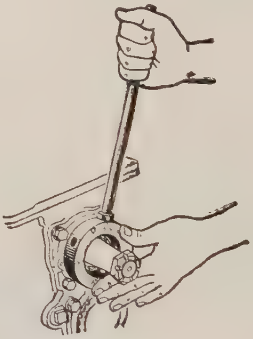

Fig. 40. Showing adjustment of roller bearings on transmission main shaft with a spanner wrench.

Adjusting bearings: Timken roller bearings are used throughout, and those on the main shaft are adjusted by the spanner nuts just outside the case at the front end (Fig. 40). Turning the notched plate outside at the rear adjusts both bearings on the square shaft.

The notched plates turn to the left to tighten the bearings. Be sure that the locking plates are in position before leaving the job, as these hold the adjustment. The inside horned nut at the rear end is a packing device. The counter-shaft bearings are adjusted at the rear by the same kind of device as used on the main shaft.

Great care must be taken not to get the bearings adjusted too tight.

Rear Axle

The rear axle is of the internal gear type. The load is carried on a drop-forged, heat-treated alloy-steel solid axle. Power is transmitted from the differential (Fig. 42) to the driving pinion shaft. The driving pinion meshes with the internal gear, as shown in Fig. 45.

Fig. 42

Fig. 41. Rear view of differential carrier. Top sectional view is shown in Fig. 42.
Fig. 42. Sectional view of rear-axle assembly on International one-ton truck.

Adjusting gears: Remove the drive-shaft packing plate (**A**) and back off lock screw (**B**) (Fig. 42) on each side of the differential housing; the adjusting ring (**C**) is then accessible through openings in the housing. These rings **adjust** the bevel gear sidewise, and take up any play in the thrust bearings.

The bevel-drive pinion is adjusted by (**E**) (Figs. 42 and 43). Remove the cap screws locking this piece. To back the pinion **out,** turn (**E**) to the right. To force it **in,** turn to the left.

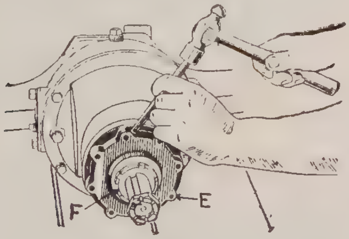

Fig. 43. Forcing the bevel pinion in by rotating the adjusting ring in the left-hand direction.

Put the lock screws back in and draw up, forcing the pinion and bearing assembly forward. There are three tapped holes close together for each screw, so that a close adjustment can be made. Pull (**E**) hard against the case with the lock screws.

The best way to determine whether the adjustment is perfect is to cover the teeth of one gear with a light coating of Prussian blue and then, after assembling, to turn the gears a few revolutions. When the blue is transferred to the other gear uniformly, from end to end of the teeth, the adjustment is right.

Be careful to have the adjustments securely locked before assembling finally, and be particularly careful that there is no pressure exerted by the adjusting nuts on the thrust bearings. If there is you may have to take the axle down again shortly, and put in new bearings.

The notched nut (**F**) (Fig. 43) **adjusts the thrust bearings only.**

While an experienced man can adjust the gearing without removing it, it is much more readily done by getting it out where it can be seen. To do this, jack up the axle, remove the wheels, remove the bolts fastening the bearing retainer to the brake anchor, and pull out drive pinion and shaft. Unbolt the gear carrier (**F**) from the housing, when the carrier with the assembly gears can be pulled forward. **Do not remove the bolts holding the housing to the axle.**

In replacing the wheels, first **be sure that the spacer and sleeve are in proper position;** then screw the axle nut up hard, and lock with the cotter pin. This does not apply to old-style axles.

To Remove Internal Gear from Wheel

1. Pry out the locking ring (Fig, 44).
2. Pry or pull out the internal gear (Fig. 45).

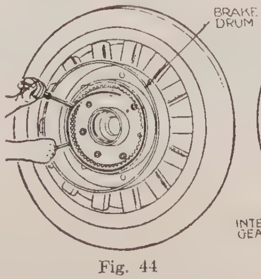

Fig. 44

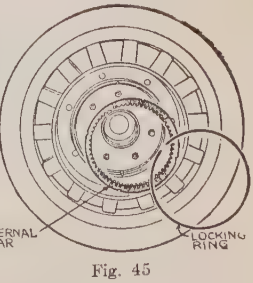

Fig. 45

Fig. 44. Showing how to pry out the gear-locking ring.
Fig. 45. Showing the ring and the internal gear removed.

3. Insert the new gear, using partly inserted round keys to locate the gear with reference to the key ways.

4. Drive the gear and keys home with a soft hammer or by using a block of wood to strike against.

5. See that the locking ring is down in its groove and that the cotter pin is inserted in the hub rim.

See illustration, Fig. 42, showing location of the internal gear, driving pinion, and drive shaft.

WHITE 3/4-TON TRUCK

Specifications

Frame: Pressed alloy steel.

Axles: Front, one-piece drop-forged I-beam alloy steel, heat treated; rear, special white type, trussed.

Springs: Semi-elliptic.

Wheels: Artillery type, fitted with ball bearings.

Tires: Pneumatic, 34″ x 5″, cord.

Capacity: 1,500 lbs.

Carburetor: White aspirating type, meaning a spray type of jet.

Ignition: High-tension magneto of the Eisemann, Bosch, or Teagle make.

Cooling: Water circulation by gear-driven centrifugal pump; cellular radiator supported on springs.

Steering: Left-side drive; worm and sector type, "fore-and-aft" method.

Brakes: Foot brakes contracting on drums on each rear wheel; hand brakes expanding on drums on each rear wheel.

Drive: Shaft drive final drive by bevel gears.

Gasoline tank: Capacity 15 gallons; gravity feed to the carburetor.

Chassis dimensions:

Wheel base: 133½ in.

Gauge: 56 in.

Length over all: 14 ft. 3 in.

Width over all: 5 ft. 6 in.

Dash to rear of frame: 10 ft. 10⅜ in.

Dash to center of rear axle: 8 ft. 7 in.

Rear of seat to rear of frame: 7 ft. 1⅜ in.

Extreme width of frame—34 in.

Height of top of frame in rear: 32¾ in.

Weight of chassis: 3,200 lbs.

Engine

The engine is of the 4-cylinder, 8-valve, L-head type; bore 3¾″; stroke, 5⅛″; cast-iron pistons.

When the valves are closed the **clearance** between the valve stem and the tappet should be .010″ (engine cold).

The clearance on the diameter of all connecting-rod bearings should be between .001″ and .002″.

Crank shaft: The White ¾-ton crank shaft is noteworthy in that it runs on **two ball bearings** (2) and (3) (Fig. 47). This necessitates a short, stiff crank shaft.

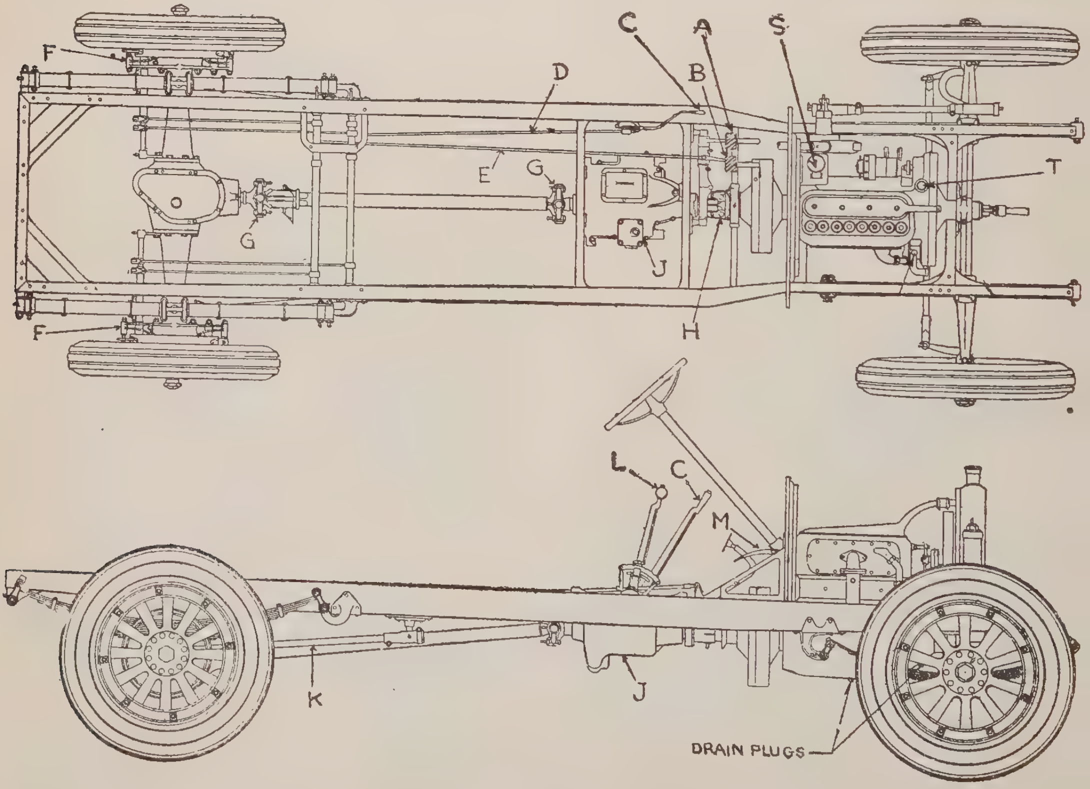

Fig. 46. Top and side view of chassis of the ¾-ton White truck.

S, Oil Reservoir.
T, Crank-case oil filler.

If it were desired to have a three-bearing crank shaft on ball bearings, it would be impossible to slip a ball race on the center bearing of a one-piece shaft. In order to obtain a three-bearing support with ball bearings, a built-up crank shaft must be used, that is, the shaft is made in two pieces; then after the center bearing is in place, the parts must be joined by some means such as disks. Therefore with the White crank shaft, using two ball bearings, the crank shaft is made very heavy in order to withstand the power impulses without "whipping" at high speeds.

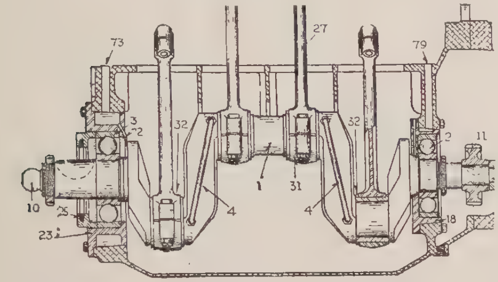

Fig. 47. Ball-bearing crank shaft.

(1) Crank shaft.
(2) Crank-shaft bearing.
(3) Crank-shaft bearing.
(4) Crank-shaft oil tube.
(10) Clutch-shaft ball.
(11) Crank-shaft gear.
(25) Crank-shaft rear bearing-ring felt washer
(23) Crank-shaft rear bearing case.
(27) Connecting rod.
(31) Connecting-rod bearing cap
(32) Connecting-rod bearing.
(72) Crank-shaft bearing oil tubes.
(73) Oil port, rear.
(79) Oil port, front.

Lubrication: Oil is supplied to a gear-driven plunger pump by the reservoir (S) (Fig. 46). The pump forces it through sight oil feeds on the dash, thence to the oil ports (73) and (79) (Fig. 47). After dropping on the conical surfaces at the end of the crank shaft, it is carried by centrifugal force through passages in the crank shaft to the connecting-rod bearings (32) (Fig. 47), thence through oil tubes (4) (Fig. 47) to the remaining connecting-rod bearings. From the connecting-rod bearings, the oil is thrown off in a spray, thus lubricating the cylinder walls and maintaining the oil level in the crank case.

The ball bearings (2) and (3) (Fig. 47) receive lubrication from the splash and from some of the oil thrown off by the crank shaft.

The only purpose of the oil in the crank case is to act as a cooling agent, and consequently it should not be too full, as explained later under the subject of general lubrication.

Transmission

The transmission is of the selective type, and has four speeds forward and one reverse. Direct drive is on the third gear, **fourth speed being geared up.** Third speed is always used when running loaded or when running light at ordinary speeds. The only time to use fourth speed is when running light on a good level road at a high rate of speed. The various gear-shift positions are shown in Fig. 48.

The total gear reductions are: first speed, 18.6; second speed, 8.57; third speed, 5.36; fourth speed, 3.99; reverse, 25.18.

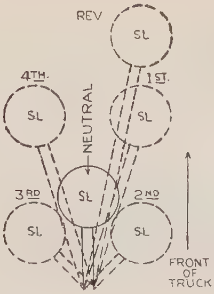

Fig. 48. Gear-shift positions of ¾-ton White (not a standard S.A.E.)

Rear Axle

The rear drive is through a bevel-gear drive. Adjustments are made as on a passenger car. The differential gears are of the straight-toothed, three-quarter floating type.

Clutch

The single-plate type, operating in oil, is similar in construction to the White 3½-ton clutch, shown in Fig. 52, page 935.

Fill the clutch through the oil plug (7) (Fig. 52) with one pint of light engine oil. After the first 500 miles, and then after each 2,000 miles, drain the oil from the clutch and refill with one pint of kerosene. Allow the engine to run at a moderate speed for one minute, meantime engaging and releasing the clutch a few times. Then stop the engine and drain the kerosene, and refill with light engine oil.

Clutch Adjustment

The space between the clutch cover (see Fig. 52 [5], page 935) **and the shoulder of the clutch flange** (29) can be adjusted to its proper width (between ¼″ and ⅜″) by depressing the clutch pedal as far as possible and removing the friction-plate ring lock (14), while in this position. A section of the notched friction-plate ring (12) (which can be turned by means of a screw-driver) will appear through the opening. To increase the space above mentioned, turn the ring in a clockwise direction, and to decrease it, turn counter-clockwise.

The clutch foot lever, which can be moved after loosening the binder bolt, at its connection to the shaft, should be ½″ from the floor board when the the clutch is thrown in.

The clutch brake may be adjusted by turning the threaded clutch brake-band pull rod so that the brake shoe comes into contact with the clutch coupling ring only on the extreme outward throw of the clutch.

Rear Wheels

The rear wheels (Fig. 49) are fastened to the rear axle spindles by a square and taper.

To remove the wheel and spindle, jack up the end of the rear axle and loosen the nuts (70) on the two bracket **hook bolts.** These bolts are located on the ends of the axle sleeves near the wheel. The outside ends of the hook bolts fit into grooved slots in a plate which holds the bearing in position. When these hook bolts are loosened the "L"-head of the bolts can be turned out of the slot, and the wheel and spindle can be pulled off.

(89) Rim
(90) Rim locking ring
(91) Rim side ring
(92) Rim clamping ring
(93) Rim bolt
(94) Rim bolt nut
(95) Rim clamp

A tight fit of the driving spindle in the rear-wheel hub must be maintained at all times in order that the driving strain be evenly distributed throughout the entire length of the hub. If the spindle is allowed to work loose, the hub becomes distorted and enlarged, allowing the entire driving strain to be taken by the square section of the spindle. This condition may result in a fracture.

The fit of the spindle is obtained by tightening the spindle nut (85), and by making sure that the spindle nut washer is tight against the wheel hub (76). The fit should be checked occasionally, especially during the first 1,000 miles of driving with a new truck..

Occasionally examine the spring clips which hold the spring to the seat and see that they are kept tight. Loose spring clips may allow the axle to shift and cause shearing of the spring center bolt or a breaking of the spring plates.

Lubricating Instructions

Engine: Place the truck on a level space. Open the crank-case overflow valve by pulling out the valve stem under the radiator. Pour filtered, medium heavy engine oil into the crank case through the filler (T) (Fig. 46) on top of the timing-gear case until it is even with, but not above, the level of the overflow valve. Pour the same kind of oil into the oil reservoir (S) (Fig. 46) until it is full.

Transmission: Fill the transmission case with transmission oil, through the filling hole on top, up to the level of the oil-level plug on the side. After each 1,000 miles, add sufficient oil to maintain this level. After each 5,000 miles, drain the case through the drain-hole plug in the bottom, cleanse, and refill.

Rear axle: Fill the rear-axle case with transmission oil through the filler-cap hole on top of the rear axle housing up to the oil-level plug on the side. Examine this case after each 1,000 miles, and add enough oil to maintain this level. After every 5,000 miles, drain it out through the plug at bottom, cleanse, and refill.

Grease lubricators: Fill with soft cup grease, using a grease gun (18) and (19) (Fig. 53, page 935).

WHITE 3 TO 3½ TON TRUCK

Specifications

Frame: Standard I-Beam; channel steel bumper.

Axles: Front, straight type solid drop-forged alloy steel; rear, steel housing.

Springs: Semi-elliptic.

Wheels: Metal, fitted with ball bearings.

Tires: Front, 36″ x 5″ solid; rear, 40″ x 5″ dual solid pressed-on type.

Capacity: 7,000 lbs.

Carburetor: White aspirating type (meaning that a spray jet is used).

Ignition: High-tension magneto of the Eisemann, Bosch, or Teagle make.

Cooling: Water circulation by gear-driven centrifugal pump; radiator, of the vertical tube type supported on springs.

Steering: Left-side drive; worm and sector type, "fore-and-aft" method.

Brakes: Foot brakes contracting on drums on drive shaft; hand brakes expanding on drums on each rear wheel.

Drive: Double reduction-gear drive by shaft to full-floating type of rear axle.

Gasoline system: Tank 32½ gals. capacity; feed by vacuum system.

Chassis dimensions:

Wheel base: 174 in
Gauge: Front wheels, center to center of tires, 64½ in.; rear wheels, center to center of wheels, 61⅞ in.
Length over all: 22 ft. 3 in.
Width over all: 6 ft. 2 in.
Dash to rear of frame: 17 ft. 5 in.
Dash to center of rear axle: 12 ft. 7½ in.
Rear of seat to rear of frame: 13 ft. 8 in.
Extreme width of frame: 42 3/16 in.
Height of top of frame in rear: 37 in.
Weight of chassis: 7,300 lbs.

Engine

Engine has four cylinders, eight valves, and is of the L-head type; bore, 3¾″; stroke, 5¾″. The cylinder head is detachable.

When the valves are closed, the **clearance between the valve stems and tappets** should be .010″, when the engine is cold.

Clearance on the diameter of all connecting-rod bearings should be between .001″ and .002″.

The crank shaft has a three-bearing support and soft metal bearings.

Engine Lubrication System

Pressure feed: The engine and clutch are lubricated by a pressure feed. The oil is taken from the crank-case sump by a gear-type oil pump mounted on the cam shaft, and is forced back to the clutch-shaft bearing and forward to the cam-shaft bearings, timing-gear bearings, and main bearings, thence through the oil ways in the crank shaft to the connecting-rod bearings.

Oil spray from the bearings provides lubrication for all other engine and clutch parts. The oil drains from the clutch mechanism on to the flywheel, by which it is picked up and carried back into the crank case. The oil then drains back to the crank-case sump through a circular strainer or screen, which effectively eliminates all dirt and sediment.

Oil level: The amount of oil in the crank-case sump is shown by a float-actuated oil-level indicator on the left side of the engine frame.

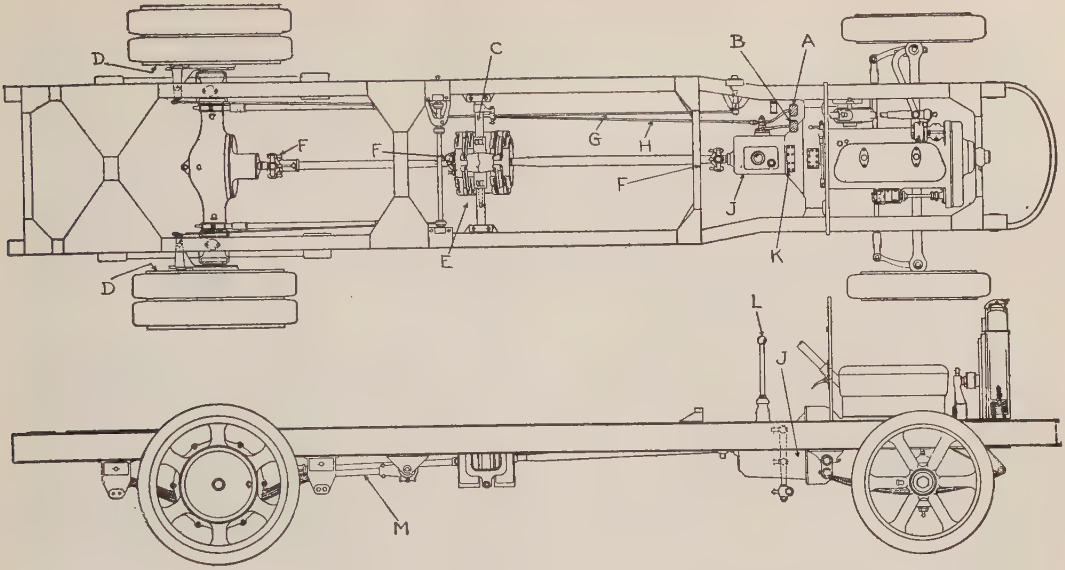

Fig. 50. Chassis views of 3½-ton White truck.

A, Clutch pedal.
B, Foot-brake pedal.
C, Foot-brake shaft.
D, Hand-brake drums.
E, Foot-brake bands.
F, Universal joints.
G, Hand-brake rod.
J, Transmission.
K, Transmission hand hole.
L, Gear-shift lever.
M, Radius tube.

Pressure: The pressure should not exceed 20 lbs., and under ordinary operating conditions 10 to 15 lbs. is sufficient. The oil will, however, show a somewhat higher pressure when cold.

Adjustment: The oil pressure is adjusted by an oil by-pass on the left side of the crank case. Loosen the jamb nut, and turn the screw to the right to increase the pressure, or to the left to decrease it, after which the lock nut must be tightened to maintain the adjustment.

Note. It is very important that the oil be thoroughly warmed when adjustment is made.

Transmission

This is of the selective type, with **four speeds** forward and one reverse. The direct drive is on the fourth speed, the **total gear reduction** being 11.6 on fourth, 19.9 on third, 31.55 on second, 47.85 on first, and 61.5 on reverse.

The gear-shift positions are standard, as shown in Fig. 4, page 912.

Rear Axle

The rear axle is of the **double-reduction** type and is shown in Fig. 51.

(1) Rear axle housing
(3) Rear axle housing pipe plug

(86) Rear wheel drum covers
(90) Rear wheel drum and cover plate
(92) Rear axle compensating case thrust bearing
(93) Rear axle thrust bearing nut

The first reduction takes place in the bevel gears in the center of the axle, the **second reduction** being obtained by means of three gears in the rear wheels. The power is delivered from the driving shaft bevel pinion (11) (Fig 51) and the bevel gear (12) by means of the differential gears (52) and (55) to the full-floating type driving spindles (34). These spindles transmit the power to the drive pinion (37).

This drive pinion meshes with an intermediate gear (41), which in turn meshes with the main driving ring gear (85) which is bolted to and drives the rear wheels. All moving parts run immersed in a bath of oil.

Maintenance of Rear System

To drain the wheels: Jack up one or both rear wheels, turn them until the pipe plug (84) (Fig. 51) is at top center; remove the plug and replace it with a piece of ¾″ pipe approximately 7″ long; then turn the wheel until the pipe is at bottom center, and the oil will drain out clear of the wheel rim.

To remove spindles (34) (Fig. 51): Take out the wheel center plugs (83), then carefully remove the ball (35). Screw into the end of the spindle (34) a standard ⅝″ bolt or rod, and then proceed to remove the spindle from the axle tube (23). After the splined end of the spindle leaves the differential gears (52), the spindle will have to be turned slightly so that it will enter the oil-retaining plug (36), and the driving pinion (37), to permit complete removal.

To remove wheels: Take off the hexagon nuts (89) (Fig. 51); then place set screws (29) (Fig. 53) in lug holes (A) (Fig. 51). Turn up equally, in rotation (a few turns at a time) on all three screws by means of the socket wrench, furnished with the equipment. This is very important as it allows the wheel to leave the ball bearing (28) without injury. The removal of the wheels can be greatly assisted by placing a four-castered dolly, a plank with rollers, or a piece of sheet iron under them, which, by lowering the jack, will take the weight of the wheel and permit it to slide off the studs (89) very easily.

To remove main driving-ring gear (23) (Fig. 51): This gear comes off with the wheel and can be very readily removed by means of wedges or flat chisels.

Note. When reassembling the wheel, inspect the ring-gear gaskets and make sure that they are in good condition. Put the gaskets and ring gear on studs before replacing the wheel, to avoid injury to the former.

To remove axle housing tube (23) (Fig. 51): Remove the axle tube locks (25), and loosen the nuts on the rear spring U-bolts, both of which are absolutely necessary in order to remove the tubes. The tube position is maintained by means of a spline in the axle housing, which necessitates the tube being pulled out straight about 6 inches.

Note. After the splined end of the tube leaves the spline of the housing, there is nothing to prevent the intermediate gear dropping from the horizontal to a vertical position.

Caution: It is important that the mechanic, for his own safety, exercise care in performing this operation.

To remove brake drums (86) (Fig. 51): After removing the tube, stand it on end and the brake drum will slide off.

To remove intermediate gear (41) (Fig. 51): Remove the bearing (29), by unscrewing the bearing lock nuts (30). The bearing and inner bearing washers can then be moved along the axle tube a sufficient distance to allow the pin (44) to clear it. The intermediate gear and bearing (42) will then slide out from between the supporting lugs of the axle tube.

To remove driving pinions (37) (Fig. 51): To remove the driving pinions, the intermediate gears must first be removed; then remove the driving-pinion-bearing lock nuts (39) (Fig. 51), and the driving pinions, complete with the ball bearings, can be taken out of the tube as an assembled unit.

To remove differential and bevel gears (11), (12), (52), (55), etc. (Fig. 51): First remove the spindles (34), as already instructed, sufficiently to clear the differential-housing bearing lock nuts (8) and (93); then remove the cap screws (5), and the differential housing (4) can be removed from the axle housing (1), as a complete assembly.

To remove driving shaft and bevel pinion (11) (Fig. 51): First loosen the binder bolt (6), then unscrew the retaining sleeve (14), and it can then be removed complete with the shaft, the bevel pinion and the bearings (17) (18) all a self-contained unit.

Adjustments: The meshing of the bevel driving gears can be adjusted by removing the lock nut locks and turning the differential-housing bearing lock nuts (8) and (93) (Fig. 51) by inserting a small bar in lock opening in the differential housing. The locks must then be replaced to lock the bearing lock nuts and maintain the adjustment.

Caution: Care should be exercised in noting the position of the bevel gears before removing the differential unit. They must be replaced in their original position in order to prevent reverse motion of the wheels.

Clutch

The clutch is of the **single-plate type, operating in** oil.

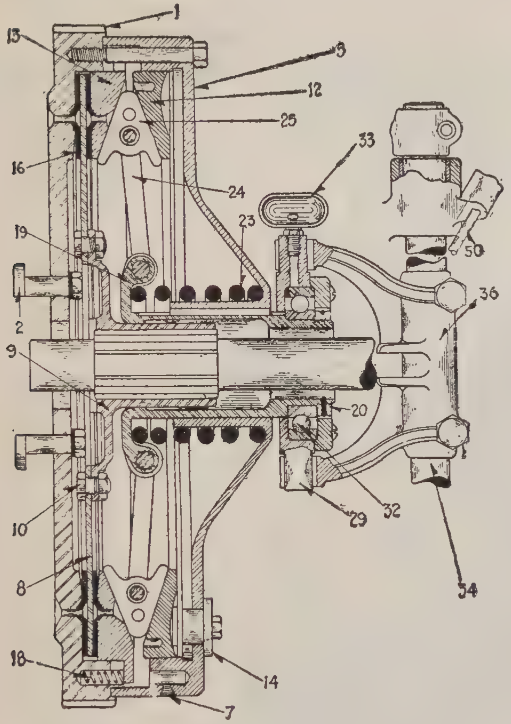

Fig. 52. Single-plate clutch operating in oil.

(1) Clutch flywheel
(2) Clutch flywheel bolt
(5) Clutch flywheel cover
(7) Clutch flywheel plug
(8) Clutch friction plate
(9) Clutch friction plate hub
(10) Clutch friction plate hub bolt
(12) Clutch friction plate ring (notched)
(13) Clutch friction plate ring (plain)
(14) Clutch friction plate ring lock
(16) Clutch friction plate shoe
(18) Clutch friction plate spring
(19) Clutch toggle spider
(20) Clutch toggle spider lock nut
(23) Clutch toggle spider spring
(24) Clutch toggle spider strap
(25) Clutch toggle spider wedge
(29) Clutch pull-out shoe
(32) Clutch pull-out shoe bearing (No. 211)
(33) Clutch pull-out shoe oil cup
(34) Clutch pull-out shaft
(36) Clutch pull-out shaft yoke
(50) Clutch oil tube

To adjust clutch: After removing the hand-hole cover (K) (Fig. 50) and turning the clutch until the ring lock appears, the space between the flywheel cover (5) (Fig. 52) and the clutch pull-out shoe (29) can be adjusted to its proper width (between ¼″ and ⅜″) by depressing the clutch pedal as far as possible and removing the friction plate ring lock (14), while in this position. A section of the notched friction plate ring (12), (which can be turned by means of a screwdriver) will appear through the opening. To increase the space mentioned above, which adjustment will bring the clutch brake into action sooner, turn the ring in a clockwise direction, and to decrease it, turn it counter-clockwise.

The clutch foot lever, which can be moved after removing the rod end pins at the bottom of the clutch foot lever, should be ½″ from the floor board when the clutch is thrown in.

The clutch brake may be adjusted by turning the threaded clutch brake-band pull-rod, so that the brake shoe comes into contact with the clutch coupling ring only on the extreme outward throw of the clutch.

Oil for the clutch is furnished by force from the engine base.

Lubricating Instructions

Engine: Pour filtered medium-heavy engine oil into the crank case sump through the filling hole until the oil-level indicator, on the left side of the engine frame, shows it to be full.

Rear axle: The best lubricant is composed of 50 per cent straight mineral cylinder stock of as low a cold test as possible and 50 per cent of the oil used for the engine. Fill each rear wheel with two quarts through the pipe-plug hole (84) (Fig. 51). Likewise put one gallon of the same mixture in the center housing through the filling hole (3). Every 5,000 miles, remove the drain plugs (3) and (84), cleanse, and refill.

Transmission: Fill the transmission case with transmission oil through the filling hole on top to the level of the overflow plug on the left-hand side of the case. Each 1,000 miles, add sufficient oil to maintain this level; and each 5,000 miles, drain the case through the drain-plug hole in the bottom, cleanse, and refill.

Grease lubricator: Fill with soft cup grease, using a grease gun (18) (19) (Fig. 53).

Truck Driver's Tool Equipment

A good set of tools should be carried on every truck. A well-assorted set is shown in the illustration below (Fig. 53). This is the tool equipment as supplied by The White Co. with all of its trucks.

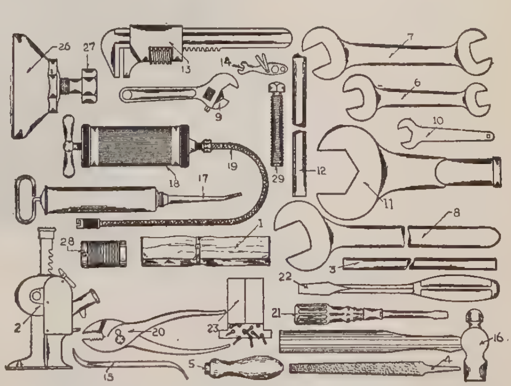

Fig. 53. The White truck tool equipment.

(1) 1 Canvas tool bag
(2) 1 Jack
(3) 1 Jack handle
(4) 1 Half-round file
(5) 1 File handle
(6) 1 Open-end wrench No. 30 (11/16″ x ⅞″)
(7) 1 Open-end wrench (15/16″ x 1⅛″)
(8) 1 Open-end wrench No. 35 (1¼″)
(9) 1 Open-end adjustable wrench (6″ long)
(10) 2 Valve-lift adjusting wrenches (11/16″)
(11) 1 Hub wrench (3¼″)
(12) 1 Hub wrench handle
(13) 1 Auto wrench (14″)
(14) 1 Magneto wrench
(15) 1 Cotter-pin extractor
(16) 1 Hammer
(17) 1 Oil gun
(18) 1 Alemite grease gun
(19) 1 Alemite grease gun tubing
(20) 1 Pliers (8″)
(21) 1 Screwdriver, small (3″)
(22) 1 Screwdriver, large (9″)
(23) 1 Package assorted cotter pins
(24) Not furnished
(25) Not furnished
(26) 1 Front wheel puller
(27) 1 Front wheel-puller screw
(28) 1 Spool of wire (No. 18)
(29) 3 Set screws (¾″-10)

A MODERN TRUCK ENGINE: CONTINENTAL MODEL "L4" RED SEAL

This engine will be used as an example of the construction of a modern truck engine. For a description of the Continental passenger-car engines, see pages 93 and 94.

Specifications

Cylinders: four, 4½" bore, 5½" stroke; displacement, 350 cu. in.; **Power,** S.A.E. rating, 32.4; Brake h.p., 25.5 at 600 r.p.m., 37.0 at 1,000 r.p.m., 42.0 at 1,200 r.p.m., 43.0 at 1,300 r.p.m.; **Weight,** 807 lbs.; **Cooling,** centrifugal pump; **Lubrication,** "full force" pressure feed (see Fig. 55); **Carburetor,** vertical outlet, 1¼" S.A.E. flange; **Ignition,** provisions for magneto or engine driven distributor; **Generator,** crank case accommodates any standard make; **Starter,** fly-wheel housing accommodates any standard make with Bendix drive; **Clutch,** multiple disk or 12" plate type can be used; **Suspension,** three-point; **Construction,** unit power plant with enclosed flywheel.

Fig. 54. **Front sectional view of model "L4," four-cylinder "Red Seal" Continental engine.** Model "L4" is designed especially for trucks with a carrying capacity of 3½ tons.

Lubrication

The main oil distributing line runs the full length of, and is cast integral with, the crank case. The passage is lined with steel to eliminate seepage. From this reservoir, secondary leads, cast in the crank case and lined with steel, run to the three main bearings of the crank shaft and to the gear case. Through passages drilled in the crank shaft, oil is supplied under pressure to the connecting-rod crankpin bearings. **Piston pins are supplied with oil** through separate lines running up the connecting rod from the lower end bearing. The cam-shaft bearings and cylinder walls are lubricated by the oil spray thrown off by the connecting-rod bearings.

The oil-pressure regulating valve, with adjustment at the top of the gear case, distributes oil over the timing gears and timing-gear bearings. An individual line, connecting with the main reservoir, takes care of the governor-drive gears.

Oil-pressure adjustment: At the factory adjustment is made at the oil-pressure adjustment screw to show 7 lbs. at 600 r.p.m. Higher pressures can be expected of a cold engine. Under ordinary operating conditions, the pressure may range from 7 lbs. to 30 lbs., depending on the viscosity of the oil and the general condition of the engine. Adjust when the oil reservoir is filled with fresh oil and the engine is warm.

After releasing the lock nut, the adjusting screw should be turned down to increase the pressure, or up to decrease the pressure, until the correct amount is indicated by the gauge on the dash. When the correct pressure is indicated, be sure to turn the adjusting-screw lock nut down until tight.

Valve Timing—Continental Model "L4"

Inlet opens 10° after top; **closes** 20° after bottom. **Exhaust opens** 36° before bottom; **closes** 5° after top.

The **inlet** open period is 190° and the **exhaust** open period is 221°. **Firing order** is 1, 3, 4, 2. **Greatest torque** is at 625 r.p.m. **Carburetor** flange opening is 1¼" (S.A.E. flange—see page 1051).

Fig. 55. **Longitudinal sectional view showing lubrication system of model "L4," four-cylinder "Red Seal" Continental engine.** Lubrication of model "L4" engine is provided with a pressure-feed oiling system, or what is termed **"full force feed."** The gear-type oil pump is **submerged** in the oil in the reservoir and is automatically primed, and supplies oil positively under a pressure varying from **7 lbs. to 30 lbs.** Note that the **end play in the cam shaft is adjustable** by means of the cam-shaft end-thrust adjusting screw.

Continental "Red Seal" Model "J4" Engine

The model "J4" (not illustrated) is a smaller model, designed for truck use. **Type:** 4-cylinder, vertical, L-head. **Size:** 3¾″ bore by 5″ stroke. **Power:** S.A.E. rating, 22.5 h.p.

Questions and Answers on Continental Engines[1]

Q. 1: What is the difference between engines designed for passenger cars and engines designed for trucks or for other heavy duty work?

Ans.: **Passenger-car engines** are constructed more lightly than commercial truck engines. The **elimination of unnecessary weight** is a most important item in passenger-car design, as **comfort and performance** are primary requirements. Weight distribution, as it affects the balance of the car, is another important item which affects directly the performance of the vehicle. Then, too, a passenger-car engine is seldom called upon for maximum power at any speed, and only a small percentage of the developed power is used under normal driving conditions. Consequently the resistance offered the power impulses is small in proportion to the developed power of the engine. In design, the weight and strength of the reciprocating parts are in proportion to the resistance offered the power impulses in average service, with a suitable factor of safety to withstand the heavy duty often encountered by passenger cars when going up hills and through bad roads. A motor of this type accelerates quickly and is usually capable of higher speeds than are developed by truck motors of the same bore and stroke.

Truck engines, on the other hand, are called upon for a larger percentage of their developed power at practically all times. For this reason, the **moving parts are more generous in size,** and the engine is otherwise designed to withstand greater strains. Performance, acceleration, flexibility, are not the important requirements of a commercial vehicle. There must be ample power, however. **Dependability and long life** are essentials. The engine must operate at full speed with maximum efficiency, day after day, for long periods of time, under a great many unfavorable weather and road conditions. This calls for more adequate cooling facilities, generous bearing surfaces, and more rugged construction throughout. See also page 911 of this instruction.

Q. 2: How is the oil pressure regulated?

Ans.: The flow of oil from the pump increases or decreases in direct proportion to the speed of the engine. Consequently, the oil pressure varies accordingly, as the capacity of the oiling system, accurately predetermined for each given engine, is a constant and fixed quantity. To prevent an excessive oil pressure, an automatic relief valve is connected to the oil line. This valve is located in the gear-case cover, but is adjusted from the outside of the engine. Regulation of this valve is taken care of through a screw held in place by a lock nut. The screw controls the tension of the coil spring against which the **ball valve automatically opens in proportion to the pressure,** and allows the surplus oil to flow over the timing gears, thereby maintaining in the oil lines the most effective pressure for adequately lubricating all moving parts.

---

[1] See pages 93 and 94 for the Continental passenger-car engine, model "7R."

Q. 3: If adjustment of the oil pressure is required, when should it be made?

Ans.: The ideal time for adjusting oil pressure is when the engine is filled with fresh oil and after it has been operating long enough to have attained its normal running temperature.

Q. 4: What are the correct oil pressures for "Red Seal" Continental motors?

Ans.: The correct oil pressure to maintain depends first upon the type of oiling system used in the engine. Continental motors in use today are provided with one of two types of lubrication.

The first, a **combination splash and force-feed system,** usually includes a plunger-type oil pump and might be termed a low-pressure system. The oil gauge will usually show a reading of from 2 lbs. to 7 lbs.

The second, a **full force-feed system,** usually includes a gear-type oil pump and might be termed medium or high pressure. Engines so equipped will usually operate under a pressure from 10 lbs. to 30 lbs. In every case the pressure is influenced to some extent by the speed of the vehicle, the viscosity of the oil, and the general condition of the engine.

Q. 5: Can valve guides be replaced and what are they made of? Are valve plunger guides replaced and what are they made of?

Ans.: Both valve guides and valve tappet guides are made of a refined grey iron. They can easily be replaced.

Q. 6: Are governors used on Continental motors?

Ans.: Motors designed for passenger-car service are not adapted to governor installation.

Motors designed for commercial vehicle work, however, have provision for standard types of engine-driven mechanically operated governors. The maximum speed is 1,300 r.p.m., usually governed to 1,200 r.p.m.

Q. 7: What is the bore of the cylinder of the "L4" in decimals?

Ans.: The bore is 4.500″ (four inches and five hundred one-thousandths, or 4½″).

Q. 8: What is the standard clearance of the piston?

Ans.: The standard clearance on the "L4" is .004″.

Q. 9: What would the standard piston then measure at the skirt?

Ans.: It would measure 4.500″ − .004″=4.496″.

Note that an allowable limit of .002″ is usually permitted for the cylinder bore and the piston, and the standard piston will usually measure **4.498″**.

Q. 10: What sizes of oversize pistons are furnished by the Continental Motors Corporation?

Ans.: .002″, .003″, .005″, .010″, .020″, .022″, .025″, .027″, .030″, .035″, .040″, .045″.

Q. 11: What would they measure, expressed in decimals?

Ans.: If the standard-size piston is 4.498″, the .002″ oversize would be 4.498″+.002″=4.500″.

.003″ oversize; 4.498+.003=4.501″
.005″ oversize; 4.498+.005=4.503″
.010″ oversize; 4.498+.010=4.508″
.020″ oversize; 4.498+.020=4.518″
.022″ oversize; 4.498+.022=4.520″
.025″ oversize; 4.498+.025=4.523″
.027″ oversize; 4.498+.027=4.525″
.030″ oversize; 4.498+.030=4.528″
.035″ oversize; 4.498+.035=4.533″
.040″ oversize; 4.498+.040=4.538″
.045″ oversize; 4.498+.045=4.543″

EXAMPLE OF ADJUSTING A LIGHT TRUCK AND TRACTOR ENGINE (WAUKESHA)

There are many different makes of truck engines. It is impossible to show them all. We will, therefore, select the **Waukesha** as an example of how adjustments are made, such as taking up on the bearings, etc.

Although the construction may vary on different engines, the same principle of making these adjustments will apply to many of the other engines on the market. See also discussion of the **Continental model "L4" engine** (page 936), which is a very popular engine in use on many different makes of trucks.

How to Put Oil in Engine

Remove the breather cap (A) (Fig. 58). Pour oil into the breather until the needle float in gauge (B) comes up to within ¼″ of the top of the glass.

Remove the crank-case hand-hole plate (Fig. 62), and fill each trough under the connecting rods.

Use a thinner oil in winter and a heavier one in summer.

(C) (Fig. 58) represent water drains for cleaning sediment or rust from the water jacket and circulating water pump, and also for draining in winter to prevent freezing.

Engine Oiling System Inspection

Drain the oil—remove the oil pan so that you can inspect thoroughly. When the system is running properly, a stream of oil is constantly forced through holes (A) (Fig. 59). Inspect each oil hole carefully and see that they are not clogged or partially clogged up. A piece of waste or dirt may have worked into one of the holes, preventing the flow of oil entirely.

To test the oil flow: With some oil in the oil pan, turn the oil pump shaft with a pair of pliers as shown. If the oil discharges through all of the holes, the pump and oil line are working properly.

Clean the screen (3M) (Fig. 59): This should be cleaned often with gasoline, say every three months, if the engine is run regularly every day. When removing the screen for cleaning, be sure to retain the supporting spring inside and to make sure of an oil-tight joint being established between the oil-pump screen-flange gasket and the crank case (see Fig. 59).

The oil pump is located at the lower left side of the engine, when standing in rear of it (see Fig. 62 and Fig. 57). It is driven by a cam shaft (see Fig. 57).

The system described above is the oiling system of the models "L," "M," "P," "N," "R," "S," "O," "SU4R," "RU4R," "LU4," "MU4," and "PU4" Waukesha engine.

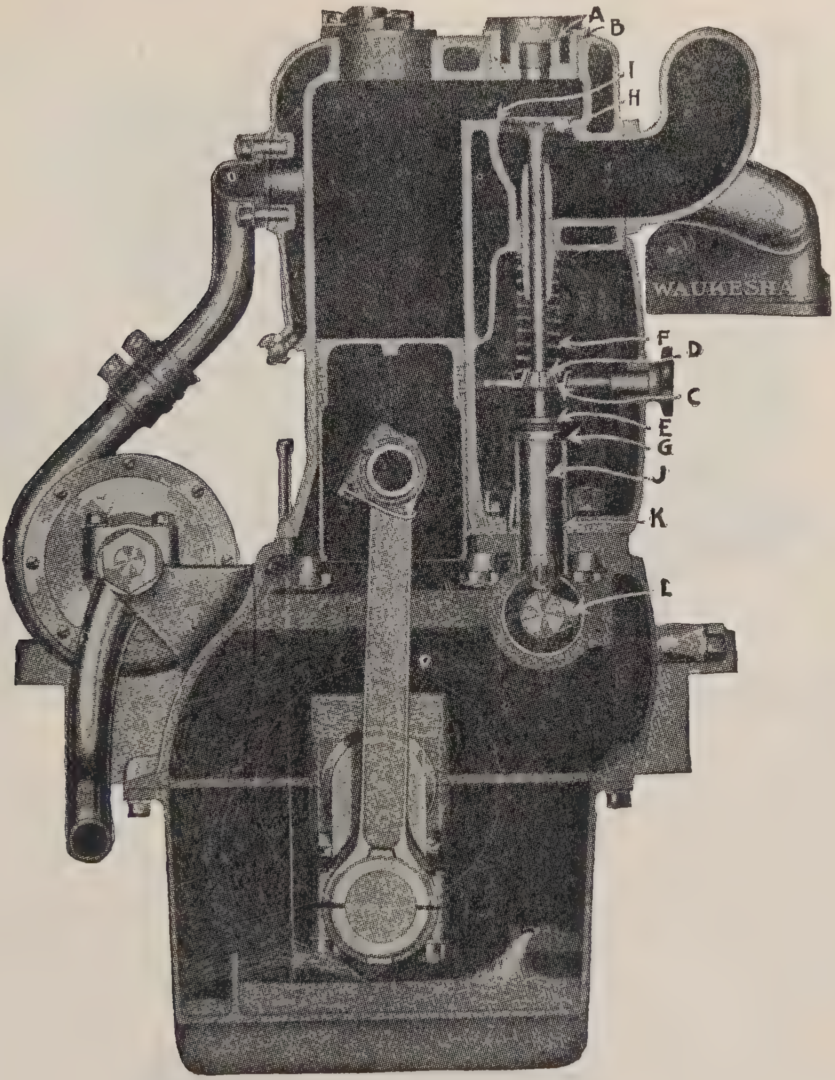

Fig. 56. **Front-end sectional view of the Waukesha 4-cylinder engine.** Lubrication is of the splash system: (**F**) valve spring; (**D**) valve spring retainer; (**C**) valve spring cap; (**E**) lifter adjusting screw; (**G**) lock nut; (**J**) valve lifter; (**K**) valve guide; (**L**) cam on cam shaft; (**A**) valve cap; (**B**) copper gasket; (**I**) valve seat; (**H**) valve face. Water circulating pump on left.

Kinds of Oil to Use

For pleasure cars, thin; for trucks, thicker; for tractors (gasoline), heavy; for tractors (kerosene), heaviest. When kerosene is used, clean the oil pan often and put in fresh oil (see page 167).

To Get at the Gears

Take off the front gear cover carefully. See that no bolts or nuts are mislaid or lost. Also be careful, in taking off the ball-race on the governor, to see that none of the bearings drop out. Do not put the front gear cover on again until you are absolutely sure that every one of the ball bearings is in place, and that the paper gasket is in good condition to prevent oil leaks.

Be sure to mark the gears. It is very important that the gears be kept in exactly the same position as when you received the engine. Mark each gear as shown in Fig. 60, that is, mark the center gear (**A**) (**B**) (**C**), as shown; then mark the same letter on the gear that connects at the particular point.

In putting the gears on again, see that the connections are **A-A, B-B, C-C,** just as marked.

In marking the gears, put the letter on the cog of one gear and on the corresponding space where this tooth meshes on the connecting gear, just as shown in Fig. 60**A**.

Operation of Waukesha Governor

Two circular weights back in the case behind gear (**O**) (Fig. 61) are held by—and swivel about—the two pins marked (**K**). These weights fly out at speed—moving the part (**A**) outward. This action presses the ball-bearing thrust contained in retainer (**B**) outward in proportion.

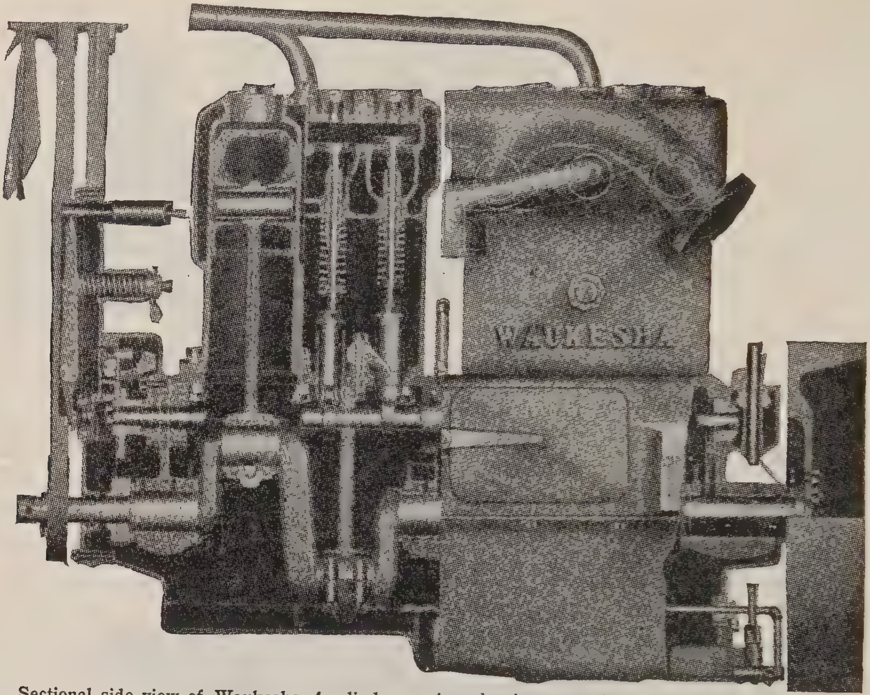

Fig. 57. **Sectional side view of Waukesha 4-cylinder engine** showing operation and interior construction. Note the governor fulcrum and the oil pump, the latter being at the lower flywheel end.

The lever (**D**) swivels on the fulcrum (**C**). The movement of (**A**) causes a movement of rod (**R**) in the direction indicated by the arrow. The movement of rod (**R**) closes valve (**h**), which is of the butterfly type, and swivels on shaft (**S**).

The adjustment for speed is made by turning screw (**L**). Turning (**L**) in the direction indicated by the arrow causes the engine to speed up, while turning (**L**) in the opposite direction causes the engine to slow down.

The governor is locked by locking nut (**G**). It is further possible to lock and seal the whole arrangement by passing a seal wire through the hole in the spring housing, and through the hole in nut (**G**).

(**F**) is a spring, the tension of which governs the speed of the engine. The governor is of the throttling type, and controls the amount of gas to the cylinder; it would, therefore, be termed a throttling type of governor of the centrifugal type—but by weights, instead of by balls.

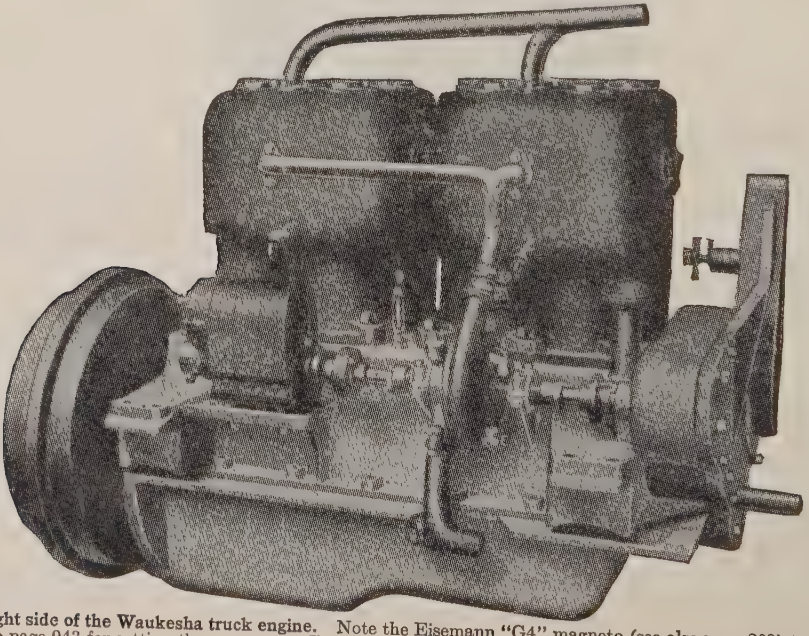

Fig. 58. **Right side of the Waukesha truck engine.** Note the Eisemann "G4" magneto (see also page 269) type used on this engine. See also page 943 for setting the magneto. The circulating pump and magneto are driven from gear (**2C**) (Fig. 60).

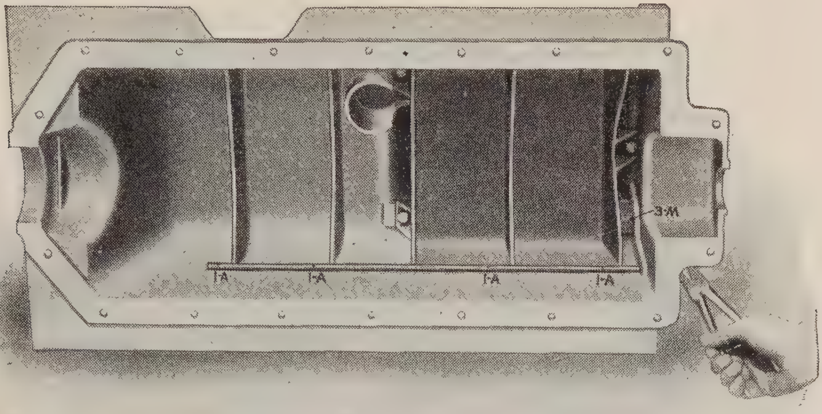

Fig. 59. Oil pan removed.

How to Time the Valves

All Waukesha engines have cylinders numbered 1-2-3-4, starting at the front, or gear end and reading toward the flywheel end.

Timing Valves by Flywheel Marks

As a rule, the flywheels are marked as to when the valves should open. The following method is applied in case the flywheel and the timing gears are not marked.

First: Turn the engine over until No. 1 piston is on upper dead center (Fig. 63). In order to determine when the piston is at upper dead center, remove the cylinder-head plug and insert a steel rule (**R**) (Fig. 62), or any marked stick. Rotate the crank shaft and watch while the rule (**R**) comes up. When it ceases to rise, the piston will be at upper dead center.

Draw two lines across the back side of the flywheel (Fig. 63); next measure off 53° on each side of the center line at the lower half of the flywheel.

Second: On the illustration (Fig. 62) note the pointer (**A**) (also called a trammel; see also page 66). This pointer points to the exact top center of the flywheel. The arrow on the dead center line (Fig. 63), shows where pointer (**A**) points, looking at the back side of the flywheel. Turn the engine over slowly until the arrow (**A**) points directly on line No. 3, as indicated in Fig. 63.

Third: Remove the idler gear (**A, B, C**) (Fig. 60). See that the push rod (**J**) (Fig. 62) is in its lowest possible position. Place a thin piece of paper between the push rod (**J**) and the valve stem (**X**) (Fig. 62). Turn the cam-shaft gear (**O**) (Fig. 61) slowly toward the right until the paper which is placed between the push rod (**J**) and the valve stem (**X**) is held tightly. Be sure that the valve stem (**X**) has not risen any. Also be sure that the cam-shaft gear retains its position and that the piece of paper is still held tightly between the push rod and the valve stem. There should be about .003″ to .004″ clearance for the inlet and .005″ to .007″ on the exhaust.

Fourth: Place a wooden wedge between the cam-shaft gear and the case, in order to keep this setting. This will give the free use of both hands for replacing the idler gear. Replace the idler gear.

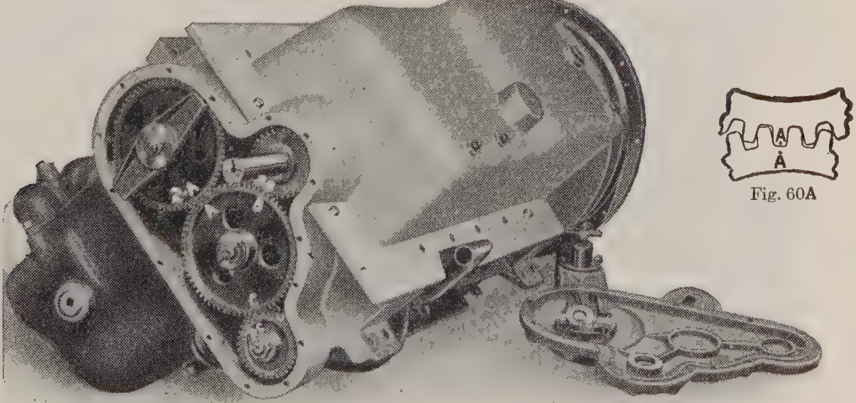

Fig. 60A

Fig. 60. Showing how the gears are meshed. Engine is up-side-down. The small gear (2C) drives the magneto and circulating pump; the next gear to it is the idler gear which is placed between the small crank-shaft gears (2B) and (2C). The gear on which the governor is attached (2A) is the gear which drives the cam shaft and oil pump, and is driven by the idler gear. Therefore the cam-shaft gear (2A) revolves at one-half the speed of the crank-shaft gear (2B).

Fig 60**A**. Shows how the tooth of one gear, marked (A) must mesh between two gear teeth marked (A). Note in Fig. 60 that **A** and **A, B** and **B**, and **C** and **C** must mesh in this manner.

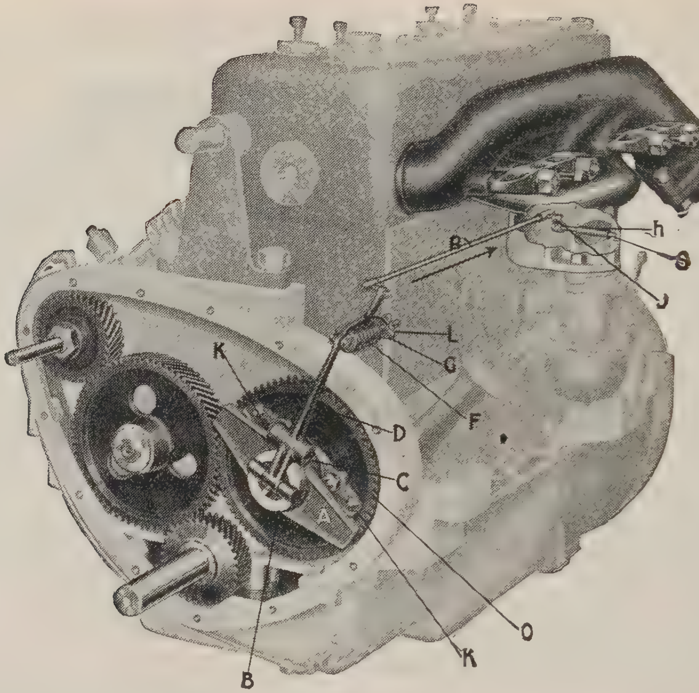

Fig. 61. Front view of engine with gear-case cover removed, **showing gears and governor action.** The large idler gear between the two small gears drives the large cam gear and magneto and circulating pump gear.

Fifth: Give the engine a slight turn (say about one half-inch on the flywheel); now see if the exhaust valve (**X**) has risen any. It should, if the foregoing instructions have been carefully carried out. You can now replace the gear-case cover and the cylinder-head plug.

Timing Valves by Position of Piston

If it is impossible to get at the flywheel, remove the cylinder-head plug, insert a ruler as shown in Fig. 62. When the upper dead center has been determined, measure the distance from the top of the piston to the top of the cylinder. For example, let us say it is 2″. See arrow marked (**D**) (Fig. 62).

Now slowly turn the engine over until the distance from the top of the piston to the top of the cylinder measures $7\frac{5}{8}''$. This means that the piston has made a drop of $5\frac{7}{8}''$, at which place the exhaust valve (**X**) should just start to open. In order to set the valve and complete the timing, refer

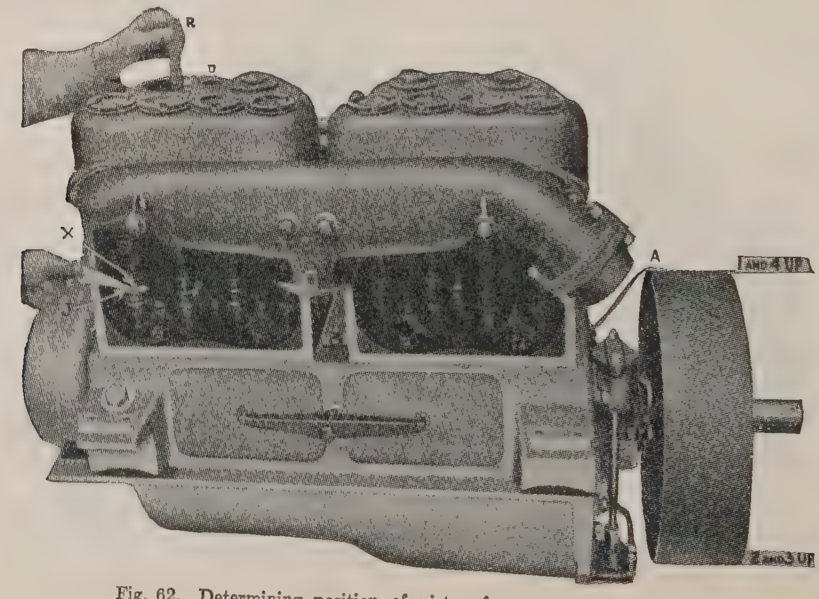

Fig. 62. Determining position of piston for purpose of timing valves.

to paragraphs, "Third," "Fourth," and "Fifth," pages 941 and 942.

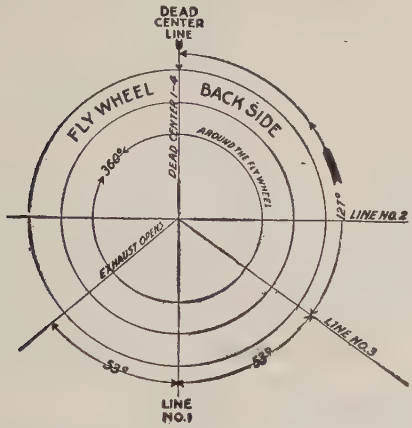

Fig. 63. Valve timing diagram of Waukesha engine models "L-LU4," "M-MU4," and "P-PU4."

This setting pertains only to models "L-LU4," "M-MU4," and "P-PU4."

For models "O-OU4-OU4R," "S-SU4-SU4R," "R-RU4-RU4R," "N-NU4-NU4R," the piston should drop $4\frac{7}{8}''$ from upper dead center; that is, the exhaust valve should open 50° before the piston reaches the bottom dead center after the explosion has taken place.

For models "T" and "TU4," "B" and "BU4," the piston should drop 4.644″ or $4\frac{41}{64}''$ from upper dead center; or the exhaust valve should open 45° before the piston reaches the bottom dead center after the explosion has taken place.

In all cases, in resetting the valves, the magneto will have to be retimed; for this operation see Fig. 64.

Example of Setting Time of Spark by Position of Piston (Magneto Ignition)

The engine used in this example is the Waukesha 4-cylinder truck and tractor engine, using a high-tension magneto for ignition.

In case the magneto has been removed from the engine and its connections have not been previously marked, it can be retimed as follows:

First: Open all the priming cups on top of the cylinders and turn the engine over slowly until the compression stroke begins in No. 1 cylinder. This can be ascertained by holding the thumb tightly over the priming cup of this cylinder and observing that both the valves remain closed (see Fig. 64).

When the compression stroke begins on No. 1 cylinder, **stop** and remove the cylinder head plug; now insert a ruler and slowly turn the engine until the piston comes to upper dead center, or when the ruler ceases its upward movement (see Fig. 62).

Second: Now measure the distance from the top of the piston to the top of the cylinder. For example, let us say that the distance measures 2″ from the top of the piston to the top of the cylinder. Turn the crank over until it measures $2\frac{1}{8}''$. This

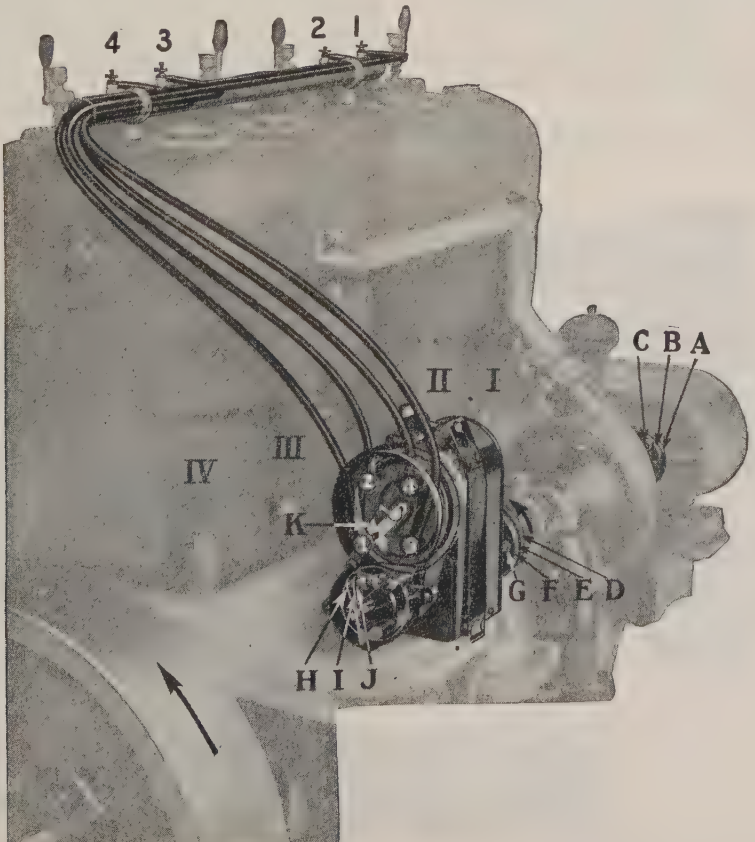

Fig. 64. Magneto setting and timing.

means that the piston has made a drop of ⅛″ after top, on firing or power stroke, at which point the spark should occur. Replace the cylinder-head plug to prevent any objects from falling in the cylinder.

Third: Remove the bolts (C) which connect the flanges (A) and (B); then connect the leather coupling (G, F, E, D) next to the magneto. The magneto is driven by a gear in front of the engine, which is driven from the crank-shaft gear, with an idler gear between.

Fourth: Set the breaker (or interrupter) cam in such a position that the distributor arm (K) will come on the No. 1 cylinder high-tension terminal in the distributor, and so that the contact screws (H-J) of the interrupter are just starting to open. Letter (I) represents the opening between the platinum contacts (H and J) with the spark lever in the **fully retarded position.**

Fifth: Replace the two bolts (C) in the flanges (A-B); that is, one on either side of the coupling.

Sixth: Attach the wire which leads from the spark plug on No. 1 cylinder to the terminal marked No. 1 in the distributor plate; No. 2 spark-plug wire to the terminal marked No. 2; No. 3 spark-plug wire to the terminal marked No. 4; and No. 4 spark-plug wire to the terminal marked No. 3.

How to Adjust Loose Connecting Rods and Main Bearings of Waukesha Engine

Connecting rods and main bearings may be adjusted without taking the engine out of the chassis as shown in Fig. 65. However, this does not hold true where it is impossible to work at the engine from below.

The following instructions will give a good idea **how to proceed in order properly to adjust the connecting rods and main bearings** not only on this engine but other engines.

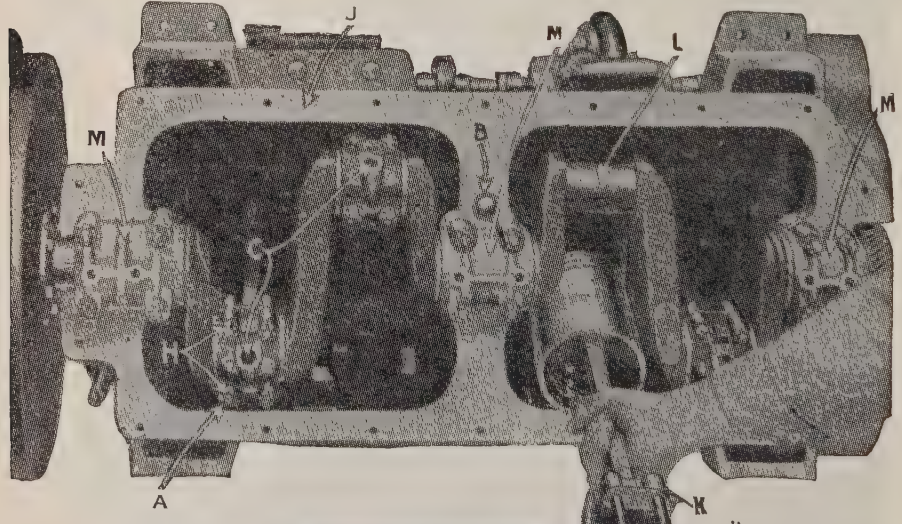
First: Drain off the oil by removing the drain or pipe plugs from the bottom of the oil pan; then place a small lift jack under the pan to keep it from dropping before all the oil pan bolts that support it have been removed. It is advisable to tie up the oil float (B) as high as possible, to prevent it from dropping into the oil pan while the latter is being removed (this can be done by unscrewing the holder of the oil-gauge glass) and thus prevent the possibility of it being damaged or bent. This also makes it easier when you are ready to replace the oil pan. Open all four compression cups on top of the cylinders.

Second: After removing the pan, scrape off the gasket from the bottom edge (J) of the crank case, and clean away all dust and dirt so that it will not get into the bearings. Clean your hands and tools before working on the bearings, and never use cotton waste or any rags which might leave shreds behind, as these might cause serious trouble to the oiling system.

Third: When working on bearings, it is a good plan to pull out the pistons and clean off the rings and piston heads. Always oil **the piston rings** before replacing the piston.

Fourth: Pull out the cotter pins (A) and unscrew the four nuts (H) (always use a socket wrench for this operation as open-end wrenches are apt to destroy the nuts); when taking off the cap be careful not to lose any shims or liners (F), and keep them in place on (K) until ready to remove them.

On this engine, as well as on most all engines, laminated shims are used between the connecting rods and their caps, allowing one to adjust the bearings to within .002″. **Laminated shims** vary in thickness, and are made up of a series of small shims —.002″ in thickness—which are pressed together as one piece. In taking the loose play out of the bearings, one can peel these shims off (Fig. 66) to any extent required to have a perfect adjustment on the bearings. Never peel off any more of the shims at one time than is necessary. Take out the shims to the extent you think necessary to take up the wear, being careful to remove an equal amount of **shims** on each side of the cap.



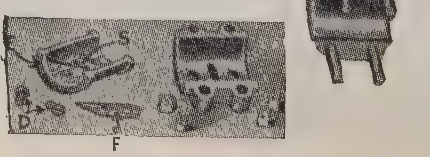


Fig. 65

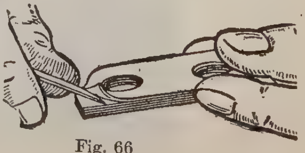

Fig. 66

Fig. 65. Showing lower part of crank case with oil pan removed; Fig. 66. Peeling off a laminated shim, as described in text.

Before replacing the cap, see that the thin shims are placed between two heavy ones, with which the connecting rods are always supplied. Replace the cap and draw it up as tightly as possible, using all four nuts, and drawing them up evenly and firmly.

Now try turning the engine over by hand in order to find out whether you have the bearings too tight or not. It should turn easily, as this represents only one tight bearing; when this bearing is right, loosen it, and proceed to fit the other bearings in the same manner.

After each bearing has been fitted and tested, draw up firmly all the nuts and use new cotter pins only; never back up the nuts to insert the cotter pins. Always draw up to the next notch. Never use wire in the connecting-rod nuts, as it will interfere with the oiling system. Have the cotter pins well bent apart, so that they cannot back out when the engine runs.

How to Replace Worn or Damaged Main Bearings

First: Take the engine out of the chassis, and before removing the pan, draw off all the oil. Refer to page 938 for instructions for removing the oil pan.

Second: Take out all spark plugs, priming cups, etc., on top of the cylinders. Now stand the engine on its head, and place props under the engine arms to keep it from wobbling while work is being done.

Third: Remove the oil pan and take out all pistons, and be sure that they are all marked so that they will be put back into their respective places. Remove the gear case as shown in Fig 60.

It is most important, before removing the crank shaft, to mark all the gears in accordance with instructions on page 941, otherwise there is a possibility of getting the engine out of time.

Take off the flywheel, but be sure that you have it marked with the flange on the crank shaft, as it is very important that the flywheel should be replaced in the same position as when you take it off.

Fourth: Take off the three main bearing caps (**M**) (as illustrated in Fig 65), and remove the crank shaft. Stand the crank shaft up on end and place it safely aside, as a fall might spring it out of shape, and later you would wonder why the bearings could not be fitted with the proper alignment. Remove the idler gear marked (**A-B-C**) (Fig. 60).

Take out the screws to remove the damaged bearing. Clean away all dirt and grit with gasoline; fit in one-half of the new bearing in the crank case. This operation is the same as described for replacing the connecting-rod bearings (page 944).

After the bearing has been fitted in the crank case, replace the crank shaft. Apply Prussian blue or red lead to the crank-shaft bearing surface and scrape off the "spottings" in the same way as in fitting new connecting-rod bearings. Strict attention must be paid to see that the new bearing does not rest too high in the case so as to throw the other two bearings out of line, nor should the bearing be too low.

Should the bearing be too high, either the two other bearings will have to be raised by shimming them up, or the new bearing must be scraped until the three bearings are on the same level. The crank shaft must fit the half of the main bearings in the crank case perfectly before you proceed to fit the caps.

Always fit the rear main bearing cap first, and tighten it up as much as possible without stripping the bolt threads. When the bearing has been properly fitted, the crank shaft will permit moving with one hand. If the shaft cannot be turned with one hand, the contact between the bearing surfaces is evidently too close, and the cap requires shimming. On the other hand, if the crank shaft moves too easily, some shims must be removed to permit it to set closer.

After removing the cap observe whether the blue "spottings" indicate a full bearing the length of the cap. If they do not, the bearing will have to be scraped. Lay the rear bearing aside, and proceed to adjust the center bearing in the same manner. Repeat this operation with the front bearing, with the two other bearings laid aside.

When the proper results have been obtained with the bearings, **replace the idler gear** and be sure that the connections (**A-A**) (**B-B**) (**C-C**) correspond, as shown in Fig. 60).

You can now replace the caps and insert the cotter pins, or wire. Be sure, when you replace the pistons, that the heads and the rings are free from grit and carbon and also oil each piston ring carefully.

Fifth: Oil the bearings well by means of an oil can, and turn the engine over (by using the crank handle) several revolutions before replacing the oil pan.

Sixth: Are you sure that holes (**C**) in all four connecting-rod bearing caps are facing the direction in which the engine runs? This is important, because, when the engine runs, oil is forced into these holes to lubricate the bearings; if one of these holes should face in the opposite direction, that bearing would get practically no oil, the bearing would heat up, and would soon cut out, resulting in a costly repair.

Seventh: Refer to the oiling system, page 938, before replacing the pan.

How to Replace Worn or Damaged Connecting-Rod Bearings

First: Remove the oil pan, as instructed on page 938; then take off the cap and pull out the piston, as shown in Fig. 65.

Second: Take out the screws (**D,** lower illustration in Fig. 65) in order to remove bearing (**E**). Be sure to fit the bearing half with the large oil hole (**S**) in the cap, and the other half in the connecting rod (**K**).

The back side of the bearing must have a perfect or snug fit in the connecting rod, otherwise it will be impossible to get a perfect, permanent bearing on the crank pin (**L**). Fitting the back of the bearing is practically on the same order as fitting the bearing to the crank pin. Using Prussian blue or red lead in the rod and cap will enable you to find the high spots between the cap and the bearings; these high spots must be draw-filed (see Index).

Third: Put in the screws (**D**) very firmly, and be sure that the heads are lower than the bearing surface so that they do not come in contact with the crank shaft. Next draw a file across the top of the cap and the rod to have the bearing flush with it.

Fourth: Without replacing the piston in the cylinder, fit the bearing to the crank pin (**L**); if the bearing is too wide, the ends will have to be draw-filed. Be careful not to file off too much. By applying Prussian blue or red lead to the crank-pin surface, it will enable you to fit the bearing to the pin to determine whether a perfect bearing surface is obtained. Remove the rod and observe whether the blue or red "spottings" indicate a bearing the full length of the cap. If they do not, the babbit should be scraped until a perfect bearing surface is obtained.

Adjust the bearing to the crank pin so that it can be moved to and fro freely, but at the same time it must not be loose.

Remove the connecting rod and replace the piston, and give the bearing the same adjustment as you did when the piston was out; then turn the engine over by hand several times to make sure that no binding takes place.

Do not be afraid of getting the connecting-rod bolts too tight, as the shims under the cap will prevent the metal from being drawn into too close contact.

GOVERNORS

Governors are sometimes used on trucks, tractors, taxicabs, and marine and stationary engines.

Purpose of the Governor

There are two reasons for using a governor: one, to regulate the vehicle speed, the other, to regulate the engine speed. The governor is set at whatever speed the car owner desires, is then sealed, and the driver can never exceed the speed for which the governor is set. The engine type of governor (Figs. 67, 68, and 69) is used to prevent undue racing of the engine when changing gears or releasing the clutch. The average driver will work his engine at high speeds a great deal more than is necessary, straining the entire mechanism of the car, and wasting both fuel and oil. By governing the engine speed, the vehicle speed is also limited.

Anything which tends to decrease the speed of the engine, namely, going up hill, through a mudhole, or with an added load, in turn **causes a decrease in the speed of the engine and a consequent decrease in the speed of the gases,** when immediately the governor opens the throttle to admit a sufficient amount of gas to maintain the speed at which the adjustment was made.

Engine drive—(Figs. 67, 68, and 69): This type of governor regulates the number of revolutions of the engine, and will keep it running at a definite, safe speed, regardless of the load it is pulling, even if the throttle is wide open. The regular **hand-throttle lever or accelerator** may be used for lower speeds. Should the clutch be suddenly released when the engine is pulling a load or running at maximum speed, the engine positively cannot race. The engine governor also limits the vehicle speed, because the engine cannot exceed the set speed.

Transmission governor drive (seldom used) is where the governor on the engine is driven by a flexible shaft and gears from the transmission or front axle.

THE SIMPLEX, DUPLEX AND McCANN GOVERNORS

The governor (Fig. 67) is placed between the carburetor and the intake manifold. It operates on the centrifugal principle. As the speed increases, the weights (W) cause the valve (T), which is of a grid construction, to close the gas passage (G0 and G1) gradually, thereby cutting off the flow of gas to the inlet manifold. Therefore it would be termed a "throttling-type governor, centrifugal type."

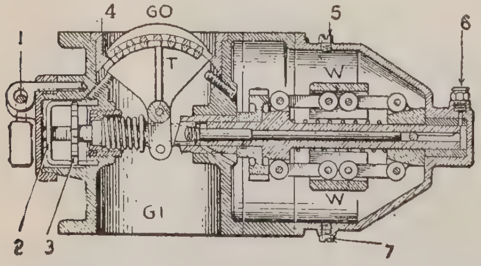

Fig. 67. **The Duplex governor:** (1) locking pin; (2) yoke; (3) hand wheel; (4) valve seat; (5) oil entrance; (6) oil cap; (7) oil discharge.

On the Simplex single-drive governor, the shaft is attached to the engine or vehicle in any manner desired.

On the Duplex double-drive governor,[1] one shaft is attached to the engine and the other is attached to the vehicle, at the wheel or transmission.

The difference between Duplex and Simplex is that with the former you can control both the **engine** and the **vehicle speeds,** whereas with the latter, either the **engine or the vehicle speeds** can be controlled.

On high gear, with a truck running at 12 m.p.h., the engine may turn over only at 900 r.p.m., but for low-gear service the engine may be governed for 1,400 r.p.m. Therefore you would be able to maintain 12 m.p.h. even in second gear.

The governor is a telltale on carburetion. If it surges, it may result from one of five causes: the mixture is too rich; the governor lubrication is bad; the ignition is faulty; the governor valve is dirty; or the cable drive is not steady and free from backlash.

To Set and Care for the Simplex or Duplex Governor

To set: First get the consent of the factory, otherwise you may lose your guarantee. Turn the hand wheel (3) out for higher, and in for lower speeds. Do not fail to lock the hand wheel with the yoke (2) after setting, if a locking spring is not provided, and see that the yoke does not bind on the hand wheel. The locking pin and seal (1) are for the protection of the governor and the engine. Do not touch the valve screws (4).

To operate the engine with a governor: For best economy, run the vehicle on governor speed as much as possible. Bring the vehicle speed up to set a maximum governor speed with the throttle lever and then advance the spark and throttle to the best normal running positions.

Do not over advance the throttle, as the engine might "hunt" with a heavy load on low piston speed. Find the best throttle position, and mark it.

Lubricate weekly at (5) by filling the chamber with medium cylinder oil; 600-W is preferred for summer, and in winter add an equal amount of light machine oil. Every 1,000 miles remove drain (7), fill half-full of light machine oil, run for ten minutes to clean the interior, and drain out. Then refill as above.

To clean the governor valve: If necessary, pour kerosene into the air inlet of the carburetor while the engine is running, varying the speed.

---

[1] Duplex Engine Governor Co., 36 Flatbush Ave., Extension, Brooklyn, N.Y.

McCann Suction Type of Governor

This governor is mounted on the carburetor (Fig. 19, page 39). When the engine is turning slowly, the full current of gas from the carburetor, as controlled by the throttle, is allowed to pass to the cylinders.

As the speed increases, resulting **suction** causes piston (**P**) to rise against the pressure of spring (**S**), thus gradually cutting off the supply of gas through the perforations, until, at maximum speed-setting, the engine cannot be further accelerated. This is termed a "suction type of governor."

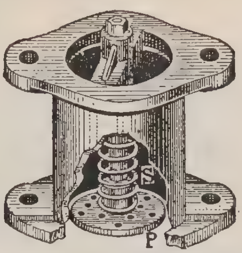

Fig. 68. The McCann governor.

CARE AND INSTALLATION OF PIERCE CENTRIFUGAL ENGINE[1] GOVERNOR

Mounting governor: Use thin gaskets of blotting paper only. **Do not use shellac**—it will cause the governor valve to stick.

Flexible drive shaft: There should be no bends in the shaft within 2″ from either end, nor should the shaft be bent into a circle of less than a 10″ radius. Make all bends as easy and large as possible.

Solid drive shaft: In mounting a solid shaft, be sure that the shaft ends properly engage in the governor, the right-angle drive, and the engine connection, and see that the lock nuts on the tube are tight. Do not screw the tube up tight enough to cause the shaft or gears to bind.

Oiling governor equipment: Before the governor is put into active service, see that the case contains about 4 oz. of good light oil (light Polarine preferred) that is not affected by change in temperature. Put in one or two ounces of oil every thousand miles. The flexible shaft should be kept packed with Artic No. 3, or a good graphite grease, renewing it every 2,000 miles. Oil the gear bearings, the right angle drives, or the engine connections, each week through the oil holes provided.

Loose connections: When driving gears or brackets are used, examine them regularly to see that none work loose and that the gears are kept in perfect alignment and are meshing properly. If a belt is used, keep it tight and free from oil or grease, to prevent slipping.

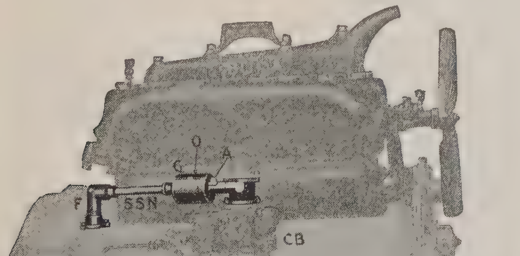

Fig. 69. Engine speed controlled by governor (**G**) driven from gear on cam shaft through adapter (**F**) and solid shaft (**S-S-N**). (**O**) oil cup; (**A**) adjusting screw and seal. The governor can be driven from any rotating part of the engine.

Regulating governor speed: Should it be desirable to change the speed adjustment, cut the wire that seals the adjusting screw and pull off the cap that it holds in place. The adjusting screw (**A**) (Fig. 70) will then be exposed. Turning this screw to the right, or clockwise, decreases the speed; turning to the left, or counter-clockwise, increases the speed. When proper adjustment has been made, replace the cap and seal it, so that the adjustment cannot be tampered with or be affected by vibration.

Note. The governor does not interfere with the regular spark or throttle levers, or with the accelerator control by hand or foot. See paragraph, "Engine drive," page 946.

Operation of Pierce Engine Governor

The governor valve box (Fig. 67) is mounted between the carburetor and the intake manifold, and is connected to the driving shaft by means of either a solid shaft (**SSN**) (Fig. 69) or a flexible shaft (**SH**) (Fig. 70), depending on the type of installation.

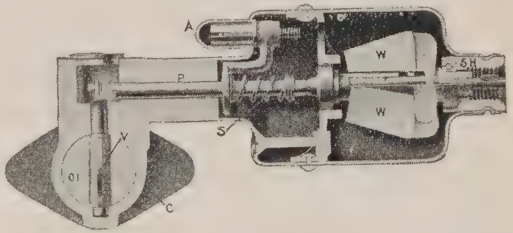

Fig. 70. **Cross-section of Pierce governor:** (**C**) connects between flanges on the inlet manifold and carburetor; (**O1**) is the passage opening for gas; (**V**) butterfly valve; (**P**) plunger operating the valve bell crank; (**S**) spring; (**A**) screw for adjusting the spring tension; (**W**) centrifugal weights; (**SH**) where driving shaft connects.

Normally the butterfly valve (**V**) (Fig. 70) is in a position that does not obstruct the flow of gas, but it closes so as to reduce the valve port area just as soon as the vehicle or engine reaches the predetermined speed. The valve is actuated by what is known as the flyball or centrifugal principle. On the controller shaft are two weights (**W**) (Fig. 70) which are so pivoted that as the velocity of the shaft increases they are swung outward, forcing a plunger (**P**) (Fig. 70) forward, which in turn closes the butterfly valve (**V**) (Fig. 70). The plunger is forced against a spring (**S**), calibrated to a standard pressure, so that as the speed is lessened the weights return to their original position and the valve is again wide open.

Governor Drive Methods

Engine governor drive controls the speed of the engine regardless of the speed of the car, and is the method usually employed. See "Engine drive," page 946.

Transmission governor drive controls the speed of the car by connection to the transmission (see page 946). When operating on low or second gear, the speed of the car will be so low that it will not affect the governor; when in high gear the car attains sufficient speed to cause the governor to act on the engine (seldom used).

---

[1] Pierce Engine Governor Co., Anderson, Ind.

PIERCE CLUTCH GOVERNOR

Heretofore the name "governor" has always been associated with devices that automatically control the speed of engines, motors, or other power generating mechanism.

The new Pierce clutch governor performs an entirely different function. As the name indicates, **it regulates the action of the clutch,** and it does this in a manner that makes the clutch mechanism on passenger cars, motor trucks, and tractors practically automatic.

Inexperienced drivers usually have a lot of trouble operating the clutch. Watch them and you will notice that nearly every one engages the clutch too quickly. As a result, they either kill the engine or give the car a vicious jerk that wrenches the transmission and rear axle and causes the rear wheels to spin. Repeat this performance a few times and you have a noisy transmission or differential, badly worn tires, and perhaps a broken axle or torque shaft.

What the clutch governor is: The Pierce clutch governor is in reality a specially designed dash pot (Fig. 71) about 2″ in diameter and 6″ long. The base is attached to a bracket (fastened either to the transmission case or to the frame of the car) and has a pivoted action. The other end connects to an extension on the bottom of the clutch pedal. Inside the dash pot is a fluid on which changes in temperature have practically no effect.

As the clutch pedal is pressed down, the piston inside the cylinder rises with absolutely no resistance, since the fluid passes freely through the poppet valves in the piston head. When the pedal is released, the piston starts to travel downward and forces the fluid through a bypass. A screw adjustment is provided so that the passage of the fluid can be regulated to suit each type of clutch.

The cylinder walls have a series of pockets, and the actual travel of the piston against resistance is only ⅜″ just before the clutch engages.

Its effect on the clutch action: The Pierce clutch governor does what the most expert driver often neglects to do—it engages the clutch gently, without jerk or jar, and always just the same.

Instructions for Installing

The governor is not a part of the clutch—nor can it improve or damage any make of clutch. It is merely to prevent abuse of the clutch—to prevent too sudden engaging through either carelessness, accident, or ignorance of the driver—and to avoid "killing" the motor, spinning the rear wheels, or wrenching the transmission and rear axle members when starting.

Do not allow the connections at either top or bottom of the governor to become tight. If these bind when the clutch pedal moves forward or backward, the governor will not operate properly.

Before starting to install the governor, take a screwdriver and entirely close the needle valve (**D**) shown in Fig. 71. When this is done, it is almost impossible to force the piston down by hand. Also loosen lock nut (**B**) just below the clevis (**A**).

Adjustments

After the Pierce clutch governor has been installed in accordance with previous instructions, see that it is carefully adjusted before anyone attempts to drive the car.

Having entirely closed the needle valve (**D**) (Fig. 71) as previously instructed, start the engine and let it idle at rather slow speed. It will be much easier if one man can sit in the seat to handle the car, engaging and disengaging the clutch, while another man adjusts the clutch governor. Disengage the clutch and place the gear shift in first speed forward. As the clutch is engaged and disengaged, with the fingers turn the knurled dust cap (**C**) to right or left, adjusting it until the governor causes the clutch pedal to pause slightly, just for an instant before the clutch takes hold and the car begins to move forward. Then tighten lock nut (**B**) firmly against clevis (**A**).

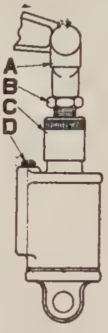

Fig. 71

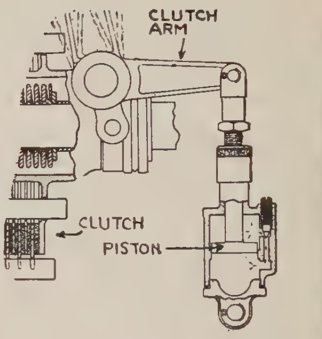

Fig. 72

Fig. 71. The clutch governor.

Fig. 72. Showing the governor piston rod connected to the lower clutch pedal or arm. The illustration shows the position of the piston as the clutch is **engaging.** This is where the strongest resistance is offered to the piston's travel, causing it to pause a second just as the clutch engages, so there can be no tendency to "grab." After the car has started, the clutch pedal travels slowly backward until it reaches normal position, and the piston is again as shown in Fig. 73.

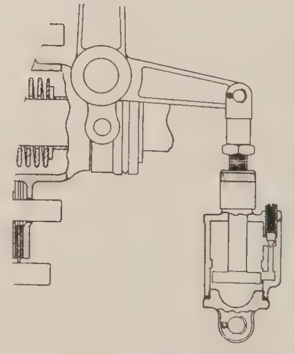

Fig. 73

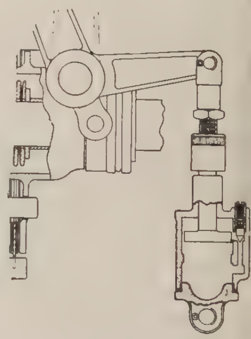

Fig. 74

Fig. 73. Showing position of piston when clutch **is engaged.**

Fig. 74. Showing position of piston when clutch **is disengaged** for changing gears.

If the clutch engages too slowly for satisfactory operation on the road, the needle valve (**D**) may be opened about one-eighth turn. When proper adjustment is obtained, the governor will automatically start the car as quickly as possible without spinning the rear wheels on first speed forward—operating the clutch under ideal conditions always.

Do not attempt to change the position of the needle valve (**D**) until you are sure that proper adjustment cannot be obtained by lengthening or shortening the piston rod (turning knurled dust cap (**C**) backward or forward), as this will take care of 90 per cent of all adjustments necessary.

Fluid inside governor: This is a special refrigerating oil on which extreme changes of temperature have practically no effect. Tests show no difference in operation at temperatures of 98° or 0°.

Readjusting after service: Should the car at any time show a tendency to start too suddenly, or with a jerk, loosen the lock nut (**B**) below clevis (**A**) (Fig. 71) and with the fingers turn the knurled dust cap (**C**) to the left from one to three complete turns. This will lengthen the piston rod and make the clutch slower in engaging.

If the car is too slow in starting after the clutch pedal is released, reverse the adjustment.

Changing speed on hills: When properly adjusted, it is possible to shift from high to lower speeds without any jerk, unnecessary strain, or loss of momentum.

Without the clutch governor, if the driver is too slow in changing gears, the car will lose momentum and may even start to roll backward. The same will be true if the governor operates too slowly. This can be instantly remedied by following instruction for "Readjusting after service."

THE MONARCH GOVERNORS[1]

The Monarch governor differs from the Pierce and Simplex, in that the speed of the ingoing gas is utilized as the motive power for operating the control member.

There are no connections to any moving parts of the engine or vehicle, neither are there revolving parts, such as centrifugal weights or balls.

The location of the governor is between the carburetor and the inlet pipe. When installing, the adjustment is made when a change in the maximum speed of engine is desired.

Monarch Governor (Model "G")

Essentially it consists of the spring (1), the rocker arm (2), the conoid (3), the butterfly (4), and cone (5). The spring is of the conventional compression type, and makes possible a wide range of governed engine speeds.

Suitable **adjustment** is secured by removing the cap at the bottom of the spring housing and turning the slotted screw provided for this purpose.

The rocker arm (2) is provided at either end with a hardened ball-point bearing that oscillates in a hardened steel cup. (Fig. 75.)

The conoid or governing member (3) in conjunction with cone (5) controls the governor action. Held normally in a wide-open position by the spring, the conoid is acted upon by the velocity of the explosive charge passing from the carburetor to the engine. The increase of velocity overcomes the resistance of the spring, and causes the conoid to rise in the tapered cone, closing the butterfly to which it is connected; thus the speed of the engine is controlled.

The short over-all length of the Monarch governor is 2¾" in the one-inch size.

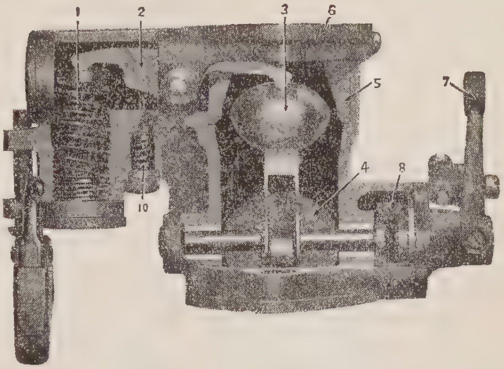

Fig. 75. **Monarch governor, model "G":** (1) spring; (2) rocker arm; (3) conoid; (4) butterfly valve; (5) cone; (6) to intake manifold of engine; (7) manual throttle control lever; (8) manual control lever clutch; (9) to carburetor; (10) bumper spring.

The Monarch Governor (Model "D")

The location of the governor is between the carburetor and the inlet pipe. When installing, the adjustment is made when a change in the maximum speed of engine is desired.

Operation: When the engine is started and the throttle is in wide-open position, the speed of the gases lifts the disk (**A**) in the tapered chamber (**B**) to a position the height of which is determined by the amount of spring tension, and it is held in that position by the speed of the gases while the engine is running. Thus the throttle (**F**) is held in a corresponding position, limiting the supply of gas.

Anything which tends to decrease the speed of the engine, namely, going up hill, through a mud-hole, or an additional load, in turn causes a decrease in the

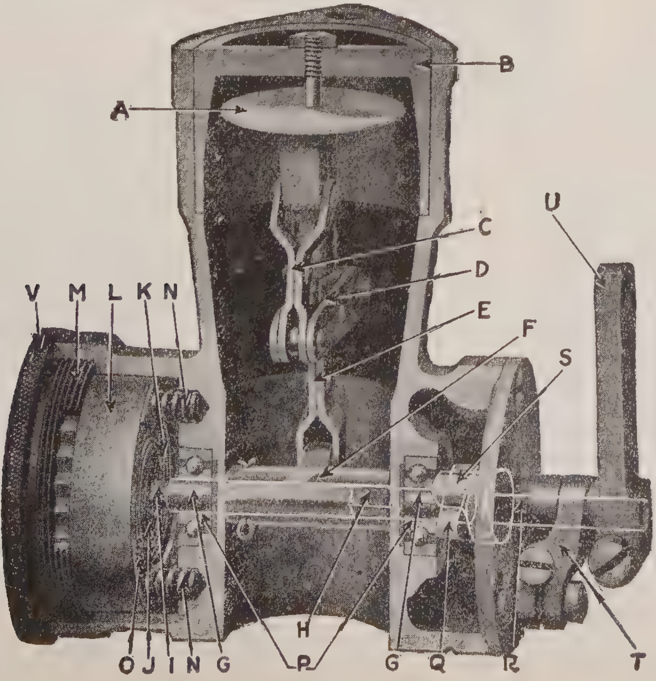

Fig. 76. Monarch model "D" governor.

---

[1] Monarch Governor Co., Detroit, Mich.

speed of the engine and a consequent decrease in the speed of the gases. In such a case, the disk drops immediately and opens the throttle to admit a sufficient amount of gas to maintain the speed at which the adjustment was made before the additional load was added. The same is also true when the engine is instantly relieved of its load; the speed of the gases increases and raises the disk to the position required to maintain its fixed maximum. It is therefore evident that, with an adjustment of spring tension made to produce a certain engin speed, that speed will be maintained regardless o load.

Adjustment

To adjust the governor to produce any required engine speed remove the lock and lock pin, unscrew the cover (V), push in o the finger boss on the spring housing (L), and turn in the direc tion indicated by the arrows "Fast" and "Slow" to increase o decrease the speed, always being sure that the control lever i in a wide-open position when the adjustment is made; and b sure that the cover (V), the lock pin, and the lock are in plac before the truck is put in service.

TRUCK DRIVE CHAINS

Chains in general use for the drive system of a chain-driven truck are the roller type of chain.

Roller chains are divided in two types: the **riveted** type, and the **detachable,** or cotter-pin, type.

The riveted type is used where there is no occasion to take it apart frequently.

The detachable or cotter-pin type of roller chain is more generally used because of the ease with which such chains can be separated at each link for the purpose of repair (see Fig. 77).

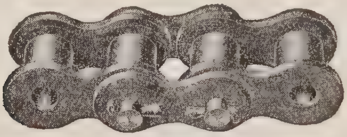

Fig. 77. The Baldwin roller chain of the detachable cotter-pin type.

In the detachable or cotter-pin type the side links are riveted to the studs on only one side of the chain, while on the other side the links are pressed moderately hard over the studs and are retained by cotter pins, as shown in Fig. 77.

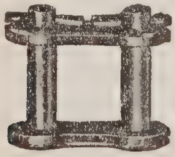

Fig. 78

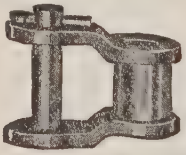

Fig. 79

Fig. 78. Connecting link.
Fig. 79. Offset connecting link.
These are also termed "master links."

The parts of the roller chain of the detachable cotter-pin type are as follows:

A roller is the round part between the link plates and is that part which rolls between the teeth of the sprocket.

A bushing is the part inside of the roller through which the pins are inserted.

A pin-link plate is the plate on each side of the roller.

A pin is the part which passes through the bushings in the rollers and in which the cotter pins are inserted at one end.

A pin-link cap is the same as a pin-link plate, except that it is the plate on the side where the cotter pins are next to it.

A connecting link is shown in Fig. 78. It is used to disconnect, add to, or take out two pitches or two rollers.

An offset connecting link is shown in Fig. 79. It is used to disconnect, add to, or take out one pitch, or one roller.

Pitch is the distance from center to center of the rivets of roller chains and from center to center of the alternate rivets on the block chains (the block chain is not shown; with this type a block is used instead of a roller).

Width is the actual distance between the two inside plates, or the nominal width of roller.

Diameter of the roller is the roller's actual diameter.

Thus, when ordering chains, the three dimension just mentioned are always given.

The sizes of roller chains are usually given in tw ways: the manufacturer's standard, and the Baldwin standard, as tabulated in the list below.

Manufacturers' Standard Roller Chains

Chain No.		Chain Pitch	Roller		Width Over Pins	Approx. Ultimate Strength	Weight Per Foot
Mfrs. Standard No.	Present Baldwin No.	Inch	Width Inch	Diam. Inch	Inch	Lbs.	Lbs.
2	113	½	¼	.306	.625	1,200	.294
2½	108	⅝	⅜	.400	.87	4,500	.564
3	9	¾	½	15/32	1.14	7,500	1.00
4	27	1	⅝	⅝	1.50	12,500	1.89
5	38	1¼	¾	¾	1.81	20,000	2.97
6	51	1½	1	⅞	2.24	25,000	4.38
7	52	1¾	1	1	2.24	36,000	4.80
8	53	2	1¼	1⅛	2.68	42,500	6.90
10	63	2½	1½	1 9/16	3.18	95,000	9.34

1 ton; pitch 1"; di. 9/16 or ⅝"; width ⅜ to ¾".
2 ton; pitch 1¼"; di. ⅝ or ¾" ; width ½ to ¾".
3 ton; pitch 1¾"; di. 1"; width ¾ to 1".
5 ton; pitch 2"; di. 1⅛"; width ⅞ to 1¼".

Note. The symbol "di." refers to the diameter of the rolle and "width" refers to the width of the roller.

To remove a chain, the master link cotter pi (sometimes a wire clip) is removed and the maste or connecting link is withdrawn.

The detachable chain can be lengthened o shortened with ease, whereas with the riveted chai the task is not so easy—a special tool must be use

Care of Drive Chains

If chains could be protected from dust and be ru in an oil bath, they would last much longer, but n method of doing this has yet been successfull devised. A case or housing cannot be fitted aroun the chain, because the construction would also r quire it to contain the brakes as well as the sprocke and it would also be necessary to surround the axl

When a chain becomes too slack, the chain an sprocket are bound to suffer in consequence.

When a chain is worn, an uneven or jerkin motion is imparted to the drive system when slowin down, coasting, and suddenly picking up speed, et Therefore a chain should be well lubricated and ke adjusted.

Cleaning and Lubricating Drive Chains

Tallow gives a chain the best protection against dust and grit. It is melted, and the chain (after being cleaned by soaking in kerosene) is laid in the liquid tallow. Then hang it up to dry, and later wipe off the surplus grease (see also Index under "Cleaning chains."

The teeth of the sprockets when worn, may be remedied in some instances by reversing.

A new chain will stretch—a link should be removed after it is well set. The rivets are cut with a chisel. Master links should be carried.

Adjusting chain tension: Slight play is necessary, but equal slack should be in each chain. A chain should be loose enough to run easily, without climbing the sprocket tooth. Adjustment is usually made by the radius rod, or by large adjusting screws provided for the purpose.

The enlarged section in the middle portion of the radius rod is an elongated nut, which is tapped with both right and left-hand threads. The rods have threads cut on them to correspond. Turning the nut in one direction lengthens the rod, and turning it in the opposite direction shortens it. The principle is identically the same as in a turn buckle. This, however, is a much stronger construction.

Chain manufacturers are Baldwin Chain and Mfg. Co., Worcester, Mass.; Whitney Mfg. Co., Hartford, Conn.; Diamond Chain Co., Indianapolis, Ind.

Miscellaneous

Springs: Inasmuch as the springs of a truck are subjected to considerable strain, they should be kept in good condition. A method usually employed is to raise the frame of the car with a jack, as shown in Fig. 80, which causes the leaves of spring to separate. Graphite is then inserted between the leaves and is wiped dry after removing the jacks. The spring-clip nuts should be tight.

When replacing the gearbox on trucks having separate jackshaft brackets (as in the chain-drive Mack), it is advisable to test the jackshaft and gearbox alignment (Fig. 81).

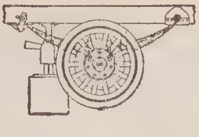

Fig. 80

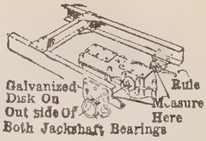

Fig. 81

To do this, cut two disks of 1/64" galvanized iron to fit the outer bores of the jackshaft brackets, and drill a small hole through the center of each. These disks are placed in the outer bores of each bracket, and a fine thread is passed through the drilled holes and the gearbox in the manner illustrated. Measurements from the outside of the bearings to the thread show when the alignment is perfect.

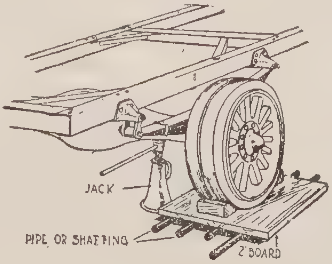

Fig. 82

To assist in removing heavy truck wheels, a simple skid can be made (Fig. 82) by placing a 2" board on top of a series of rollers made of old shafting or heavy pipe. Chocks are fastened to the board to prevent the wheel rolling.

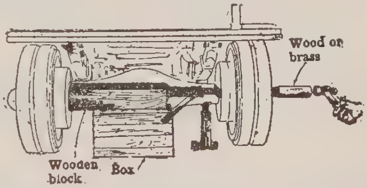

Fig. 83. Removing stubborn truck wheels.

To remove wheels from a truck axle when stuck or rusted on, see Fig. 83

DUMP BODY AND HOIST

A dump body is used for hauling coal, sand, gravel, etc. The body is made to fit on a hinge at the rear of the chassis, as shown in Fig. 84. A hydraulic hoist, which derives its power from the engine raises the front end of the body. The operator can raise the body and dump its contents in about thirty seconds. Hoists which can be operated by hand are also in use.

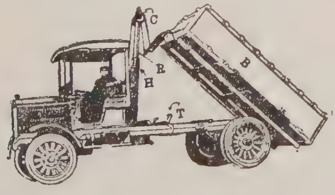

Fig. 84. Dump body with hydraulic hoist.

The principle of operation of the hydraulic hoist is shown in Fig. 85. It is essentially identical in principle of construction with that of a hydraulic elevator.

To raise the body: An oil pump (gear type) at the base of the cylinder (**H**) draws oil from the top of the cylinder at (1) and forces it into the lower part at (2), raising the piston, which in turn raises the rod (**R**) to which is attached grooved pulleys, in which grooves the cables (**C**) are placed. One end of the cable is attached to a stationary rod (**U**), and the other end to the body. As the rod (**R**) is raised, the body is also raised.

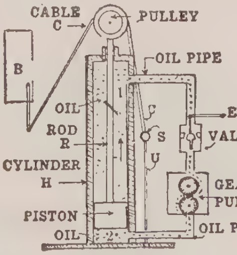

Fig. 85. Diagram of hydraulic hoist.

To hold the body at any desired angle: The oil pump is shut off and the valve closed.

To lower body: The drive of the oil pump is shut off and the valve (by-pass valve) is opened by a lever (**E**). The weight of the body forces the piston down, driving the oil back to the upper part of the cylinder. **The oil pump** is driven from the gears in the transmission by a special and separate arrangement whereby the car is not driven when in operation. The cylinder is usually filled within ½" of the top with ice machine oil.

WINCH EQUIPMENT

A winch (Fig. 86) is a drum located under the rear end of the frame, supplied with 200 or more feet of ⅝″ cable, for unloading and loading heavy material and for various other purposes.

The power for driving the winch (on the F. W. D. truck) is taken from gears in the transmission (T) through (D), which is equipped with a separate clutch to a "power take-off" drive shaft to the gears in housing (V), which connects to the winch through a spur gear (G).

The winch is controlled by means of the clutch foot pedal, after the clutch in (D) has been engaged.

The winch may be operated while the truck is eithe standing still or in motion, but not when the transmission is on high speed. Diameter of the winch drum, 7¾″; length, 22¾″; total gear reduction to winch, 33.2:1.

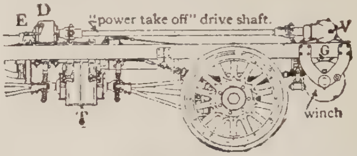

Fig. 86

TRAILERS

Trailers are attached to the rear of cars, and are now extensively used. They are particularly desirable where goods of relatively light weight and great bulk have to be carried; also where the hauls are short and the time required for loading is great. In the latter case, the truck is equipped with two or more trailers, so that one trailer can be hauled while the others are being loaded and unloaded. The trailer can be adapted to many uses.

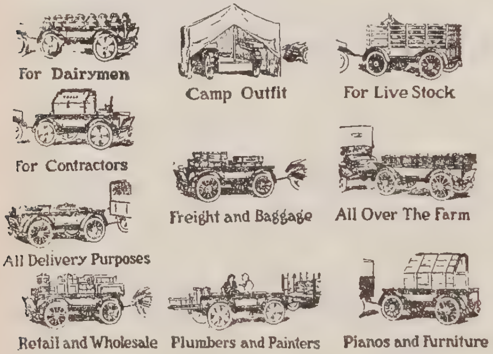

Fig. 87

There are three general designs, as follows: The **four-wheel trailer** has a large possible field of utility and can be used in practically any service, for instance, the freight and baggage, by dairymen contractors, for live stock, pianos, and furniture by plumbers and painters, for farm products, and fo camp outfits.

The two-wheel trailer has the load balanced on it axle.

The semi-trailer also uses two wheels, but the load is not balanced over its axle; rather, the front end of the load rests on the tractor vehicle.

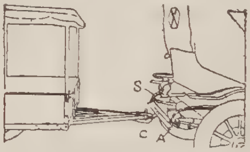

Fig. 88

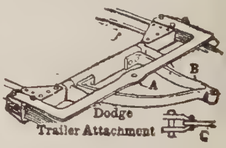

Fig. 89

Trailer attachments: Fig. 88 shows a traile attached to the rear of a car by means of a piece o angle iron (A) which is attached to springs (S) This is not recommended, as the strain is too grea on the springs. Fig. 89 shows two methods which are better. (C) is one type of coupling.

Addresses of some of the trailer manufacturer are: Highway Trailer Corp., Edgerton, Wis.; Kin Trailer Co., 741 Main St., Ann Arbor, Mich.; Lapee Trailer Corp., Fair St., Lapeer, Mich.; Lee Traile and Body Co., 2343 S. La Salle St., Chicago, Ill.

INSTRUCTIONS FOR CARE AND ADJUSTMENT OF TIMKEN-DETROIT TRUCK AXLES

Care of Truck Wheel Bearings

In ordinary truck service, wheel bearings should be removed, cleaned, and readjusted at least four times a year. If the service is unusually severe, it is advisable to inspect the condition of the lubricant and the adjustment of the bearings every two months.

To Remove, Clean, and Readjust Front Wheel Bearings

First of all, remove the hub cap; then put a jack under the front axle, and raise the wheel clear of the floor. Wipe the grease from the end of the spindle, and with your pliers remove the cotter pin from in front of the outer lock nut. Take off the outer lock nut with a wrench; a thin lock washer comes off next; then take off the inner lock nut.

Now kneel directly in front of the wheel. Grasp the rim with both hands and pull directly toward you, being careful not to let the outer bearing slip from the hub and fall to the floor, as this may bend or damage the cage so that the bearing will not render perfect service when replaced. The oute bearing having been removed, lift the wheel off th spindle, exposing the inner bearing.

Now, with a stiff brush and gasoline or kerosene clean all old grease from both the inner bearing and the inside of the hub. It is not necessary t remove the inner bearing from the spindle in order t do this, although it may be removed if desired. I is a good idea occasionally to remove both bearings placing them in a pan containing a mixture of washing soda and hot water, allowing the water to com to a boil, thus cleaning off any grease from behin the rollers that the brush and gasoline may hav failed to remove.

The bearings having been thoroughly cleaned an dried, replace the largest, or inner, bearing on th spindle, covering it thoroughly with good, clea grease, that is, free from acid, grit, or any soli matter. Care should be taken to have no grit o dirt on the paddle.

The inside of the hub should be thoroughl cleaned, and the space between the two bearin cups should be repacked with clean grease.

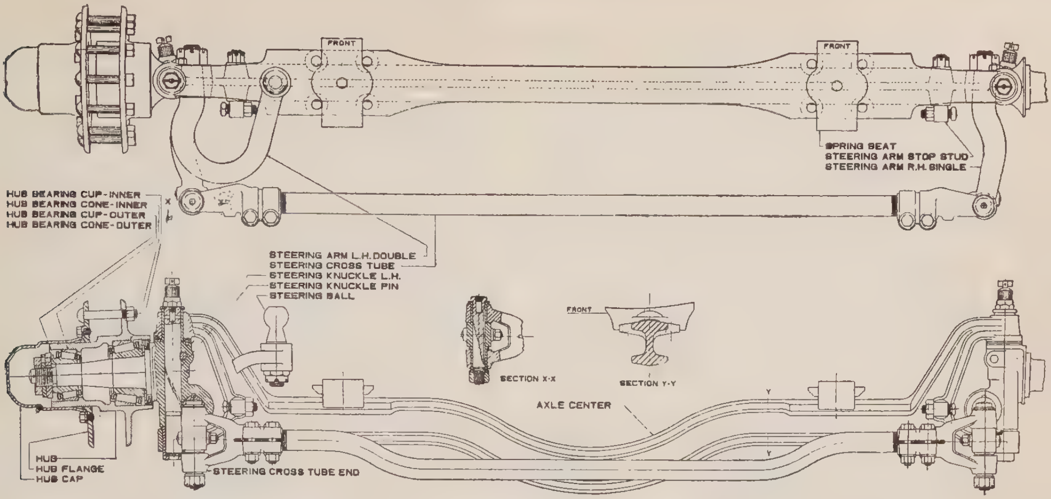

Fig. 90. Timken truck type of front axle with a plain steering knuckle bearing

Now replace the wheel, and, holding it firmly in position, slide the smaller or outer bearing on the spindle, pressing it firmly into the hub. Next screw on the adjusting nut, turning it up tight against the outer bearing so that the wheel binds, at the same time revolving the wheel to be sure that all working surfaces come into contact. Then back off the adjusting nut enough to allow the wheel to rotate freely—but without noticeable end play. Test the adjustment by taking a short bar, placing the end of it between the tire and the floor, at the same time holding one finger on the cage of the outer bearing. Now work the bar up and down so that you can detect any excessive play or looseness. When you can feel a barely perceptible shake and the wheel will oscillate when given a slight spin, your adjustment is right. If there is too much looseness in the bearings, tighten up on the lock nut. If, on the other hand, the lock nut is set too tight to allow the wheel to oscillate, loosen it about a quarter turn.

Now replace the keyed washer which goes between the two lock nuts and which prevents the inner nut from turning. Replace the outer lock nut, and screw it up tight; also replace the cotter pin in the end of the spindle to prevent the outer nut working loose.

Again test the adjustment with a bar as before, because, in using a heavy wrench to tighten the outer lock nut, it is sometimes possible to jam this nut so tightly against the inner nut as to destroy the adjustment. By taking the extra precaution to test the adjustment before replacing the hub cap, you can always be sure that your bearings will render perfect service. Now cover the end of the spindle and the lock nuts with grease, and put on the hub cap, tightening it securely.

To Adjust Bearings in Steering-Knuckle Heads

To adjust the steering-kuckle bearing when a Timken roller bearing is used at this point, simply tighten up on the nut on the bottom of the knuckle pin after the cotter pin has been removed (Fig. 91). This forces the bushing in the lower yoke of the I-beam up against the steering spindle, which in turn forces the bearing up into the cup for a proper seat.

Do not fail to lubricate this bearing thoroughly with good quality cup grease through the cup provided on the top of the knuckle pin.

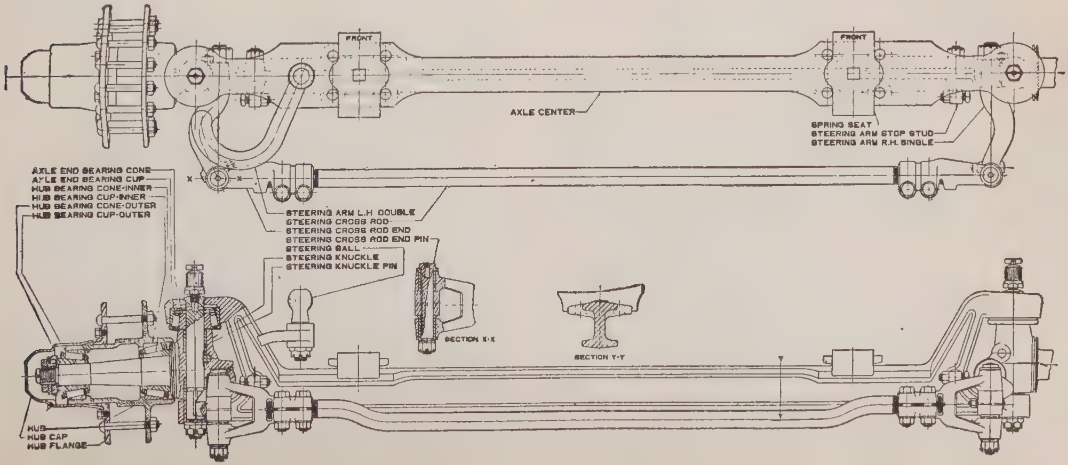

Fig. 91. Timken truck type front axle with a steering knuckle roller bearing.

To Adjust Rear Wheel Bearings—Full Floating Type

Remove the cap screws around the axle-shaft drive plate (Fig. 92), and pull out the axle shaft. Put a jack under the housing, raise the wheel off the floor, and wipe the grease from the end of the housing tube and the lock nuts. Take off the outer lock nut; then remove the thin lock washer and the inner lock nut. As the wheel is too heavy to be easily lifted off the tube, the following method can be used to remove it. Take a short piece of board and cover the upper surface with grease; slide this under the wheel, and then lower the jack several notches until the wheel rests lightly on the board. Remove the outer bearing, being careful not to allow it to fall on the floor which may bend or otherwise damage the cage. The wheel can now be eased off on the greased surface of the board and rolled to one side.

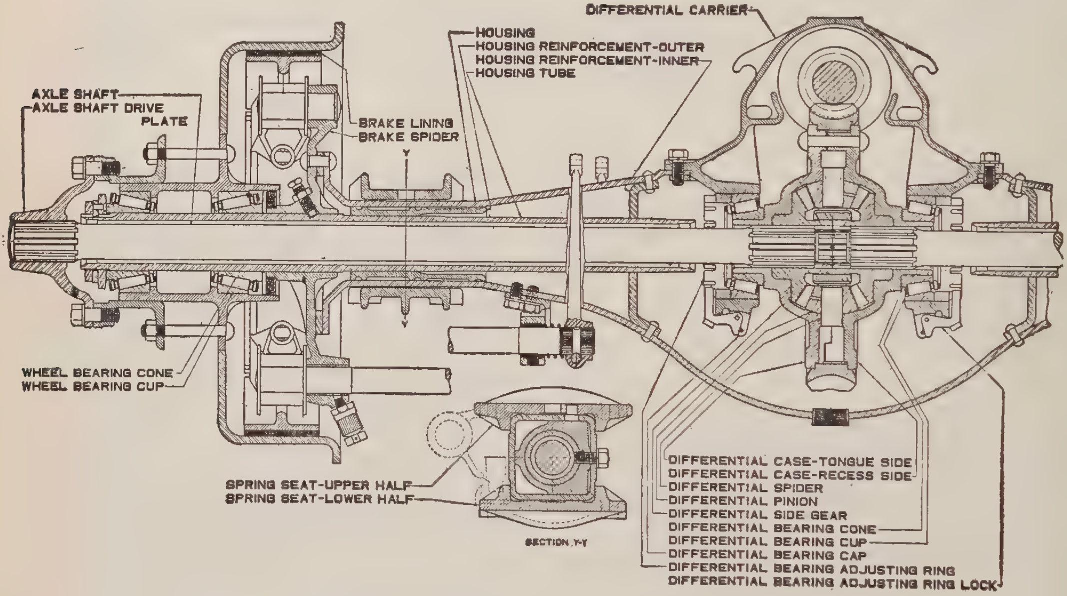

Fig. 92. Timken full-floating type of truck axle.

To clean parts: See page 864.

To lubricate wheel bearings: see page 864.

Replacing the wheel: See page 864.

Bearing adjustment: See page 864.

Test the adjustment by taking a bar, placing the end of it between the tire and the floor, at the same time holding one finger on the cage of the outer bearing. Now work the bar up and down so that you can detect any excessive play or looseness. When you can feel a barely perceptible shake and the wheel will oscillate freely, your adjustment is correct.

Now replace the lock washer and outer lock nut, screwing the nut up tight. Before replacing the drive shaft test the adjustment again with a bar as before, because in using a heavy wrench to tighten the outer lock nut it is sometimes possible to jam the nut so tightly against the inner nut as to destroy the adjustment. By taking the extra precaution to test the adjustment before replacing the drive shaft and plate, you can always be sure that your bearings will render perfect service.

Now cover the end of the axle tube and the lock nuts with grease and replace the drive shaft, being careful to tighten up the cap screws in the plate securely.

To Adjust Rear-Wheel Bearing—Fixed-Hub Semi-Floating Type

On this model of axle the rear wheel is keyed to the axle shaft. The bearing cone is pressed on the shaft, and the cup is mounted in an adjusting ring which is screwed into the axle housing.

Adjustment of bearings is made by turning this ring. These bearings should be cleaned and repacked with grease once a year.

To clean or adjust the wheel bearing, remove the wheel from the shaft, using a wheel puller if necessary. Next release the lock (Fig. 93), which prevents the bearing adjusting ring from turning, and with a flat tool unscrew this ring from the housing.

The axle shaft, carrying with it the bearing cone and rollers, can now be pulled out of the housing.

To clean bearings: See page 863.

To lubricate bearings: See page 863.

Adjusting bearings: See page 864.

To Adjust Differential Bearings

Differential bearings are lubricated by the oil in the axle housing. They require no attention in connection with lubrication beyond keeping the correct amount of the proper lubricant in the housing and seeing that the oil grooves are kept clean.

In adjusting the differential bearing, a combination adjustment is necessary (Fig. 93). First, all play must be taken out of the bearings by screwing up the adjusting rings on both sides of the differential, and second, the worm and worm wheel must be set in proper alignment by adjusting the differential bearings on both sides, end for end, moving the differential and worm wheel to one side or the other, as required for correct alignment.

All ordinary adjustment of these bearings should be made on the left-hand bearing (standing at the rear and facing toward the front of the truck); never disturb the right-hand bearing except when it is necessary to take down the entire differential assembly. By making the adjustments on the left bearing only, the alignment of the worm and wheel will not be destroyed.

To adjust the bearings (Fig. 93), the differential carrier must be removed from the housing; take out both drive shafts, remove the cap screws holding the carrier to the housing, and, having disconnected the propeller shaft, lift out the entire carrier assembly. In most cases it will be necessary to remove the axle from the chassis before the carrier can be pulled out. Now release the lock on the left-hand adjusting ring and tighten up the bearings by screwing in this ring with a flat tool until all end play or shake in the differential housing has been removed. Having obtained a good tight adjustment, unscrew the ring one notch, and lock in this position with the locking finger.

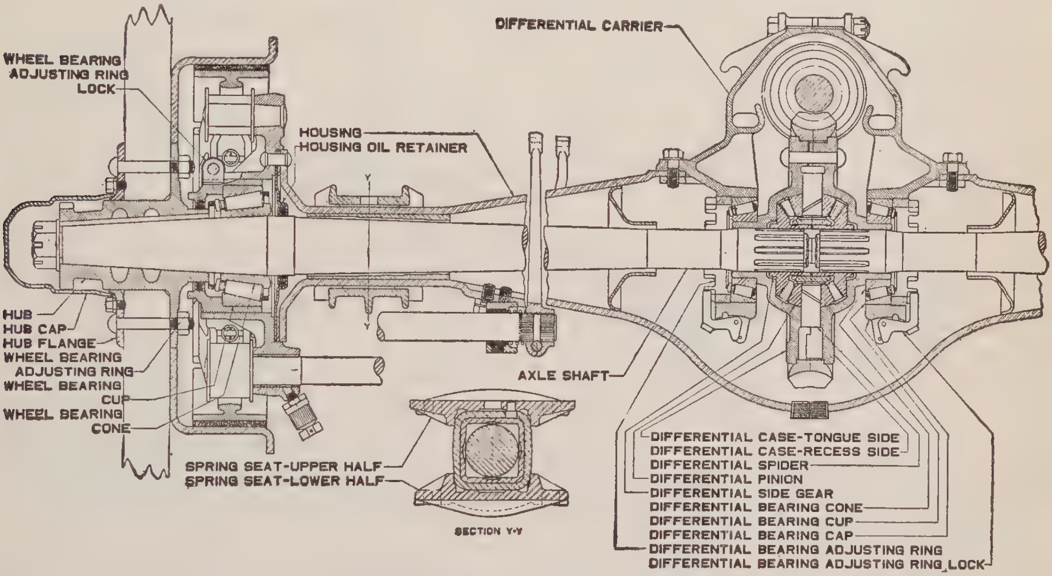

Fig. 93. Timken semi-floating or fixed-hub type of truck axle.

If the alignment of the worm and wheel is not correct, unscrew one ring, at the same time tightening up on the other the same number of notches until the center of the worm wheel is directly under the center of the worm. Check up again for end play, to be sure that the adjustment is all right. The carrier assembly may now be replaced, the drive shafts put in, and the axle reassembled under the truck. In replacing the carrier assembly, be sure to tighten up well on the cap screws holding the carrier to the housing.

To Adjust Worm-Shaft Bearings

To adjust the worm-shaft bearings (Fig. 94), first remove the packing gland from the carrier to avoid binding on the shaft and to allow free movement of the shaft. Next remove the lock from the slot, and, with a flat tool, screw in the forward bearing adjusting ring until the shaft binds. Now unscrew the ring several notches to allow end play, so that the shaft can expand when it becomes heated under running conditions. The exact extent to which the ring should be backed off is shown in the following table:

Size of Axle	Play in Inches	Number of Notches
¾–1½ ton	.011″–.015″	3
2 –3½ ton	.016″–.020″	4
5 ton	.020″	4

Lock the adjusting ring in this position with the locking finger and replace the packing gland on the shaft, tightening up on it sufficiently to prevent oil leaking out at this point.

On the older type of axles (6456—1½-ton, 6552—2½-ton, and 6652—3½-ton), it is necessary, after backing off the cage, to see that the bearing cup is properly seated in the cage. This can be done by driving on the rear end of the worm shaft or by starting the truck up slowly in low gear.

Fig. 94. Worm-shaft bearings.

On the old type of 5-ton axle (6752), where the worm-shaft bearings are set the other way, no end play to take care of expansion is necessary. On this axle the adjustment of bearings is made at the rear of the shaft.

Worm Shaft Bearings and Mounting

The Timken roller bearings, as used on the worm shafts shown in Fig. 94, page 955, are mounted by what is termed a **"direct mounting" of the worm shaft,** meaning that the thrust at the forward operation is taken on the **rear** worm bearing.

Owing to the fact that the worm shaft heats faster than the differential housing during service, the worm shaft will expand, and provision should be made for a certain amount of initial looseness in the adjustment.

The direct mounting is used on trucks up to 3½-ton capacity, and on trucks ranging from 1 to 3½-ton capacity, this looseness should be from .011″ to .020″, according to the size of the worm.

Refer to Fig. 94, and note that a thrust to the rear would be absorbed by the rear roller bearing.

On **"indirect" worm-shaft bearing mounting** the thrust at the forward operation is on the **front** bearing instead of on the rear bearing, meaning that the thrust to the rear is absorbed by the front roller bearing, because the tapers of the rollers are in the opposite direction to that shown in Fig. 94.

The initial looseness in adjustment should be .010″.

TO COMPUTE THE GEAR RATIO OF A WORM DRIVE

The gear ratio of a worm drive is dependent on two factors, namely, the number of **teeth** on the worm gear and the number of **threads** on the worm.

Explanation of One-Thread Worm

Examine the worm shown in Fig. 95.

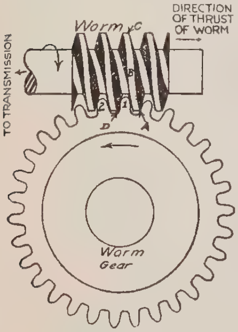

Fig. 95

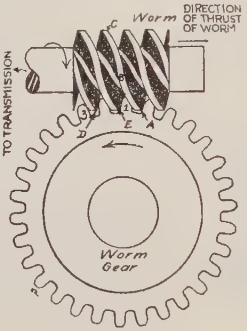

Fig. 96

Fig. 95. A one-thread worm.

Fig. 96. A two-thread worm.

Commencing at the point (**A**), let us trace the thread once around the worm. We will pass from (**A**) to point (**B**), then to point (**C**), then passing around the other side of the worm, we shall come to point (**D**).

It will be noticed that by passing around the worm once, we have advanced the distance of one thread. In other words, there is **one continuous thread** cut on the worm.

This being the case, we see that during one revolution of the worm the gear tooth (1) (Fig. 95) will advance to the position of gear tooth (2). Therefore in a one-thread worm, one revolution of the worm causes the worm gear to advance the distance of one tooth.

If there are 30 teeth in the worm gear, it will require 30 revolutions of the worm to cause one revolution of the worm gear. Consequently the gear ratio would be 30 to 1.

Conclusion: In a one-thread worm, the gear ratio equals the number of teeth on the worm gear.

Explanation of Two-Thread Worm

Examine the worm shown in Fig. 96.

Commencing at the point (**A**) let us trace the thread once around the worm. We will pass from (**A**) to point (**B**), from (**B**) to point (**C**), then passing around the other side of the worm, we shall come to point (**D**).

It will be noticed that by passing around the worm once, we have advanced the distance of **two threads.** Note that in going from (A) to (D), we did not touch point (**E**). This is because the point (**E**) is on a separate thread. So we see that there are **two separate and distinct threads** cut on the worm. This is known as a two-thread worm.

Examination of Fig. 96 will show that during one revolution of the worm, the gear tooth (1) will advance to the position of gear tooth (3). Therefore in a two-thread worm, one revolution of the worm causes the worm gear to advance the distance of two teeth.

If there are 30 teeth in the worm gear, it will require $30 \div 2 = 15$ revolutions of the worm to cause one revolution of the worm gear. Consequently the gear ratio would be 15 to 1.

Conclusion: In a two-thread worm, the gear ratio equals the number of teeth on the worm gear divided by 2.

General Rule for Determining Gear Ratio of Worm Drive

In the same way, a **three-thread worm** causes the worm gear to advance 3 teeth during one revolution of the worm; a **four-thread worm** causes a 4-tooth advance during one revolution, etc.

Therefore we come to the conclusion that **the gear ratio of a worm drive is equal to the number of teeth on the worm gear divided by the number of separate threads cut on the worm.**

Example: In the rear axle of a truck, there are 29 teeth on the worm gear and 4 separate threads cut on the worm. What is the gear ratio?

Ans. $29 \div 4 = 7.25$

Trucks are generally equipped with worms of 4, 5, or 6 separate threads cut upon them. The G.M.C. on the 2-ton truck, uses four separate threads; the Ford standard has four threads also; the Ford special high-speed truck has six threads.

BRAKE ADJUSTMENT AND LUBRICATION OF TIMKEN TRUCK REAR AXLES

Brake Adjustment (Timken Truck Axle)

To tighten up the brakes, first take up on the brake rods. After all the adjustment possible has been made in the brake rods, take off the nut, lock washer, and clamp bolt which clamps the brake levers on the axle to the brake cam shaft. Lengthen out the brake rods again, and move the lever back two or more serrations on the cam shaft and clamp into place with the clamp bolt. Now make a final adjustment of the brakes by means of the adjustment on the brake rods. All possible or necessary adjustment can be made in this way up to the point where the brake shoes require relining.

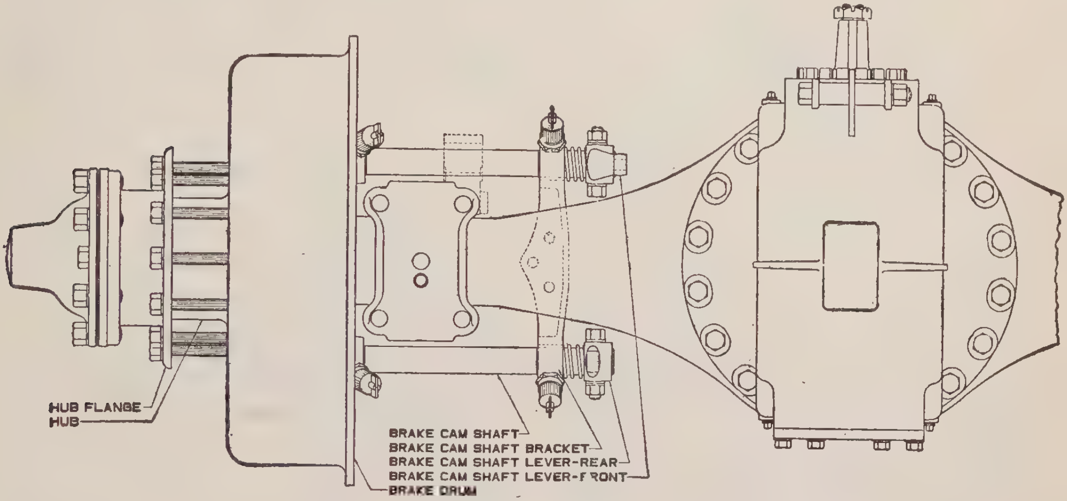

Fig. 97. Showing the location of the brakes on the rear axle and parts of the brake mechanism.

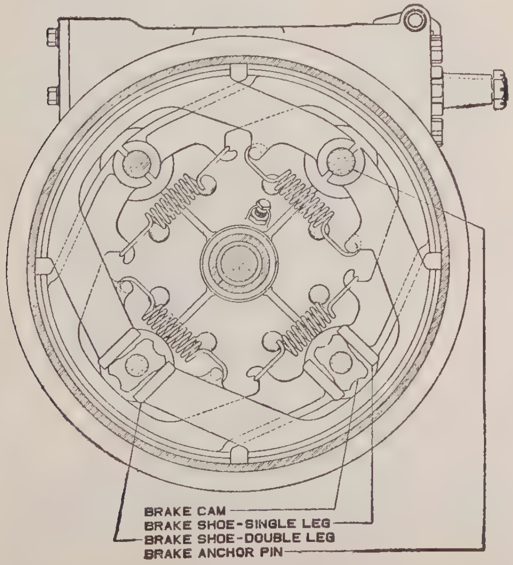

Fig. 98. View of the brake and internal construction of the **Timken duplex internal expanding brakes.** There are four friction fabric lined shoes, so located that the pair of brakes takes up no more room than the ordinary single-shoe type. Note that the internal brake shoes are actuated by a cam.

Lubrication of Timken Rear Axles

Proper lubrication of all points is of the greatest importance. Experience shows that nine-tenths of the troubles of Timken axles can be traced directly to lack of lubrication.

Examine the wheel bearings in the hub about every 5,000 miles and see if they are properly adjusted and lubricated. To lubricate wheel bearings, fill the hub full with a light grease, free from acid and grit.

To lubricate the worm and worm gearing (Fig. 99): Remove the filler cap and pour in oil until level with the opening. Examine the condition and amount of oil weekly. If it contains grit or is so thick that it will not circulate, drain the housing by unscrewing the plug at the bottom. Run kerosene through to cleanse, then refill with oil.

The worm wheel revolving in the oil carries it to the upper part of the housing (Fig. 100). The worm as it revolves throws the oil to the sides, where it is caught by troughs, as shown by arrows in Fig. 100. The oil runs by gravity to the front and rear of the housing, and is drawn through the bearings by their pumping action, and from there flows back to the starting point.

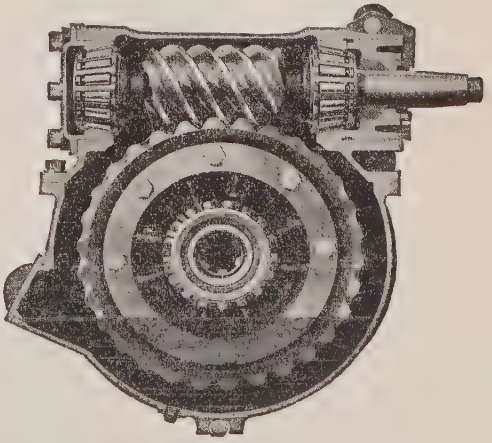

Fig. 99. Showing oil level in Timken worm-drive truck rear axle.

Once every month remove the axle-housing plate and clean out the oil ducts with a wire. Although the housing is dirt proof, the oil may become so thick that it will not circulate.

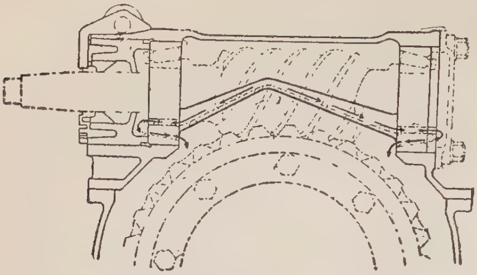

Fig. 100. Showing **oil path**, as explained in text above.

When replacing the housing plate, coat the washer on it with shellac and tighten all bolts.

Occasionally an axle will leak oil at the forward end of the worm shaft. If this happens, draw up on the packing gland (Fig. 94, page 955).

Oil to use: Do not use oil which will clog the oil passages. Use only high-grade oil, free from acid and grit, and that will stand a cold test of zero or below. Light steam cylinder oil is recommended. Do not mix graphite or other solid matter with the oil.

Cautions

The same cautions mentioned on page 865 relative to Timken passenger-car wheel bearings apply to the truck wheel bearings also.

SHELDON HEAVY-DUTY TRUCK AXLES

Front Wheels

To mount front-wheel bearings—taper roller (Fig. 101): (1) insert bearing (**A**) in the hub and press against shoulder (**C**); (2) screw retainer (**G**) in place and lock with screw (**H**); (3) insert bearing (**B**) and press against shoulder (**D**); (4) mount the hub on the spindle (**J**), and tighten nut (**E**) against the shoulder of axle (**K**); (5) there should not be more than 1/1,000″clearance between nut (**E**) and bearing (**B**). To secure this fit, the hub should be so that it cannot slide back and forth. There should be no endwise movement of the spindle, but the bearings should not be bound, and the hub should move freely. The shoulder on nut (**E**) could be filed down if the hub does not fit freely. If the wheel revolves freely, you know that the adjustment is properly made. If not, try another nut, having shoulder (**K**) more full.

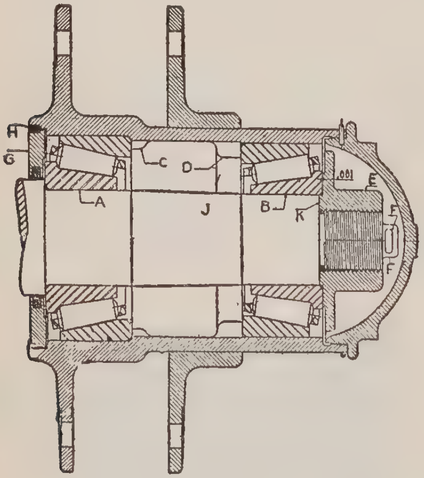

Fig. 101. Sheldon front-wheel bearings.

Care must be taken that the inner bearing seat is tight against the collar on the spindle. Test by moving the wheel from side to side.

Wheel alignment: To test; jack both front wheels up; with a piece of chalk held in a fixed position against the tires, spin the wheels, drawing a line around the tire. The distance between the lines measured at the front of the wheel should be from ⅜″ to ½″ less than in the rear.

To "take in" or "let out" on wheel alignment: Loosen the clevis jam nuts on the end of the cross-rod (Fig. 102). Remove the pins; screw the clevis either in or out, as needed. If the steering knuckle is bent, or if the steering arm is bent, replace it. If the cross-rod is bent, straighten it before realigning the wheels. The front wheels are "cambered," so they are a little closer together at the bottom than at the top.

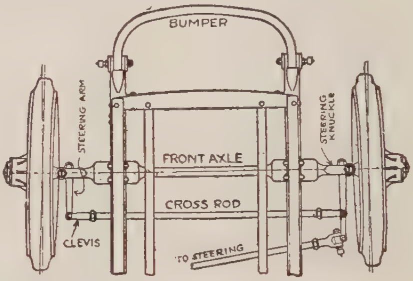

Fig. 102. Sheldon front axle.

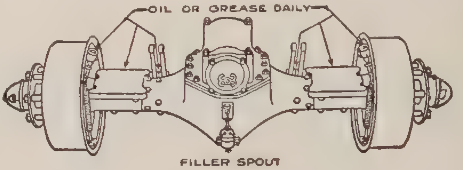

Fig. 103 Sheldon rear axle.

Rear Axle

The rear axle is of the semi-floating type. The axle is mounted throughout on ball bearings except that straight roller bearings on the wheels are sometimes provided. Lubrication of the worm gears is very important. To put oil into the housing (see Figs. 103 and 104), unscrew the filler cap and pour oil in until it overflows. When new, it may be necessary to add oil every two or three weeks, if the

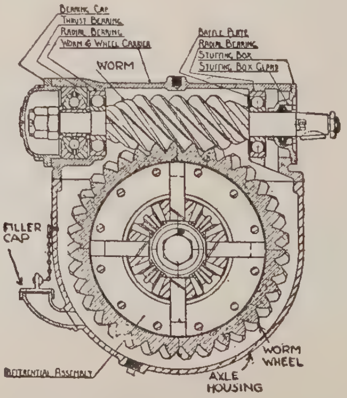

Fig. 104. Sheldon worm drive.

oil level goes down. Drain the old oil out every 5,000 miles, and flush out with gasoline and thoroughly clean. Heavy oil, such as 600W (steam cylinder oil), is best for worm-gear lubrication.

Removing Rear Wheels

To remove the rear wheels, a wheel puller (Fig. 106) is provided. Jack up the axle, unscrew cap screw (**A**), remove hub cap (**B**), remove drive-shaft nut (**C**), press out disk (**D**), replace hub cap (**B**), insert set screw (**E**), and jam it against drive shaft (**F**), tap back of wheel (**G**).

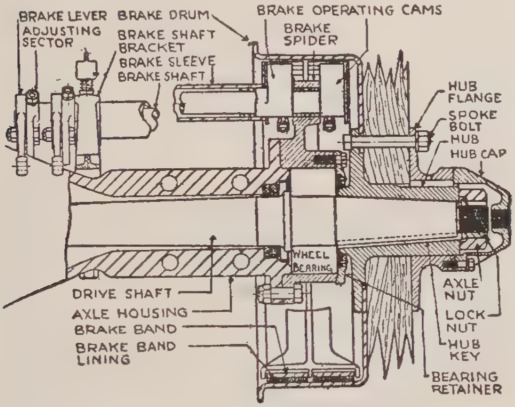

Fig. 105. Rear wheel on Sheldon axle.

Do not attempt to pull the wheel off by simply tightening up on the set screw. Be sure to tap against the rim of the wheel on the inside, after you jam the set screw against the shaft, otherwise you are liable to strip the threads.

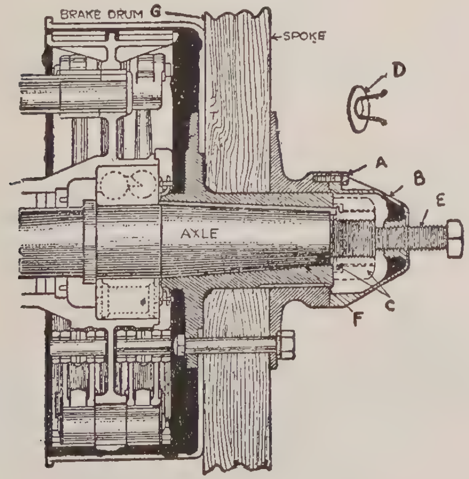

Fig. 106. Rear wheel puller.

Replacing Rear Wheel

In replacing the wheel on the shaft, put the key in position in the key way, then place the hub over the shaft with the key way in the hub in line with the key on the axle shaft. You may not be able to get the nut (which jams the key) screwed in far enough at first, because the hub will not be far enough up on the shaft. Do not attempt to draw the hub up with the key jam-nut alone, but drive the wheel on and take up with the nut as the hub creeps on the shaft. When the hub is well up in position, take off the outer nut, jam the key tight against the bearing with the jam-nut, and then place the outer nut back in position before putting on the hub cap.

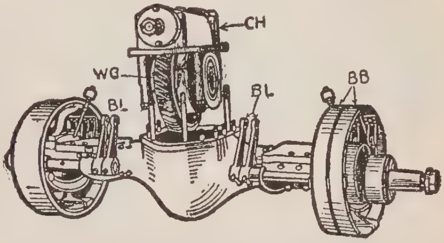

Fig. 107. Removing Sheldon worm and worm-wheel carrier.

Removing Worm and Worm-Wheel Carrier

These come out as a unit complete with the worm gear, differential, etc. (Fig. 107). Before lifting out the carrier, the axle shaft must first be removed and the carrier (**CH**) unbolted from the axle housing.

Procedure: Jack up the wheels and remove; take off the wheel-bearing retainers by unbolting them from the brake spiders (Fig. 108); pull out the axle shafts, remove the nuts which fasten the carrier to the axle housing marked "remove" (Fig. 109). These nuts are all near the outside edge. Do not disturb any of the other nuts, as they have nothing to do with the carrier removal. Fit an eye bolt (any blacksmith can make it) into the hole in the top of the carrier (Fig. 109), and lift out the carrier with a chain hoist by means of this bolt. If the entire axle lifts up with the carrier, bump the housing lightly on each side of the carrier with a heavy bar at the points marked by black squares (Fig. 109), applying force downward. Do not use a small hammer or hit too hard.

A top view of the carrier and housing is shown in Fig. 109.

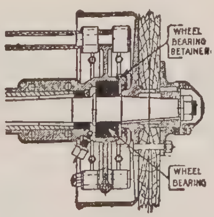

Fig. 108

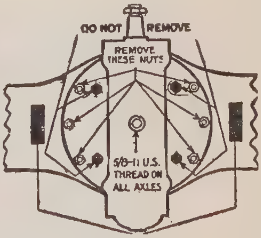

Fig. 109

Do not destroy the gasket by driving a chisel between the carrier and the housing.

On W-30 and W-50 axles, used on 3 and 5-ton trucks, there is a thrust bearing on each side of the differential, as shown in Fig. 110. Be careful that they do not fall into the housing when the carrier is lifted out. They can be held in place by reaching the hand in the axle tubes and smearing them with heavy grease, while the carrier is being lifted out. It is important that the right-hand bearing be reassembled on the right-hand side, and the left-hand bearing on the left-hand side. Do not interchange.

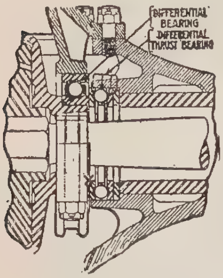

Fig. 110

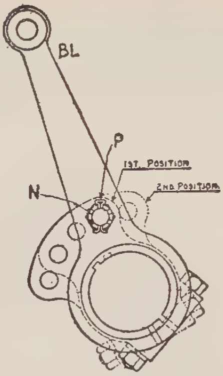

Fig. 111

Fig. 110. Differential bearings on Sheldon rear axle.
Fig. 111. Brake adjusting sector on Sheldon rear axle.

Reassembling Worm and Worm-Wheel Carrier

Reassembling: Remove the drain plug and wash out the carrier and housing with gasoline, and clean thoroughly. See that all parts are clean. See that the gasket between the carrier and housing is in perfect condition. Set the carrier back in place.

On W-30 and W-50 axles put the thrust bearings on the same side from which they were removed. On these axles they must be put in place before the carrier is dropped in, and must be held until the carrier gets down far enough to keep them in their proper position. This can be done by smearing with heavy grease, as before mentioned. Bend a short hook of ¼″ iron, insert the hand holding the hook in the axle tube, and hook it over the bearings at the bottom, at point (X) (Fig. 110), applying sufficient pressure, pulling towards you, to keep the bearings from falling out.

Bolt the carrier in place. Put the axle shafts in place, making sure that the "hex" part of the shaft is shoved well back in the hex part of the differential case.

Replace the wheel bearings, first washing them with gasoline. Pack the bearings, and also the brake spider, with grease. The grease will then work into and through the bearings when shoved back in place.

Put on the wheel-bearing retainers, and draw up tight.

Replace the wheels, being sure that the key that fastens the hub to the axle shaft is driven up well.

Refill the housing with oil, and then run the axle by hand by twisting on the front end of the worm shaft, to make sure that it is in good condition, before attaching the universal joint.

Sheldon Brakes

The **foot brake** is the regular service brake. The **hand brake** is the emergency and for use when it is desired to set brakes while the car is standing still. Both brakes on Sheldon axles are of the internal type. On the small axles they are of the cam type, and on the larger sizes of the "wrap-up" type. In this latter type the brake action gradually increases automatically.

Adjustment: Equal adjustment is essential. There is no adjustment in the brakes themselves (it being all in the parts which pull the brake levers).

On the late type of axles the adjustment is made by a sector attached to the brake pull lever, as shown in Fig. 111.

To tighten up on the brake levers, simply take out the bolt which fastens the sector to the lever, and move the hole in the lever one hole (towards the rear) on the sector.

On older type of axles the adjustments were made by simply tightening up the pull rods.

In braking the truck with the engine, with the switch off and on low gear, care must be taken. If you intend using the engine and low gear on a hill, engage your low speed before you reach the incline, because changing gears while a truck is rapidly descending is likely to strip the gears. The engine used in this way makes a powerful brake and saves the brakes. The spark should be given just before reaching the bottom of the incline, in order to start the engine before the bottom is actually reached.

THE INTERNAL-GEAR DRIVE AXLE

There are several makes of internal-gear-driven truck axles, one example being shown below. See also the internal-gear drive on the White truck (page 933), and the International truck (page 929). The ring gear (B) is driven by a bevel-driving pinion (N), which is driven by the drive shaft (S) from transmission. Note that the differential housing is fastened to the rear axle.

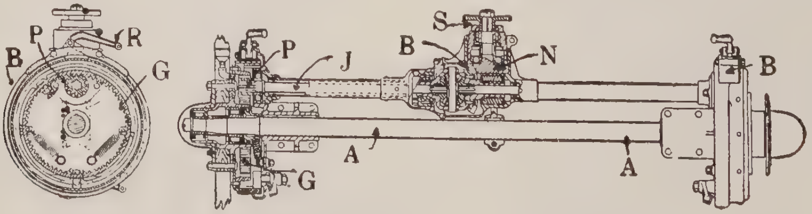

Fig. 112. Internal-gear drive axle.

This rear axle differs from the other types in that the rear axle (A) is solid. An **internal gear** (G) is on the inside of the wheel hub. A **spur-gear pinion** (P) drives this gear (G), which revolves the wheel. The spur-gear drive-pinion (P) is driven by a **jack shaft** (J) enclosed in a tube. The jack shaft (J) is driven in the same manner as a regular split axle, through differential gears and a ring gear (B).

The brake band (B) is of the external contracting type, and is controlled by lever (R), which is connected with the foot-brake pedal.

The adjustments on this axle are similar to a "live" split axle, in that the parts necessary to adjust, are the ring gear (B) on the differential and the bevel-drive pinion (N).

The adjustment of the differential ring gear (B) is to provide the proper center distance for gears (B) and (N), which can be done by shifting the ring gear with the adjustments provided. **The adjustment of the drive pinion** (N) is to provide the proper mesh between the gears (B) and (N). Manufacturers of this type of axle are: Russell Mfg. Co., Middletown, Conn.; Torbensen Co., Cleveland, Ohio, also manufacture an internal gear-drive axle, which is used on a number of different makes of trucks.

GAS-ELECTRIC TRUCK

A very unique and satisfactory combination gas-electric power truck is called the Couple-Gear.

The drive system is by means of an electric motor in each wheel, as shown in the illustration (Fig. 113). This would be termed the transmission.

This gives a four-wheel drive and a four-wheel steer without complications. No universal joints are used on the drive. All chains, sprockets, clutches, sliding and reverse gears are dispensed with.

"Couple-gear" transmission consists of an electric motor in each wheel, the motor armature having a pinion on either end, one pinion pulling up on one side of the wheel, the other pulling down at the opposite side, and both working at the periphery (Fig. 114). Each pinion meshes with a separate gear mounted on the rear wheel drum, as shown by the two illustrations (Fig. 114). Each illustration represents a separate part.

The gear reduction is 25 to 1 direct, and is supposed to deliver 97 per cent of the motor energy to the rim of the wheel. Tires are solid, 3½″ x 36″.

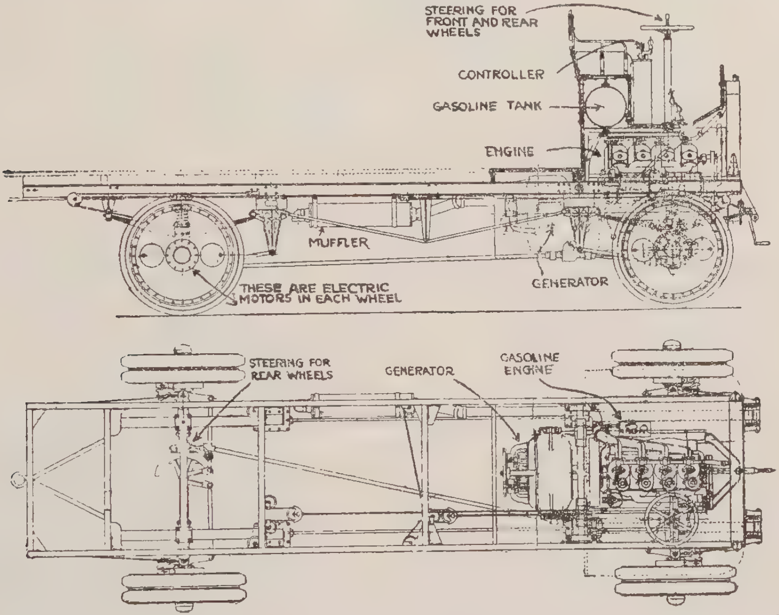

Fig. 113. A couple-gear four-wheel drive and four-wheel steer **gas-electric motive-power truck.** Especially designed for suburban and other long-distance work. Made in 3½, 4, 5, and 6-ton capacity.

The power plant is self-contained, and consists of a gasoline engine connected to an electric generator. The speed of the generator, controlled by the speed of the engine, governs the speed of the electric motors in the four wheels. The engine is equipped with Bosch ignition, a Stromberg carburetor, and a 2⅛″ five-bearing crank.

The generator is designed especially for this class of work. It is rated at 12½ k.w. at 100 volts, 680 r.p.m., and will run completely sparkless with an ampere load 200 per cent in excess of its normal rating, and with a 100 per cent rise in speed. The voltage at the maximum speed can be held down as low as 40. It is a six-pole machine, with the same number of commutating poles, compound wound, with a dropping characteristic, which automatically assists the engine to hold or increase speed at approximately the same rate as the increase in power is demanded for the vehicle propulsion. It is equipped with a rheostat connected to the fields by means of which the operator may raise or lower the gear ratio at will. The voltage can be held down to 40. The voltage drops when the amperage exceeds 70. Weight 765 lbs.

The engine is 4-cylinder, 5″ bore, with a 5½″ stroke.

Control

The throttle is operated by foot lever. **Ignition** is fixed. The **motors** are operated either in series, series parallel, or parallel, which is governed by a controller of street-railway type. There is also a reverse lever on the controller, giving the same range of speed backward as foward, and it also operates an electric brake. **Speed** is from 7 to 15 miles per hour (12 miles, loaded; 15 miles, without load).

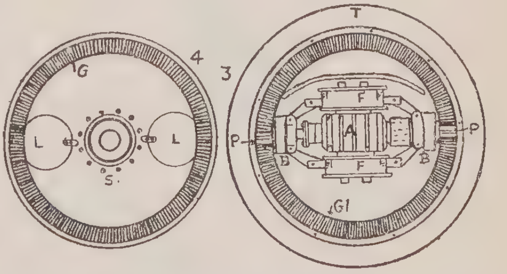

Fig. 114. Front disk and side of motor removed, giving access to the armature, field coils, and bearings. It will be noted that the electric motors are mounted in the wheels, which is the **method of transmitting the drive power.** 33-ampere 80-volt motors are used in each wheel.

(T) rubber tire; (F) field winding; (A) armature; (B) armature bearing; (P) pinion (gears which drive G1); (G) (G1) gear in wheel; (4) steel band for tire; (L) wheel inspection door; (S) roller bearing.

The motor is suspended by half of the motor casting, which is a heavy stub passing through the knuckle shaft, making the motor frame itself a component part of the axle. The armature is carried rigidly within the motor frame. The wheel shell then revolves about the motor frame, on roller bearings, one of which is on the rear of frame (3), and the other in frame (4). A cover which fits over armature (A) carries this bearing for (3), but is not shown. (Couple-Gear Freight Wheel Co., Grand Rapids, Mich.)

FOUR-WHEEL DRIVE TRUCKS

Nash Quad Truck

Drive method: All four wheels are driven by means of two drive shafts leading from the transmission (Fig. 115) to a differential housing (Fig. 117) mounted on "dead" rear and front axles.

Fig. 115. Top view of Nash Quad truck chassis.

In order that the front wheels may be turned for steering, universal joints (B) (Fig. 118) are connected to shaft flanges (F) (Fig. 117). There are internal gears in all wheels by which they are driven. All four wheels are steered (see Fig. 118).

Specifications of the Nash Quad[1]

The engine is 4-cylinder (Buda); L-type cylinder 4¼" x 5½"; 28.9 h.p.; **ignition** is type "G4" Eisemann magneto (page 269); **carburetor,** the model "L" Stromberg (see Index); **governor** is the Simplex (see Index); this governor cuts off at a speed of 14 m.p.h., or an engine speed of 1,500 revolutions; the **clutch** is the Borg & Beck (page 23); the **brakes** are internal, expanding in each wheel, and one external, contracting on the drive shaft; the **tires** are solid rubber, 36"x5"; the **wheel base** is 142" and 124"; **tread,** 56"; the **capacity** of truck is 4,000 lbs., maximum is 5,200 lbs.; the **fuel tank,** 26.7 gallons, with reserve tank of 5 gallons; the **water capacity,** 11 gallons.

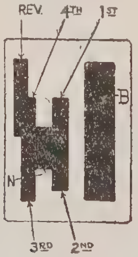

Fig. 116. Gear shift is a 4-speed shift (not a standard S. A. E. truck-gear shift).

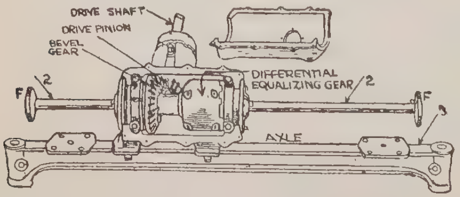

Fig. 117. Illustrates the **method of placing the differential housing** on the "dead" front and rear axle with drive shafts (2), which drive the universal joint (B) (Fig. 118), by flange connection (F).

Fig. 118. One of the four wheels, illustrating how the shaft (D) of universal joint (B), on which is a pinion (E), drives the internal gear in the wheel. Steering is by connection, in the usual way, of the knuckle arm with the steering device.

F. W. D. Four-Wheel Drive Truck

Drive: Power from the engine (Fig. 119) is transmitted through a Hele-Shaw clutch (see Fig. 6, page 22), to the main transmission, thence through a silent chain to a sub-transmission, thence to the front and rear "live" axles through drive shafts (P). The front and rear axles are similar to other automobile "live" rear axles, except that it is necessary to have universal joints connected with the spindle of the front wheels so that the front wheels can be turned for steering. The steering device connects with the front wheels, not the rear.

The locking center differential: A feature of this truck is a center "locking differential" in the sub-transmission. Normally this differential is in action to compensate for the difference in speed between the front and rear axles when turning corners. Thus, by the center differential action, tire economy is assured. Should the truck be in a position where

---

[1] Nash Motors Co., Kenosha, Wis.

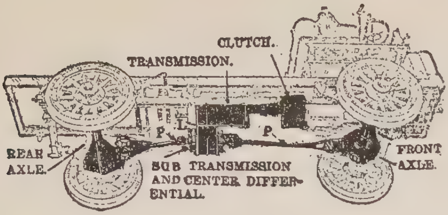

Fig. 119. View underneath the F. W. D. truck, showing how the front and rear wheels are driven.

the rear or front wheels are slipping, the center differential can be locked by means of a lever (L), operating a clutch connecting with each drive shaft, so that the differential action is thrown out of use and all four wheels are driven at the same speed. When the truck has been extricated from the soft spot, the locking lever (L) is released, and the differential is again in action. If one of the axles is permanently damaged or disabled, the propeller shaft (P) can be disengaged and the other axle used. There are also differentials in the front and rear live axles.

Specifications of F. W. D. Truck

Model B: 3-ton; **engine,** Wisconsin T-head, 4-cylinder bore, 4¾″ x 5½″stroke, with cylinders offset ¾″, and rating of 36.1 h.p.; **ignition,** Eisemann high-tension magneto with impulse starter; **carburetion,** Stromberg model "G"; **governor,** Pierce (page 947), adjusted for maximum speed of 14 m.p.h. on high speed; **tires,** 36″ x 6″; **gasoline tank,** gravity feed, 30 gallons; **gearshift,** same as shown in Fig. 19, page 29; **load distribution,** designed so that 45 per cent of the total load is carried on the front wheels and 55 per cent on the rear wheels; **transmission gear ratio,** 1:1 on high, 2:1 on second, 4:1 on low, and 4.13:1 on reverse; **total gear reduction,** 8.9:1 on high, 17.80:1 on second, 35.60:1 on low, 36.07:1 on reverse. (Four wheel drive Auto Co., Clintonville, Wis.)

Fig. 120. **Top view of G. V. 2-ton electric truck.** The G. V. truck is made in 6 sizes: the 1,000 lb. wagon is made with worm or chain drive; the 2,000 lb. is chain driven; the 2 and 3½ and 5-ton trucks are chain driven.

Specifications

Carrying capacity 2 tons; speed, 9 m.p.h.; mileage travel (approximately) on one charge, 45; number of batteries, 42; amperage (approximately) in starting, 75 to 80; amperage when running, 35; weight of truck, including batteries, 6,395 lbs.; weight without batteries, 4,050 lbs.; price (chassis), $3,000; wheel base, 112½″; track or tread, 61″; overall lentgh, 167″; tires (solid), front, 36″x 4″, rear, 36″ x 3″ dual.

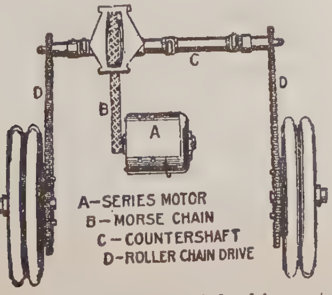

Fig. 122. **Note the simplicity of the drive system, which is a double-chain drive.**

The horsepower of the motor at 84 volts and 40 amperes is approximately 4 h.p. Starting cold, this motor will run 100 per cent overload for one half-hour and 200 per cent overload for 10 min.

The wiring diagram (Fig. 121) shows the connections to be used for either a differential shunted "three-wire" ampere-hour meter, or a "two-wire" ampere-hour meter equipped with variable resistor element.

Explanation of Parts

The controller box is placed in front, convenient to the driver. It contains the controller, resistance unit, fuse block switches, etc. The current is disconnected by the switch (Fig. 123) which is a 3-way running switch and is thrown to the left when the battery is being charged, to the center when current is off, and to the right when running.

When charging the battery, connection is made with the "charging receptacle" (Fig. 121) from an outside source of electric supply. In case the current charging the battery should fail for any reason, the circuit breaker (Fig. 121) will disconnect, so that the current from the battery would not flow back.

The ampere-hour meter (Fig. 121) shows the amount of current taken from the battery when running.

When charging, a compensating shunt is used, so that the meter runs approximately 15 per cent slow. The Sangamo Electric Co., Springfield, Ill., manufactures the meter used on this truck.

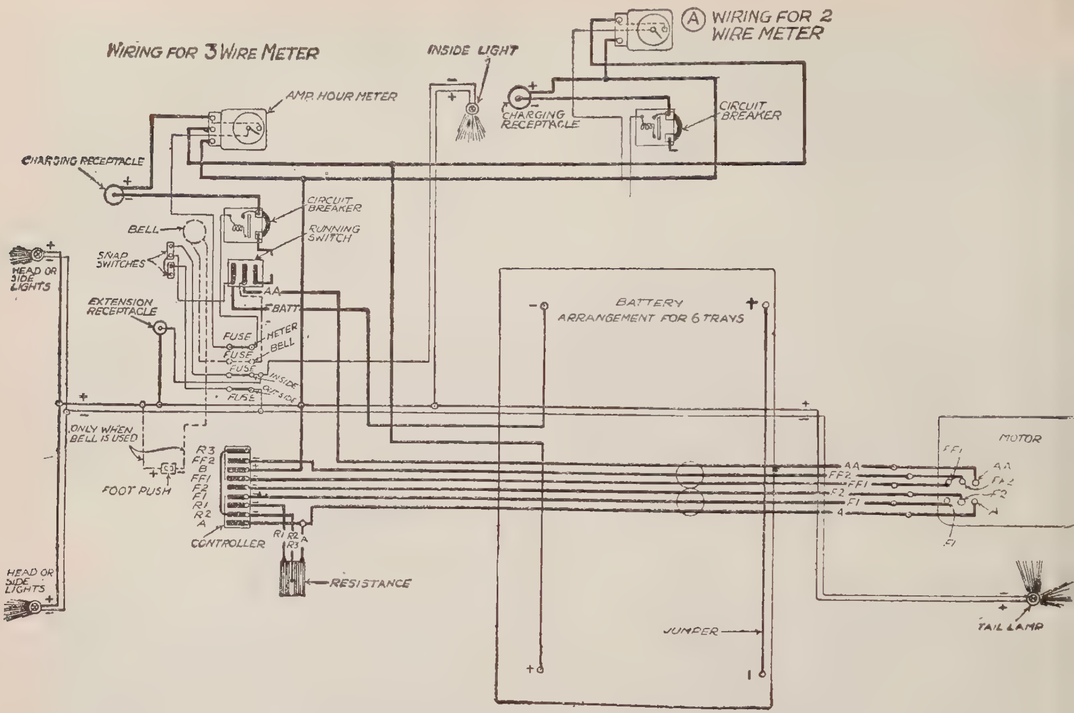

Fig. 121. Wiring diagram of G. V. 2-ton electric truck.

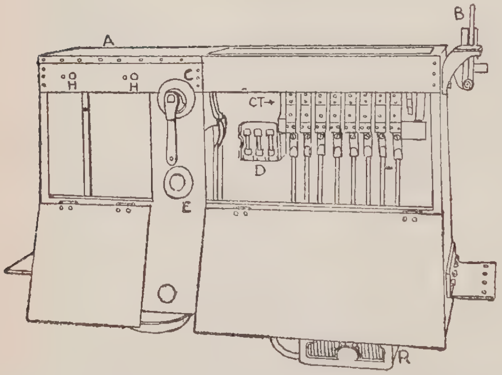

Fig. 123. **Controller box:** (A) sheet-steel controller box; (B) controller handle; (C) three-way switch; (D) lamp-circuit fuses; (E) plug for portable lamp; (R) resistance.

The Controller of G. V. Electric Truck

The controller is used to make connections for the different speeds. Refer to Fig. 124, and note the movement of the lever for the five speeds forward and the two speeds reverse.

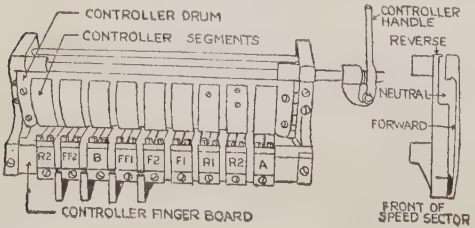

Fig. 124. **Controller.** Note the connections of the fingers, which refers to diagram (Fig. 125).

The controller is of the "constant torque" type, and the batteries are connected in series at all times. The various speeds are obtained by cutting out or in resistance (cast iron), and also by making "field" connections of the motor, as explained below.

Controller Connections

By referring to Figs. 124, 125, 126, and 127, the connections from the controller to the resistance and field circuits can be traced.

(R1) (R2) (R3) mean resistance; at (R1) all resistance is in the circuit; at (R3) about one-half is in; at (R2) about one-third is in (see Figs. 126, 127).

(F1) and (FF1) constitute one set of three field windings; (F2) and (FF2) are the second set, and are connected in series. The two windings are connected in series on speeds 1, 2, 3, 4, and in parallel on fifth speed.

(A1) and (AA) are two armature brushes; there are two brush holders with three brushes each, on the motor.

In Fig. 125, **the letter (O) is the neutral or "off" position of** the controller, and the black dots denote the controller fingers.

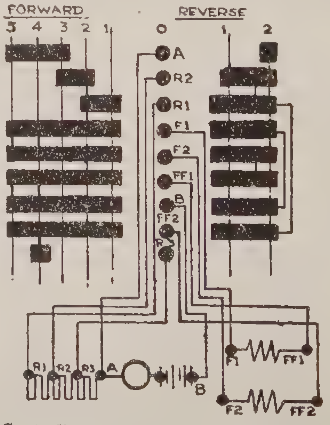

Fig. 125. **Controller connections:** (O) is off or neutral position. Black dots denote the controller fingers; black squares denote the controller copper segments. The five speeds forward and two speeds reverse are shown.

Forward Speeds

First speed: see Fig. 126 (1 forward); both fields are in series, and all resistance (R1) is in the circuit. This is the slowest speed.

Second speed: see Fig. 126 (2 forward); both fields are in series, and part of the resistance is cut out (R2).

Third speed: see Fig. 126 (3 forward); both fields are in series, and all resistance is cut out.

Fourth speed: see Fig. 126 (4 forward); resistance (R3) is shunted across the series field.

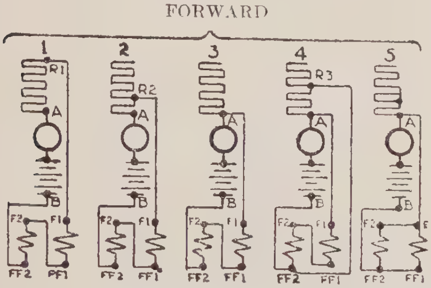

Fig. 126. Illustrating the resistance connections (**R1**) (**R2**) (**R3**) and field connections (**F1**) and (**F2**) and (**FF1**) and (**FF2**). (**A**) shows the armature brush connections; (**B**) battery connections.

Fifth speed: see Fig. 126 (5 forward); fields are in parallel; all resistance is cut out.

The forward speeds are divided approximately equally, each notch of the controller being an increase of approximately 20 per cent in speed.

Reverse Speeds

Reverse speeds (Figs. 127 and 125) are the same connections as second and third forward (Fig. 126), but passing through first speed to prevent a heavy rush of current. The direction of flow of the current is changed through the field, which reverses the rotation of the armature.

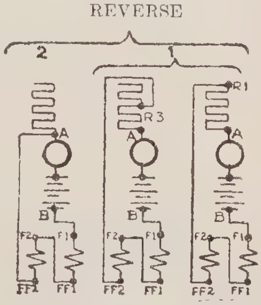

Fig. 127. Reverse connections.

Resistance: For resistance, cast iron is used.

STEINMETZ ELECTRIC TRUCK

The present model has a capacity of 1,500 lbs., and is rather remarkable for its simplicity, freedom from freak design, and its abundance of power. The feature which is expected to do so much to bring the electric to the fore ground is in the motor and rear axle. Other parts of the car are of a conventional design.

The high speed at which the electric motor operates efficiently makes it necessary to have a high gear reduction, which is objectionable in this kind of a vehicle. Steinmetz's first designs called for a revolving field rotating in an opposite direction to the armature. This was found to be impractical from a service standpoint, and the gear reduction is accomplished in this latest design in a **double-reduction spur-gear axle** of which the motor is a unit part.

MOTOR DRIVE PINION
REAR AXLE HOUSING
SPUR DRIVE GEAR ON BEVEL GEAR
MOTOR WIRES
BRAKE MECHANISM ON MOTOR SHAFT

Fig. 128. The motor and axle using a double reduction drive.

A standard battery is supplied.

The truck is fitted with pneumatic tires, 33″ x 5″. There is a hood in front of the driver's seat, resembling very much the hood on a gasoline truck. A portion of the battery is contained under this hood and another portion is under the driver's seat. Both sections of the battery are contained in trays, and can be rolled out of the car in a very few minutes by simply disconnecting the leads and loosening the clamp bolts.

Drive: Power unit of the Steinmetz truck, made up of the electric motor gearing of the rear axle is a self-contained or integral unit, the motor being readily bolted to the one-piece gear case casting, in which are mounted all of the driving gears. This gear is in turn readily bolted to the rear axle, thus insuring perfect alignment of all important parts, which means not only high efficiency when the truck is new, but high efficiency over a continued period of years.

Bearings: All important bearings throughout the car are ball bearings. The parts containing ball bearings are front wheels, rear wheels, motor shaft, gear-case counter shaft, and the differential bearings. All other bearings throughout the car subject to wear are bronze bushed, and the majority of them are of the oilless type. Ample lubrication is provided for all bearings.

Wheels: Schwarz wood wheels, standard S. A. E. dimensions, 12 spokes for 33″ x 5″ pneumatic tires or 34″ x 4″ solid tires (special wheels for the latter).

Steering gear: Irreversible nut and trunion type, easily adjustable for wear.

Controller: Continuous torque, drum type; all contacts and connections in plain view and very accessible. Controller segment mounted on metallic segment bases. Segment bases are properly insulated from each other and from the controller shaft, thus insuring against short circuits and possible burning of the controller segment bases.

Main switch: Double pole, double throw, rigidly constructed, and of large capacity; three positions—running, off and charging; locks in any position. When in charging position, this switch isolates the battery from the controller so that adjustment or repairs may be made to the controller with perfect safety to the mechanic.

Wiring: All power wire used through the truck is of flexible copper conductor, heavily insulated with 30 per cent Para rubber insulation.

Ward Electric Truck

A popular make of electric truck using a worm-driven rear axle is the Ward, made by the Ward Motor Vehicle Co., Mt. Vernon, N.Y.

Although the worm drive is used on 68 per cent of the gasoline-driven trucks the worm drive has not heretofore been adopted for electric trucks.

A TAXICAB

As an example of the construction of a taxicab we will use the Yellow Cab, as manufactured by the Yellow Cab Co. of Chicago, Ill.

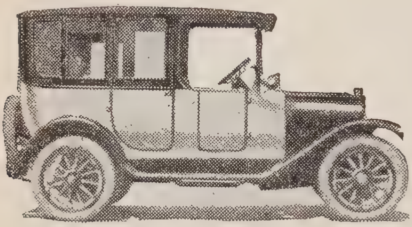

Fig. 129. The Yellow-Cab.

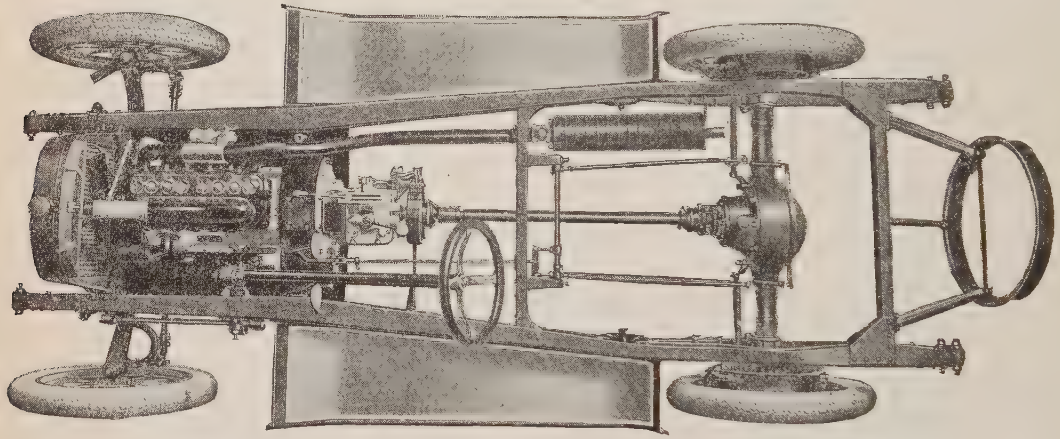

Fig. 130. Top view of chassis of the Yellow Cab, showing the location of parts.

Yellow-Cab Specifications

Engine: Continental Red Seal, similar to the Continental model "N" (see page 94); main-frame unit power plant construction, three-point suspension; four-cylinder, four-cycle, 3¾" bore, 5" stroke cylinders cast en bloc; valves all on one side, easily removed; valve stems, springs, and push rods enclosed, well lubricated, and free from cutting action of sand and dust; accessible by means of removable plate; spiral timing gears, under spring tension to overcome backlash; drop-forged connecting rods with bronze-backed bearings; crank shaft of special alloy, drop forged, and all bearings ground; self-contained constant-level oiling system, has oil-level indicator; average speed of the engine is 1,060 r.p.m.; average speed of car, 20 m.p.h., and will operate from 5 to 35 m.p.h.

Gasoline capacity: 10 gallons, gravity feed, tank under front seat.

Clutch: Brown-Lipe; multiple disk; Raybestos against steel plates; special radial-thrust ball bearing for clutch release; clutch housing integral with transmission case, and bolts to special flange on crank case, making unit power plant.

Transmission: Brown-Lipe; three-speed and reverse, nickel steel gears and shafts mounted on Timken roller bearings and annular ball bearings.

Universal joints: Spicer; double universal between transmission and rear axle, with slip joint to allow for spring action; each universal joint is enclosed in a steel case which is grease tight; drive is obtained through rear springs with spring saddles solid on rear axle, no torque arm or radius rods being used.

Front axle: Timken-Detroit, drop-forged I-beam section; extra heavy wheels mounted on Timken roller bearings.

Rear-axle: Timken-Detroit; semi-floating type, Timken roller bearings on shafts and differential; differential and main drive adjustable and easily removable; driving gears are of the helical bevel type; rear-axle ratio is 4 9/10 and 4 1/12.

Frame: Pressed steel; vertical section 6¼"; width of flange in front 1¾"; width of flange in widest part 3⅝"; tapering to 2⅛" at rear end.

Springs: Chrome vanadium steel; front, semi-elliptic, 2" wide, 36½" long, 8 leaves; rear, semi-elliptic, 2¼" wide, 53" long, 10 leaves; all springs, pins, or bolts of special steel; springs and spring hangers bronze bushed; Alemite system of lubrication used on spring bolts and all other parts of the car that require grease.

Cooling system: Thermo-syphon circulation; radiator of ample capacity to cool the motor under all weather conditions; radiator is mounted on trunnion supports cast integral with the front motor support.

Ignition: Bosch high-tension magneto; latest D.U.4 type with spark in fixed position.

Wheel base: 109"; 8½" road clearance.

Wheels: 1½" spokes; artillery type; 32" x 4"; rims demountable; straight side type.

Tires: 32" x 4" cord, non-skid all around.

Control: Levers for gear shift and emergency brake directly connected to transmission-case cover, giving center control; left-hand steer, no hand spark or throttle levers; spark is fixed and entire carburetor control by foot accelerator; entrance to front seats from either side.

Steering gear: Gemmer; worm-and-sector type; adjustment for lost motion.

Braking system: Service brakes external on rear wheels; brake bands 2½" wide and 15½" in diameter; emergency brake operates directly on gear set; brake band 2¼" wide and 8¼" in diameter.

Carburetor: Zenith model S-4; steering-post adjustment for starting; hot-air stove connection.

Equipment: Two cowl lights, search light, tail light, dome light, large lighting battery, Stewart-Warner hand horn, tire carrier, jack, jack handle, hub cap wrenches, rim wrench, and port plug wrench.

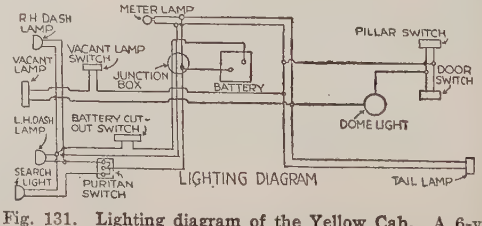

Fig. 131. **Lighting diagram of the Yellow Cab.** A 6-volt storage battery supplies current for lights, and a Bosch high-tension magneto supplies current for ignition. The "Puritan switch" is an ignition switch under the cowl. "Vacant lamp" denotes a lamp placed on the front center of the roof at the top of the wind shield, which shows whether the taxicab is occupied or vacant. "Pillar lights" denote lights placed on the rear door pillar in front of the rear door outside. The "meter lamp" is to light the meter.

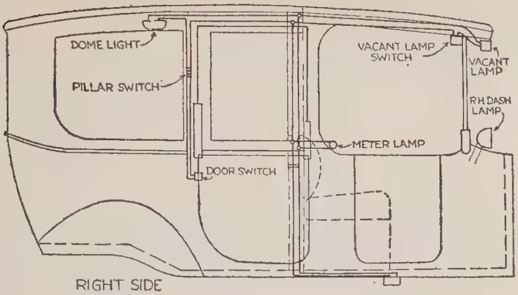

Fig. 132. Right side view of body and lighting connections.

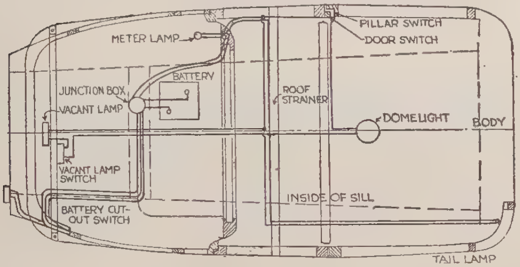

Fig. 133. Top view.

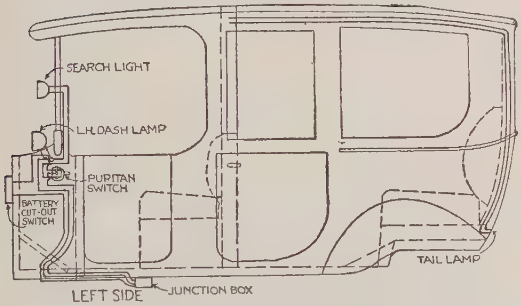

Fig. 134. Left side view of body and lighting connections.

Taxicab Rates

The rates given below are those of the Yellow Cab Co., of Chicago.

For One Passenger

For first one-half mile	$0.25
For each succeeding half-mile	.10
For each four minutes waiting	.10

Additional Passengers

Each additional passenger for entire trip	.20

Cabs by the Hour

Rate per hour	3.00

Time to start when cab is engaged.

Baggage

Hand baggage carried free—trunks, each	.20

"Extras" mean extra passengers.

There is no uniform price regarding the charging of extras, and the rates of fare in use throughout the United States are almost as many as there are cities in the United States.

Chicago has the lowest taxicab rates in the United States.

The most prevalent rates of fare throughout the United States are as follows:

30c. for first one-third mile or fraction thereof,

10c. for each succeeding one-third mile, or fraction thereof,

10c. for each four minutes of waiting time,

Extras, 20c., etc.

In some cities the taxicab companies haul two, three, or four passengers as cheaply as they do one, but the usual price charged is 20c. for each passenger over one.

A few years ago, a great many cities had ordinances requiring taxicabs to haul passengers to practically any place in the city at prices of 50c., 75c., or $1.00.

Today there are only four cities of 50,000 population, or more, that still adhere to this obsolete practice. Practically all the other cities in the United States now have ordinances requiring the use of meters on all taxicabs. The reason for this is obvious. All taxicab operation costs must be figured on a basis of so much per cab per mile.

The selling of transportation should be on the same basis.

In other words, figured on a cab-mile basis, this is equitable both to the passenger and to the taxicab operator.

It would certainly be illogical to do as was done in the past, namely, to charge the same amount whether the passenger rode ten yards or ten miles. It certainly is unfair to ask the short-distance passenger to pay an amount so great that he will be helping to pay for the distance traveled by the long-distance rider, who, in turn, pays too little.

The Ohmer Taximeter as Used on the Yellow Cab

A taximeter is used on taxicabs for the purpose of keeping tab on the distance traversed and the cost per mile to a passenger.

When a car is standing, the meter is shown with the vacant sign standing upright and all dials at zero (Fig. 136).

The Ohmer printing taximeter, as it is termed, not only gives a visual indication of the fare due, but it also has two more **vitally important functions**, as follows:

1. It issues a ticket for the customer or passenger.
2. It keeps a printed record for the operating company's use.

No. 3429

260 JUL 23 9522 .20

Fig. 135. **An example of the receipt issued** is shown above The ticket as issued by the machine serves as an invoice to the customer to show him the amount of money that he owes for his ride. It also serves as a receipt in the hands of the customer showing that he has paid for his ride. The fare is shown on the left, and includes the money due for the mileage and also for any waiting time. The amount shown under "extras" includes any charge that is made for hauling baggage, extra passengers, etc.

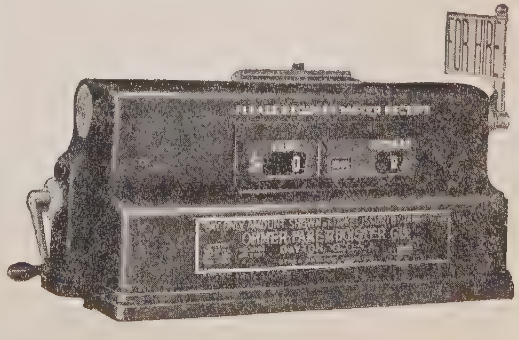

Fig. 136. The Ohmer taximeter with "For Hire" sign up, indicating that the taxicab is not engaged.

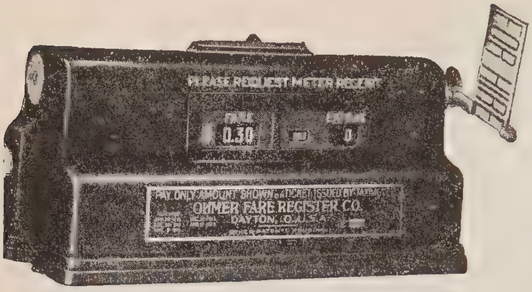

Fig. 137. The Ohmer taximeter flag in "Hired" position.

When the cab is hired, the meter flag is pulled from its "For Hire" position (Fig. 136) to the "Hired" position (Fig. 137), and the machine immediately starts computing. If the cab is running at a speed less than six miles per hour, or stops, the charges are computed on the basis of time consumed, but if a higher rate of speed is maintained, the machine automatically computes on the basis of the established mileage rates.

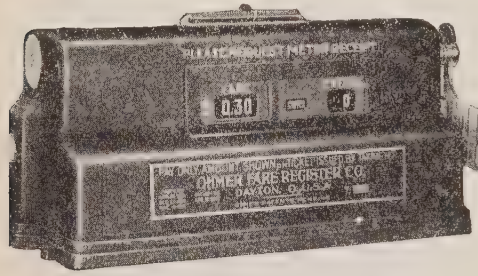

Fig. 138. Flag on "Non-recording" position.

If it is desired to set the meter so that no charge will be computed while the cab is stopped for accidents, tire repairs, engine troubles, etc., the flag is moved another quarter-turn to the non-recording position (Fig. 138). The time lost is recorded by the machine on the company's record, but no charge is made therefor. The flag can then be returned to the "Hired" position, but it can be moved to the "For Hire" position only by printing a ticket, or receipt, and the corresponding record, which is done by turning the crank, after first throwing the flag to the non-recording position.

It is, therefore, mechanically impossible for the driver, after having once put the meter in operation, to avoid making a complete printed record of the job.

Extras are recorded by turning the extras knob through one complete turn for each extra to be recorded.

Each driver is provided with a numbered identification key, which must be inserted in the machine before it can be operated, and which cannot be withdrawn until the flag has been turned to the "For Hire" position. This key prints the driver's number on the record each time a ticket is issued, so that there can be no question at any time as to the responsibility for each charge.

The address of the manufacturers of the Ohmer Taximeter is Ohmer Fare Register Co., Dayton, Ohio.

The Atco Taximeter

This taximeter is not used on the Yellow Cab, but is used on some of the other makes of taxicabs.

By way of illustration, we will explain the function of a taximeter recording as follows:

30 cents for the first half mile;
10 cents for each succeeding ¼ mile;
10 cents for each 4 minutes of waiting time;
20 cents for each extra passenger over one for the trip.

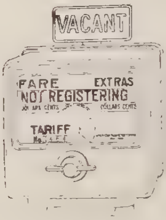

Fig. 139

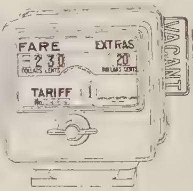

Fig. 140

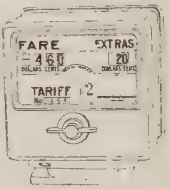

Fig. 141

When the vehicle is hired, the driver releases the flag lock and places the flag in its recording position (Fig. 140) at which time the figure 1 appears on the face of the meter under "tariff." At this time the initial fare, 30 cents, appears on the fare dial. From that minute the fare is accumulated for both distance and waiting time.

When two different rates are charged (such as another rate at 8 cents for each succeeding ¼ mile) a two-tariff meter must be used.

Where a two-tariff meter is used when the vehicle is hired, the driver releases the flag lock and places the flag in second tariff position (Fig. 141). In this position the flag is at the bottom of the meter (flag not shown), and the figure 2 appears on the face of the meter under "tariff." At this time the initial fare of 30 cents appears on the fare dial, and 8 cents will be charged up for each ¼ mile after a ½ mile.

Assuming that there is a second passenger, the driver operates the extra button for a complete turn, thereby recording one extra of 20 cents which appears on the dial under "extras" on the face of the meter.

For the 30 cents initial fare the passenger receives one ½ mile in distance, or 8 minutes of waiting time, or any proportion of either. After this, the fare mechanically changes to 40 cents, entitling the passenger to one ¼ mile of travel or 4 minutes of waiting time, or any proportion of either.

Every minute or fraction of a minute consumed by traffic stops, or when the cab is operating at a speed less than 4 miles per hour, deducts from the distance the passenger would ordinarily receive for the dime previously registered.

At the expiration of the trip, the driver places the flag in its "not recording" position, which stops the time clock. This prevents any additional fare recording while the passenger is paying the fare. Should the driver attempt to operate the cab with the flag in this position, money for distance is registered on both the front and rear of the meter, and all mileage records are recorded.

After the fare recorded on the face under "fare and extras" is collected, the flag is placed in the "vacant" or "upright" position (Fig. 139), by completing the circle through which it travels. When so placed, the flag locks itself and cannot be tampered with to the detriment of the driver, who would be held accountable at the rate of 30 cents for each time the flag is removed from its upright position. (Manufacturer is the American Taximeter Co., 16–24 W. Sixty-first St., New York, N.Y.)

INSTRUCTION No. 77

TRACTORS: Types; Engines; Kerosene as a Fuel; Fordson Tractor

The definition of the word "tractor" is "that which draws, or is used in drawing."

Fuel: The tractor was formerly propelled by a steam engine, but is now usually propelled by a gasoline engine, which uses gasoline or kerosene for fuel. Two methods of using either gasoline or kerosene are explained farther on.

The engine can be either a multiple cylinder, vertical, or of the horizontal opposed type. The **4-cylinder engine** is used quite extensively, and for the same reason as it is used on trucks. The engine varies in but a few details from that used on automobile passenger cars.

The tractor engine must stand continued running at at least three-quarter power for an aggregate of several hours steady work. Therefore the bearings and parts of the engine should be heavier, and capable of withstanding this strain.

The engine ignition is generally by means of a magneto and with an "impulse" starter, as explained farther on.

The governor is used, as the tractor engine does not vary in speed so much as an automobile engine. See Index under "Governors."

The drive systems differ, however; but the same underlying principles, such as clutches, jack shafts with differentials, etc., are employed, but of much heavier and larger design, as explained farther on.

We would advise the reader to send for catalogues of some of the leading tractor manufacturers. These catalogues will give information on the drive methods, and the instructions in this book on engines, ignition, etc., will give sufficient information on the engine. In this way one can gain a good working knowledge of tractors.

A leading concern who has agreed to send descriptive catalogues pertaining to tractors to our readers, is the Minneapolis Steel and Machinery Co., Minneapolis, Minn., manufacturers of the "Twin City" tractors. Some of the other tractor manufacturers are Holt Mfg. Co., Peoria, Ill.; C. L. Best Tractor Co., San Leandro, Cal.; Yuba Mfg. Co., 433 California St., San Francisco, Cal.

The addresses of some of the gas-engine magazines are: *Farm Machinery*, 1827 Prairie Ave., Chicago, Ill.; *Gas Engine*, Cincinnati, Ohio; *Gas Review*, Madison, Wis.; *Gas Power*, St. Joseph, Mich.; *Farm Machinery-Farm Power*, St. Louis, Mo.

What a Medium-Size Tractor Will Do

The medium-size, medium-priced tractor, operating under average conditions, will plow one acre 7 in. deep on 2½ gal. of gasoline and 1/5 gal. of lubricating oil. This, in brief, is the result of an extensive inquiry made by the United States Department of Agriculture, embracing data received from 200 tractor users in the corn belt in Illinois.

The information is given in bulletin No. 719 of the department, entitled "An Economic Study of the Farm Tractor in the Corn Belt," which includes information from the users of tractors of various sizes and on various sized farms.

Best Size of Tractor to Purchase

Belt work represents 50 per cent of the total work of a tractor. For belt work to be thoroughly efficient, the engine needs about the same power as is required for four plows, making the three and four-plow outfits the best sizes for general utility on the farm.

Another important conclusion drawn from the data collected indicates the size of tractor most suitable for a given size farm, and lays particular emphasis on the fact that the medium-size, medium-priced tractor "appears to have proven a profitable investment in a higher percentage of cases than any others." The sizes recommended for various sizes of farms are:

Acreage of Farm	No. Plows Handled
200 or less	3-plow
201-450	4-plow (3-plow second choice)
451-750	4-plow (5- and 8-plow second choice)

It is further noted that the smallest farm upon which the smallest tractor in common use—the 2-plow machine—may be expected to prove profitable, is one of 140 acres.

The bulletin further states that the **chief advantages of the tractor for farm work,** according to the operators, are: (1) its ability to do heavy work rapidly, thus covering the required average in the season; (2) the saving of man labor, and (3) the ability to plow to a good depth, particularly in hot weather. The **chief disadvantages** are put down as difficulty of efficient operation and packing of the soil when wet.

One significant fact brought out is that the purchase of a tractor seldom lowers the actual cost of conducting the farm, and that the purchase of the tractor usually must be justified by increased yield.

With regard to the number of days a tractor is used, the report gives figures which vary from 49 for the 2-plow machine to 70 for the 6-plow machine. Nearly 45 per cent of the tractor users report that they do custom work for others, which would seem to indicate that the tractor is too large to be kept busy on the home farm. The life of tractors, as estimated by their owners, varies from 6 seasons for the 2-plow machine to 10½ seasons for the 6-plow outfits.

Repairs Cost 4 Per Cent of Purchase Price

The longevity of the tractor brings up the question of repair expense, and in this connection the bulletin points out that though no accurate statistics are available on this, it would seem fair to count upon probably less than 4 per cent of the initial cost annually. This represents the average for farm machinery generally.

Under favorable conditions a 14-in. plow drawn by a tractor covers about 3 acres in an ordinary working day. Under unfavorable conditions, large gang plows will cover less ground per day per plow than will the small ones. Plows drawn by tractors do better work on the whole than do plows drawn by horses, the average depth in Illinois with tractors being 1½ in. greater than with horses. It is stated that the tractor displaces about one-fourth of the horses used on the average farm.

Power Required Depends upon the Soil

The resistance that soil offers to the passage of a plow bottom varies from 2 to 20 lbs. per square inch, depending upon the character of the soil.

This being so, a bottom which requires a pull of only about 400 lbs. at the draw bar to turn a furrow 14 in. wide and 6 in. deep, may require as great a pull as 850 lbs. in a soil of different constitution, or a maximum of nearly 1,700 lbs. in the most intractable soil.

Therefore the **power of the tractor** must be determined by the **character of the soil and the number of plows it pulls.** One should secure a soil map of his locality from his State Agricultural College and post himself on the relative condition of the soil in his neighborhood and the power required before purchasing a tractor.

What a Tractor Must Do

1. It must work efficiently after six years.
2. It must reduce horses to the minimum.
3. It must supplant horses.
4. It must cultivate row crops.
5. It must both plow and cultivate.
6. It must handle two plows under bad conditions and three under good conditions.
7. It must operate a 7- or 8-ft. binder at 2½ to 3 m.p.h.
8. It must have power to operate a road grader, a manure spreader, etc.
9. It must have belt power to operate any hay-baler or 24- to 28- in. threshing separator with a self-feeder and wind stacker; it must operate a corn sheller, a feed grinder, a sawmill, etc.
10. It must cost less than $1,000.
11. It must weigh less than 5,000 lbs., and be guaranteed one year.
12. All working parts must be in oil; it must be self-steering; it must have a direct drive for all speeds and a belt pulley, and speed enough for plowing and road work; with a low center of gravity.

Class of Work.	LIGHT WORK.	HEAVY WORK.
BELT WORK	Pumping, Washing, Cream Separating, etc.	Feed Grinding, Ensilage Cutting, Shelling, Shredding, Threshing, etc.
HAULING	Hauling People, Farm Produce, Merchandise, etc.	Hauling Grain, Building Material, etc.
FIELD WORK	Planting, Cultivating, Mowing, Raking, etc.	Plowing, Discing, Harrowing, Drilling, Harvesting, etc.

Tractor Designs

The following matter and illustrations, taken some time ago from *Motor Age*, will give a good general idea as to the variation in the design of tractors. See Fig. 1.

1. Four-wheel tractor design, with two large driving wheels in rear and two smaller steering wheels in front. The front wheels vary in diameter and also in tread. They are generally placed farther apart than shown.

2. Four-wheel tractor design, in which two front wheels are so close together as really to serve as a single wheel.

3. Three-wheel tractor design, with two large driving wheels and one steering wheel located at one side and in front. The diagram shows a two-cylinder engine.

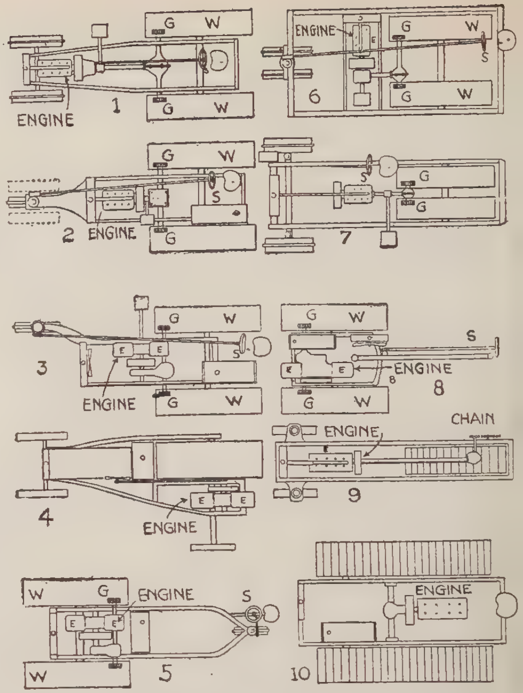

Fig. 1. Tractor designs: (E) is the engine; (G) gears driving internal gears in rim of tractor wheels; (W) tractor drive wheels; (S) steering.

4. Three-wheel tractor design, with a double steering wheel and one very large rear wheel for driving. There is a second rear wheel made quite small for balancing.

5. Three-wheel tractor design, using two large driving wheels and one very small wheel in the rear for steering.

6. Four-wheel tractor design, with large driving wheels in the rear and relatively small front wheels for steering. Note the cross-method of engine mounting.

7. Unusual tractor design, with two large steering wheels mounted very far apart and with two driving wheels placed very close together at the rear.

8. Two-wheel tractor design, to which can be coupled any piece of farm machinery. The entire power plant is mounted between the two driving wheels.

9. The combination wheel and caterpillar tractor, with a single caterpillar for driving in the rear and two steering wheels in front.

10. The short caterpillar using a caterpillar, or flat wheel construction, at each side. This design has been on the market for some time.

Tractor Drive Methods

For a tractor to travel over all kinds of roads, it is necessary that it lay its own track or road in many instances. Therefore some means of presenting a large surafce to the ground must be provided, on which the weight may be supported, to prevent sinking into soft soil. There are several methods employed, the most common being the **"flat-wheel tread,"** the **"chain tread,"** and the **"rail-track tread."**

The "flat-wheel tread" is the type used on the Ford and "Twin City" (page 984) and other light tractors. On some tractor wheels the **projecting treads are detachable** and can be removed, and deep or shallow treads may be applied according to the condition of the soil.

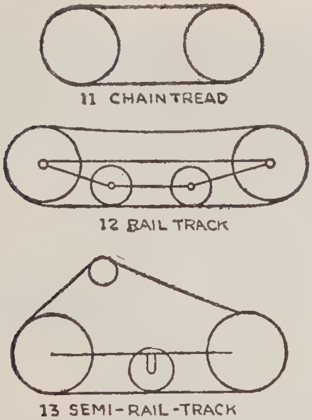

Fig. 2. Illustrations explaining the "chain tread," "rail-track tread" and "semi-rail-track tread."

The "chain tread" is furnished by stretching a movable chain of various constructions over and around two wheels, which has the effect of presenting considerable flat surface to the ground between the two points of support. The tread is made to move or crawl by driving the sprocket support wheels which have cogged teeth to engage cogged teeth on the inner face of the chain. See (11) Fig. 2.

This would be termed the chain tread, because the weight of the tractor is supported on the wheels with direct ground contact with the chain tread and minus the rail track.

The "rail-track tread" is represented by the Caterpillar and Cleveland. It differs widely in principle from that of the "flat wheel tread," and differs also from the chain tread in that a "rail track" is provided.

The point aimed at by the designers is to insure, not merely that the entire weight of the machine shall be evenly supported on the large surface of the chains, but that there shall be no arching of the chains, and that the wheels which do the driving shall carry little or no weight, while the wheels which carry the weight not only do no driving at all, but run on rails and are not affected by the pull of the chain. This result is secured in the following manner:

The weight of the tractor is supported on two axles or trucks, which carry, the one the driving or track sprocket wheel, and the other an idle wheel of similar size. The axles also support a beam or connecting bar beneath which are mounted a series of smaller idle or truck track wheels with smooth faces, formed to run on the rails or track.

The weight of the machine is carried on wheels which run on rails or track.

The chain itself, it will be noted (see Fig. 3), is driven by the track sprocket which is driven by the engine through a counter-shaft and gear transmission. As the chain tread (also called track link shoes) is made to revolve over the drive sprocket and track idler, the tractor, it will be noted, is really running on rails or a track, which are being laid down for the track wheels to revolve upon.

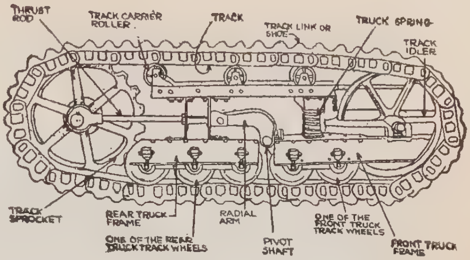

Fig. 3. **The track-laying portion of a Holt caterpillar.** The rear sprocket transmits the drive pulling on the portion of the chain which is lying flat on the ground. The weight of the tractor is carried by the 5-truck track wheels.

Although there are numerous methods of design employed for the construction of this chain or outer shoe, as it is termed, the principle is very much the same in all.

The difference, however, between the "chain tread" and the "rail-track" tread is made quite clear in the illustrations (11) and (12), Fig. 2.

Tractor Steering

When the three-wheel design is used, the third wheel is operated for steering.

Where four wheels are used, as on the Cleveland, for example, the steering-gear arrangement is as follows: a train of gears are operated by the steering wheel, and these in turn apply a brake to one side or the other of the axle. This slows up the crawler belt of one side of the machine, allowing the other to go ahead at a speed ratio corresponding to the resistance placed upon the opposite member by the brake pressure. When the brake is applied altogether, so that one belt or chain crawler is stopped, the reduction is 1½ to ½, or, in other words, 3 to 1, through the differential gears. The actual drive connection between the rear axle and the crawler wheel is by an internal gear. The emergency brake is applied against a band mounted on the outside of the differential drum.

The Transmission of Power

The transmission of power is usually from engine to clutch, thence to a gear transmission, thence to a countershaft, from which the drive sprocket is driven by a chain. On wheel-driven types there is often an internal gear drive in the wheel.

On several machines a regular truck gearset is employed with three ratios, this being coupled to a jackshaft incorporating a constant large reduction through a pair of spur gears. More than one machine is using a worm gear ahead of the last spur train, so that the worm speed is the same as that of the crank shaft on high gear. There are usually two or three speeds plus a reversing gear, which allows the different ratios to be used ahead or astern.

Clutches: Many are still using the old-style expanding or band clutch. The cone or disk clutch is coming into favor.

A clutch lever for throwing out the clutch is used more than a clutch pedal; however, many are now adding the clutch foot pedal.

A typical example of a "flat-wheel tread," light tractor transmission system is shown in Fig. 4, which is the "Twin City 16."

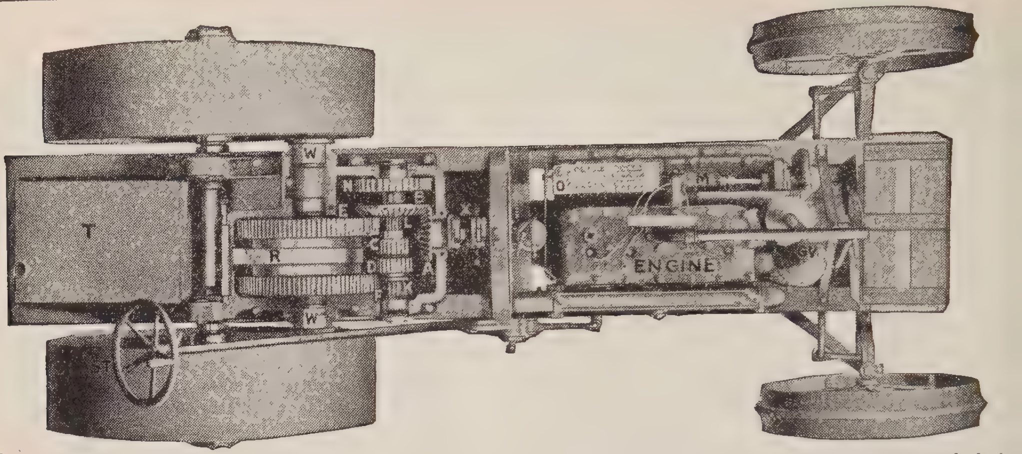

Fig. 4. **(R) is a band brake** around the drum which contains the **differential gears**. **Belt power** is obtained by a shaft (no shown) above and forward, driven from gear **(N)**.

The clutch is the contracting band type which fits over the projecting rim (C) on the flywheel (Fig. 9, page 986). It i operated from the seat by shifting the clutch yoke **(X)** above.

For high speed (2¾ m.p.h.), the power is transmitted through gear **(A)**, then through **(B)**, through sliding gear **(D)** to **(F** thence to the bull pinions on the end of shafts **(W)**, which drives the internal gear in the wheels.

For low speed (2 m.p.h.), sliding pinion **(C)** meshes with **(E)**.

For reverse (2¾ m.p.h.), power is delivered from **(D)** to **(F)** through a floating pinion mounted in the upper half of the trans mission (not shown). The floating pinion is also a sliding pinion, so that when in neutral position it is slid out of mesh wi gear **(F)**, but continues to run idle with pinion **(D)** when in neutral—the position in which **(D)** is now in the illustration.

The Cleveland Tractor

It weighs 2,750 lbs. and is characterized by its small size, being but 52″ long by 50″ wide. It is rated at 12 h.p. at the drawbar and at 20 h.p. at the pulley, and with its crawler or creeping type of tread, 600 sq. in. of traction surface are provided. The overall length of the tractor is 96″.

As may be seen from the illustration (Fig. 5), the powerplant is set well back toward the center of the crawler drive; thus the traction surface carries the weight well toward its center, so that a maximum tractive effort can be secured. The radiator, which is at the front of the tractor, is the only part projecting forward of the driving wheels, and at the rear the driver is seated slightly behind the rear axle.

The frame of the tractor is made up of two side bars mounted on trunnions at the rear axle, and the crank-case transmission and rear axle housings also have their value as structural supports. The effect of the three-point suspension is secured by having the rear connections of the side bars mounted on trunnions, and in front these are connected with the cross-spring by shackles. This gives a flexible drive which allows the tractor to work at an advantage on unequal stretches of ground.

The engine is a Buda model "R," 3½″ by 5¼″. The characteristics of this engine are such that with the gear ratio used on the tractor, an efficient working speed is obtained at 3½ m.p.h., with a maximum working speed of 4 m.p.h. The revolutions per minute of the engine are 1,450 at 4 m.p.h. and 1,272 at 3½ m.p.h.

From the engine the drive is transmitted through a Borg & Beck dry-plate clutch to a transmission unit developed by the Cleveland Tractor Co., provided with one speed forward and one reverse. The reduction is 25 to 1 in either case. From this unit the drive is transmitted through bevel gears to the axle, which transmits the torque to the crawler mechanism. The belt pulley is 8″ in diameter and has a 6″ face. The width of the track is 6″, and the length, 50″, giving 300 sq. in. of tractio surface on each side of the machine.

The carburetor is a Kingston, fitted with a Ben nett air washer, the magneto an Eisemann, an the radiator a built-up cellular type. The gasolin tank is mounted just behind the engine and forwar of the steering wheel, the latter being mounte upon a vertical steering post with the driver seate on a support mounted at the end of a flat stee bracket which acts as a spring.

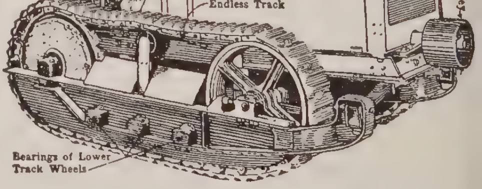

Fig. 5. **The Cleveland light tractor:** Drive, "rail-track also termed the "crawler" principle of drive. Note the pull in front for belt-power use; also note that the driving sprock is in the rear.

The Caterpillar Type of Tractor

Drive: Typical "rail-track." The drive sprock is driven by chains from a countershaft which driven by a gear transmission and clutch.

Engine: Six-cylinder; **vacuum fuel feed** (method employed. Gasoline or kerosene is use the fuel tank is **(T)**. A mechanical oiler **(O)** is use

Ignition by K. W. magneto **(J)**. A throttli type of governor for controlling the speed of t engine through the carburetor is employed. In fact, the principle of operation of the engine is similar to that of an automobile engine. Access to the crank case is through the hand-hole plates (L).

Steering by wheel **(S)** which operates wheel **(W)**.

Radiator is at **(R)**.

Spark and throttle control **(C)**

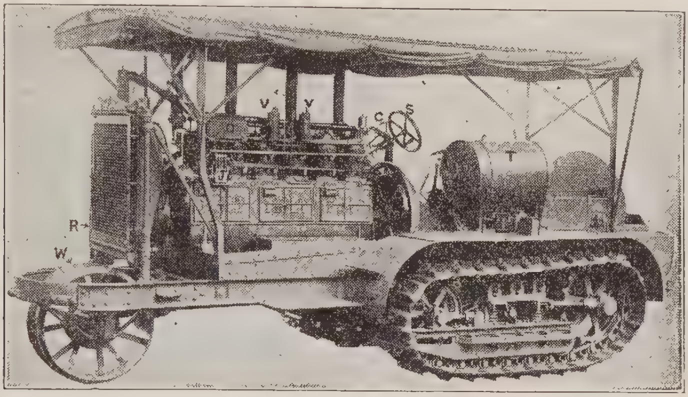

Fig. 6. The Caterpillar type of tractor. The drive is of the "rail-track" type.

TRACTOR ENGINES AND IGNITION

The type of engine used on tractors, as previously stated, differs from the regular automobile engine only in a few details. It is constructed heavier, with larger bearings. It runs at a constant speed most of the time; therefore greater heat is developed, and more cooling surface is necessary. A governor is employed. Engines for tractor use are usually of the four-cylinder or double-cylinder opposed type. The average compression of a truck or tractor engine is 60 to 70 lbs. It has usually a long stroke and slower speed, and operates either on gasoline or kerosene. Many of these engines have cylinders which are fitted with sleeves.

Tractor Engine Ignition

The **magneto** is generally used with an impulse starter. The **spark plugs** on a tractor engine must be the very best, as the tractor engine, unlike an automobile engine, runs for long periods of time at full power, and the use of low grades of fuel means higher temperature, and consequently more carbon.

K. W. Magneto

The K. W. magnetos are used on tractor engines quite extensively, and we shall therefore use this type as an example.

Model H (4 magnets): For engines having normal speed greater than 300 r.p.m., and which have provision for starting or can be cranked at a fair speed by hand.

Model HK (4 magnets): For use on engines the same as model "H," but has the impulse starter for hot starting spark.

Model HT (5 magnets): For use on engines having normal speed of less than 300 r.p.m., and which have provision for starting with air, etc., and will furnish a hot spark as low as 30 r.p.m., and will fire any sort of fuel.

Model HTK (5 magnets): For use on engines the same as model "HT," but the impulse starter allows the engine to be started by hand if the air supply is lost; or for use on large engines which previously had to be started with battery ignition.

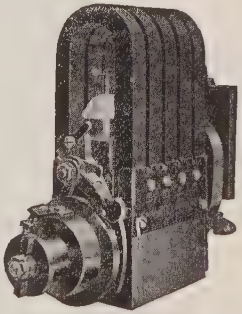

Fig. 7. The K. W. high-tension magneto, model "HTK" with impulse starter.

K. W. Impulse Starter

This attachment allows the engine to be started regardless of cranking speed, as the rotor of the magneto (inductor type) is held stationary while the coupling is moving 80°, then it is tripped and thrown ahead at the rate of 500 r.p.m., assuring a very hot spark for starting. When the engine comes up to speed, the starting device is automatically thrown out of action, and simply revolves with the shaft. See also page 281.

To time with an impulse starter: (1) place the piston 3° to 5° past top center on the power stroke; (2) mount and connect the magneto so that the tripping mechanism will not trip the impulse starting device until the engine is from 3° to 5° past dead center on the firing stroke.

In starting up the engine, place the circuit-breaker in full retard position and press down on the ratchet catch lock (ST-14) (Fig. 8) next page, which releases ratchet catch (ST-13) and allows it to engage with the notch in the ratchet (ST-6).

The ratchet (ST-6) will now be held stationary until the drive shaft has turned about 80°. This will bring the engine from 3° to 5° past the firing center, at which time the trip cam (ST-11) is in such a position as to disengage the ratchet catch

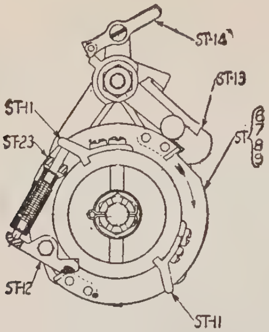

Fig. 8. **The K. W. impulse starter** is located between the magneto drive and the armature. When the engine is cranked, the armature is held stationary, while energy is being stored in the compression spring, which is then tripped.

(ST-13), thus allowing the magneto rotor to fly forward at a high rate of speed, creating a hot spark in the cylinder under compression, thus firing the engine, no matter how slowly the flywheel is turned over.

If these instructions are not clear, then put th ratchet catch (ST-13) out of engagement, and tim the magneto as usual. See Index under "Timin K. W. Magneto."

Example of a Tractor Engine

The engine illustrated in Figs. 9 and 10 is tha of the Twin City tractor engine, as used on the ligh duty tractor (Fig. 4)

Carburetion: Gasoline to start on and kerosen alcohol, distillates of 42° Baume or higher, and flas point of not over 120° F.

Fuel tanks: Kerosene, 33-gallon; gasoline, 3-ga lon. A Stewart vacuum system is used.

Cylinders: 4, L-type, 5″ bore x 7½″ stroke.

Speed of engine, 650 to 750 r.p.m.

Valves, on the side.

Ignition, K. W., magneto model "TK," enclos type.

See also page 938 for the Waukesha engine.

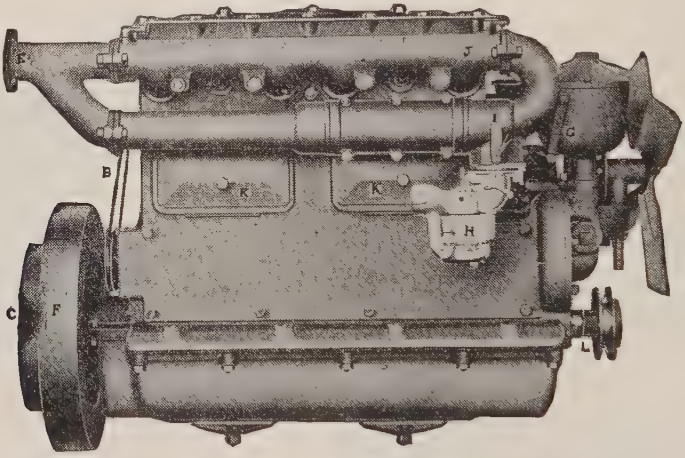

Fig. 9. **Valve, exhaust and inlet side:** (C) clutch member on flywheel (F); (K) valve covers; (H) carburetor; (I) inlet manif around one branch of exhaust manifold which heats mixture; (J-E) exhaust manifold; (G) governor—the lever operates butterfly valve in the carburetor; (L) fan belt pulley.

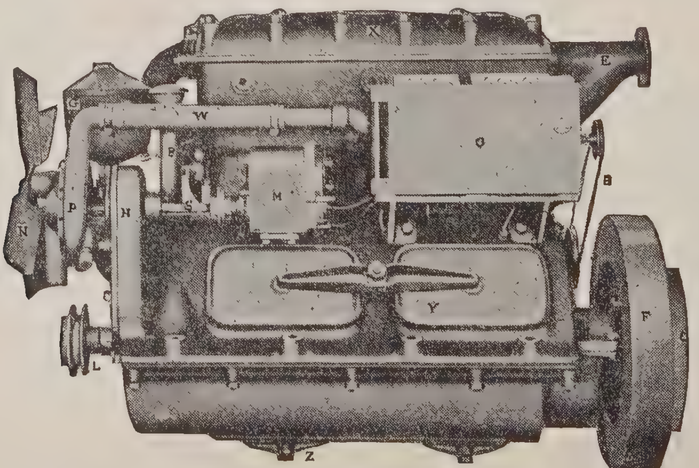

Fig. 10. **Magneto and lubricating side:** (M) magneto, K W. high-tension; (S) shaft driving magneto, which is driven by in gear case (H); (O) force feed lubricator driven by belt (B) (see page 157 for the "mechanical type") (P) water pu (R) breather pipe; (Y) hand-hole plates to reach bearings, and through which pistons and connecting rods can be remo (G) governor, "fly-ball" or "centrifugal" type.

CARBURETION FOR TRACTOR ENGINES

As previously stated, many tractor engines use gasoline to start on and kerosene to run on. Very few tractors operate on kerosene alone with any degree of satisfaction. It is practically impossible to start an electrically ignited engine with kerosene when the engine is cold. Kerosene does not give off vapor until heated nearly to the boiling point of water—it must be heated and kept heated, otherwise it will condense.

Kerosene needs more than a heated carburetor—the mixture itself must be heated to prevent condensation in the manifold.

The consequences attending the use of kerosene and the resulting condensation are described by a manufacturer as follows: "If kerosene is used, it will be absolutely necessary that the oil in the crank case of the engine be changed after every 20 hours of running." This is due to the fact that the kerosene condenses if not properly heated, and mixes with the lubricating oil and thins it down to such an extent that it loses its lubricating qualities.

Experiments conducted by the Holley Co. bear out the fact that once the kerosene has been thoroughly vaporized (heated) and mixed with a sufficient quantity of air to take the vapor by means of heat applied in the proper manner, it is possible to carry the charge several feet without experiencing condensation.

When the engine smokes excessively from the exhaust, and the smoke is black, this indicates that the fuel is not being properly combusted, either as a result of feeding too great a quantity at the carburetor or of not being properly vaporized.

Examples of gasoline-kerosene carburetors are given below.

Schebler Kerosene Carburetor—Single Type

Schebler model "D" (single) carburetor: The successful use of kerosene is not a problem of the carburetor alone, but involves both the carburetor and a proper design of the engine.

It is absolutely necessary, and must be understood, that kerosene can be burned only with the application of the proper amount of heat.

It is also advisable on some sizes of engines to heat the incoming air to the carburetor, and we find that it is rarely the case that too much heat can be applied to the air supply.

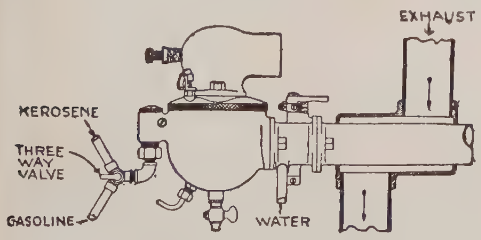

Fig. 11. The Schebler model "D" "single" carburetor, with special water throttle for use with kerosene on tractors and stationary engines.

The intake manifold must be kept as hot as possible, preferably by the exhaust heat, for if heat is not applied, there will be a precipitation on the walls of the manifold.

Heat on the manifold is necessary for two reasons: First, to aid evaporation of the heavier parts of the fuel; second to neutralize the refrigeration produced by the evaporation, so that the incoming charge of gas introduced into the engine is in an intimate mixture and at a uniform temperature.

Note. **Refrigeration** is caused by the fact that as the fuel is drawn through the inner pipe, heat is required to evaporate it; consequently heat is drawn from the pipe, leaving it cold. Evaporation then stops. For this reason extra heating is supplied.

Users of kerosene have always found it advisable to use water to prevent pounding under heavy loads. Moreover, water injection prevents excessive deposits of carbon. In this water or kerosene throttle attachment, there is a small hole in the carburetor side of the throttle, through which may be introduced a stream of water controlled by any suitable type of needle valve. While the engine is pulling a load, this needle valve, which controls the supply of water from any suitable source, should be opened only sufficiently to remove the pound. When the engine is stopped, the water must be shut off. The engine must be started and warmed up on gasoline, and can then be switched over to kerosene.

Kingston Dual Carburetor

The Kingston dual carburetor was designed for handling kerosene and some of the lower grade distillates.

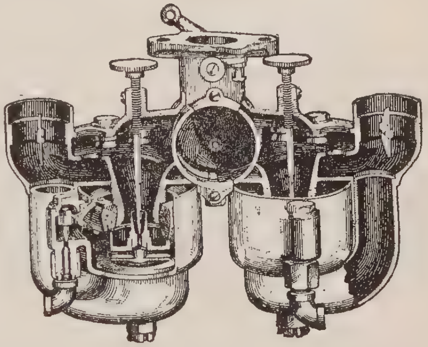

Fig. 12. Kingston dual carburetor for use with two kinds of fuel.

In construction, it is a dual combination of the well-known "Kingston enclosed-type model," one side being adapted for the use of **kerosene** or distillates, the other for **gasoline,** which may be used for starting or continuous running, as the operator may choose, either unit being brought into communication with the manifold and motor through the agency of an integral three-way valve. Both units are subject to individual adjustments, therefore may be operated on either fuel.

Switching from one fuel to the other is accomplished by means of a single lever, which may be connected to a point convenient to the operator.

Should water be required, the small valve shown in Fig. 13 may be used with good results, and is very simple, having but one adjustment which controls the amount of water admitted to the mixture.

It is entirely automatic, admitting water only when needed.

In operation, the engine is started on gasoline and is allowed to warm up sufficiently to permit of kerosene or distillate being used, at which time the fuel switch or three-way valve (31) (Fig. 13) is turned to its corresponding position. Should the engine fail to maintain its cycle (due to lack of sufficient heat having been generated), the switch should be immediately returned to the gasoline side and more time allowed for the warming period. With sufficient heating facilities this should not exceed three or four minutes.

The following installation is recommended:

Pre-heated air to the intake of each carburetor.

The kerosene side requires a much higher temperature than the gasoline side; therefore the collector around the exhaust manifold should be liberal. Care should be taken to provide openings totaling at least one and one-half times the area of the carburetor intake, and should be so located that the greatest amount of air shall pass over the heated surface of the exhaust manifold.

Exhaust jacketing the intake manifold throughout its entire length, if possible, or at least a generous portion leading from the carburetor, including the first bends.

Applying heat directly to the fuel line near the carburetor assists materially.

The temperature of the fuel in the bowl should not, however, exceed 100° F.

Action and Principle of Kingston Dual Carburetor

Fuel is admitted into the cup at fuel connection (**A**) and continues to flow until valve (**B**) is seated, owing to the buoyant action of float (**C**).

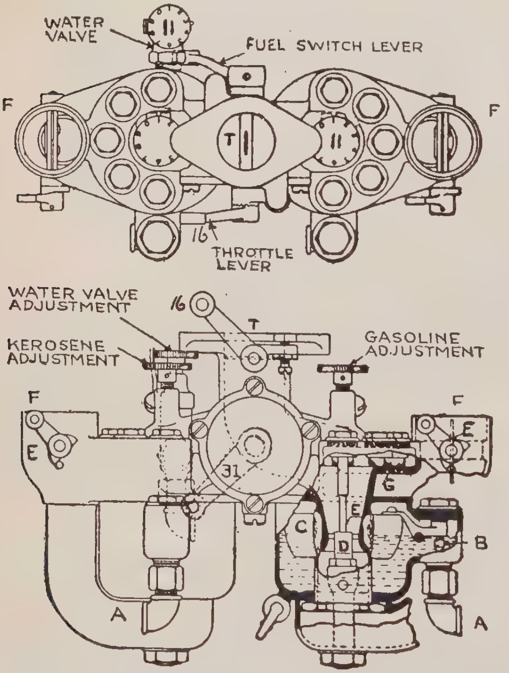

Fig. 13. Top and side sectional views of the Kingston dual carburetor.

Attention is particularly called to the shape of spray nozzle (**D**), which forms a cup around needle valve (**E**) above its seat, the fuel level being 1/16″ below its top.

For starting, this excess of fuel is drawn up with the constant air, and furnishes a very rich charge for starting.

At higher speeds this cup becomes empty; the supply is then drawn from and regulated by the adjustment of needle valve (**E**) at its seat.

Both **constant and auxiliary air** is drawn from a common source, passing by the controller, or (choke) throttle (**F**), located in the air opening, after which it divides, the constant air passing down through the constant air passage and up through the venturi tube, at which point it becomes thoroughly impregnated with the gasoline spray drawn from nozzle (**D**). It then continues upward, combining with the auxiliary air which has been admitted through the bronze ball ports (**G**), these balls lifting automatically in correct proportion as the engine speed varies.

These balls (auxiliary air controllers), after being drawn from their seats, as a result of the vacuum (or suction), remain floating in the air until the engine speed is reduced sufficiently to permit them to return again to their seats. The controller or (choke) throttle (**F**) is so placed that it is possible entirely (or nearly so) to cut off the source of air, thus producing a strong vacuum (or suction) at the venturi tube, and thereby obtaining a very rich mixture for starting purposes in low temperature.

The stop valve at each of the supply tanks should be shut off when the tractor is not being operated. The float valve in the carburetor might stick or fail to keep the supply of fuel to the bowl or float chamber cut off. This would mean that the carburetor would flood and the fuel would run out and be wasted.

For tractor use: Fuel must be connected to both bowls from both tanks when operating the tractor.

Air washer: The Kingston carburetor (Kokomo, Ind.) uses an air washer, called the Bennett, type manufactured by Wilcox-Bennett Co., Minneapolis, Minn.

The Fuel System as Used in the Fordson Tractor

Kerosene as a fuel is desirable on account of its low cost, as compared with gasoline. One of the main difficulties to overcome is the fact that kerosene is less volatile (is harder to evaporate) than gasoline, consequently it is found to be helpful to **preheat** the kerosene before it enters the cylinders. Another essential is the use of **clean air,** and the addition of **moisture** to the air materially aids the operation of the engine by preventing preignition.

Slight alterations in the engine design are necessary for the use of kerosene. This is the result of the experience of the Holley Co., which manufactures the kerosene vaporizer to be described. On the average engine, a compression of about 55 lbs. per square inch is best for kerosene.

Notable Features of Holley Vaporizer

The outstanding features of the Holley vaporizer are:

1. **The amount of heat** (used to preheat the kerosene vapor) **can be regulated.**
2. **The coils in which the kerosene vapor is heated are made of very thin-walled brass tubing, thus effecting quick results.**
3. **Only one float chamber is necessary.**

How the System Works

A diagram sketch of the entire fuel system is shown in Fig. 14.

Air washer (M): Air from the atmosphere enters at the bottom of the air washer (**M**) and passes into guide (**P**) which is closed at the top. Therefore it must come out at the bottom of the guide which is maintained below the water level by float (**J**). The air then bubbles through the water and is washed, and absorbs moisture.

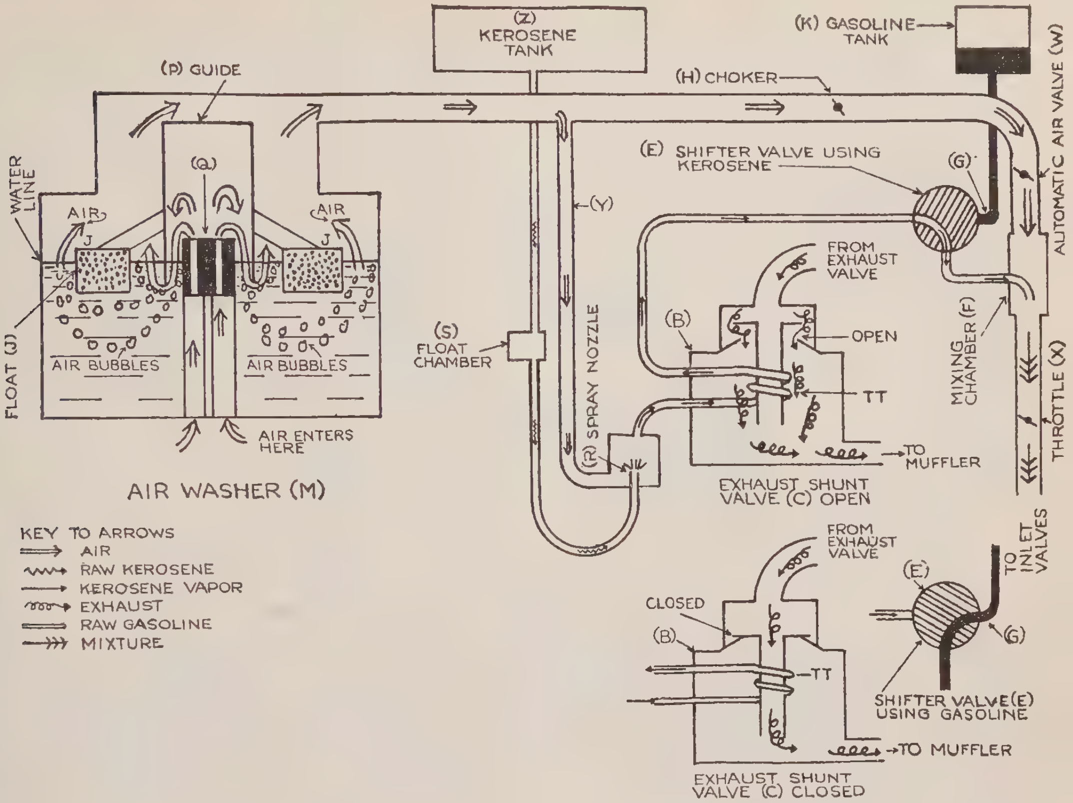

Fig. 14. The fuel system as used on the Fordson tractor.

The absorption of moisture causes the water level to go down, carrying the float and guide with it. When the tank is nearly empty, the top of the guide (P) closes down on surface (Q), thus shutting off the air. The engine stops and the driver knows that he must put more water in the washer.

The flow of air is caused by the suction stroke of the engine cylinder.

When starting the engine, turn shifter valve (E) to the position shown in lower sketch. This will permit the gasoline to flow through a spray nozzle (not shown), then into the mixing chamber (F), where it is mixed with air, the mixture passing through throttle (X) to the engine.

In cold weather, the choker (H) may be closed, thus causing a rich mixture.

After the engine is warmed up, turn the shifter valve to the position shown in main sketch (Fig. 14), thus permitting the kerosene system to operate. Raw kerosene from tank (Z) flows into the float chamber (S), where its speed is regulated, and then through spray nozzle (R), where it is mixed with about 10 per cent of the necessary air, the air coming down the primary tube (Y). The resulting kerosene vapor passes into coils (TT).

The shunt valve being open permits the hot exhaust gases to pass into the heating chamber (B), therefore directly over the coils (TT), thus preheating the kerosene vapor. The warm vapor then passes through the shifter valve (E) and into the mixing chamber (F), where it is mixed with the remaining quantity (about 90 per cent) of air necessary for combustion. The resulting mixture passes through throttle (X) and into the engine.

Exhaust shunt valve (C): During starting, when the engine is running on gasoline, the **exhaust gases must not pass directly over the coils** (TT). To avoid this, the exhaust shunt valve (C) is closed to position shown in the lower sketch. The exhaust gases cannot now enter the heating chamber (B), but will pass through the valve and thence to the muffler. The metal in the valve protects the coils from intense heat.

In very warm weather, it is sometimes advisable to close the exhaust shunt valve partly.

Automatic air valve (W) is for the purpose of regulating the quantity of air according to the speed of the motor. As the speed increases, the valve opens farther, allowing more air to flow to the mixing chamber (F). It is entirely automatic, and is not controlled by the operator.

The actual shape of the Holley kerosene vaporizer is shown in Fig. 15 (page 990).

The figure is lettered to correspond to the lettering of the diagram (Fig. 14).

The exhaust shunt valve is controlled by lever (D).

The heating chamber (B) has an extension (A).

The quantity of kerosene entering the spray nozzle (R) is controlled by the needle valve (N).

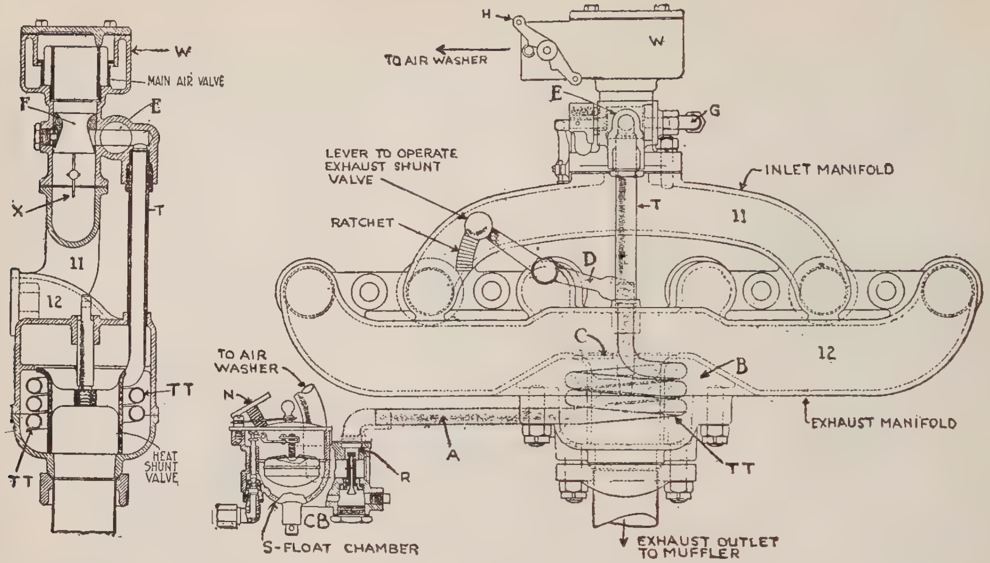

Fig. 15. Holley kerosene vaporizer.

FORDSON TRACTOR

A tractor is a "hard puller." It is designed for the purpose of pulling heavy loads at slow speeds over almost any kind of ground.

The Fordson tractor is manufactured by the Ford Motor Company, Detroit, Mich.

From an engineering standpoint, the Fordson tractor differs, and possesses characteristics which distinguish it from others.

Specifications

Price f.o.b. Detroit, $395.00.

Engine: Four-cylinder; cylinders cast en bloc; bore 4"; stroke 5"; extra large bearings throughout; all bearings burned in.

Lubrication: Splash system; oil circulation is maintained by oil thrown off the flywheel by centrifugal force; capacity of oiling system, 2¼ gals.

Cooling: Thermo-syphon system; radiator is of vertical-tube type, and is cooled by a fan.

Fuel: Engine is started with gasoline from a two-quart gasoline tank; once started, the engine is operated by kerosene from 21-gallon kerosene tank; fuel supplied by gravity feed.

Air washer: The air supply is drawn through water which removes all dust, thus reducing wear on the cylinder walls.

Transmission: Constant mesh selective type, three speeds forward and one reverse; all shafts run on ball bearings.

Clutch: Multiple disk, running in oil.

Front axle: Drop-forged and heat-treated; it is attached in the center directly to the front of the engine, giving three-point suspension to the tractor.

Steering is through a bevel-gear sector and pinion, with a ball-end drop arm connecting through a large rod to the front axle cross-arm; system is fore-and-aft type.

Wheels: Front wheels have steel spokes cast in the hub and riveted to the rim.

Rear axle: Semi-floating, four-pinion differential running on ball bearings.

Belt pulley: Special fibre paper construction, does not require refacing, and prevents slipping of drive belt (optional).

Performance: Size of thresher 20" x 36"; plows, 2–14"; average work, 6 acres in 10 hours.

Turning circle: 21-foot radius.

Data

Weights: Weight of tractor less driver, water, oil, and lugs, 2,425 lbs.; **total weight** of tractor, including all liquid supplies and 150 lb. driver, 2,920 lbs.; **distribution of weight,** front wheels 1,063 lbs., rear wheels 1,857 lbs.; weight of engine with vaporizer and coils, 661 lbs.

Dimensions: Wheel base, 63"; distance between front rims, 40⅛"; distance between rear rims, 37⅜"; width of front rim, 5"; diameter of front rim, 28"; width of rear rim, 12"; width of extension rim, 7" (for light soil); diameter of rear rim, 42" (3" cleats riveted on rim); **overall length** of tractor, 102"; **overall width** of tractor, 61⅜"; **overall height** of tractor, 54¾"; ground clearance, 11⅝", lowest point being the flywheel housing; height of draw bar from ground, 12"; lateral adjustment, 7"; vertical adjustment, none.

Engine: L-head type with detachable cylinder head; has 4 cylinders and 8 valves; firing order, 1, 2, 4, 3. Three main bearings, 2" diameter by 3" long; connecting-rod bearings 2" diameter by 2¼" long; pistons have 3 rings each; piston clearance, top .0150", bottom .0045"; piston displacement, 251.3 cu. in.; oil system capacity, 2¼ gals., using heavy gas-engine oil; temperature of oil when pulling steady maximum load, 150° to 200° F.

Cooling: Fan, 18" ball-bearing belt-driven; water capacity, 12 gal.; vertical tube radiator.

Ignition: Current supplied by flywheel magneto; there are 16 magnets clamped to the flywheel which rotate behind the stationary armature; **voltage of magneto** varies with speed of engine; a high-tension coil is used; the timer and distributor (commutator) are fastened on the end of the cam shaft.

Carburetion: See description of Holley vaporizer on page 988.

Air washer: Float type, 7-quart capacity.

Clutch has 17 hardened disks running in oil; spring pressure is 900 lbs. total, or 3.41 lbs. per sq. in.; lubricated by oil in the crank case.

Transmission gears: Speeds based on 1,000 r.p.m. of engine.

Gear	Final Ratio	Worm R.P.M.	Axle R.P.M.	Tractor Speed
Low..........	84.28	207.6	11.86	1.48 M.P.H.
Intermediate. .	45.77	382.3	21.85	2.73 M.P.H.
High..........	18.26	958.3	54.76	6.84 M.P.H.
Reverse.......	47.76	366.4	20.9	2.61 M.P.H.

Lubricant, heavy gear oil, capacity 3¾ gals.; oil temperature when pulling steady maximum load, 175° to 250° F.

Worm: Of undermounted type; it has two threads (see Index under "Worm gears"); it is made of chrome vanadium steel; the worm shaft is supported at the rear end by a duplex ball bearing which withstands both radial and end thrusts.

Worm gear (worm wheel): Made of aluminum bronze; it has 35 teeth.

Belt pulley: Width, 6½"; diameter, 9½"; spiral-bevel gear drive from transmission drive shaft; belt speed, 2,480 ft. per minute at 1,000 r.p.m. of engine (Ford data sheet gives the belt horsepower as 18).

Description of Fordson Tractor

As already stated, the purpose of a tractor is to pull heavy loads at slow speeds over almost any kind of ground.

Energy is put into the tractor in the form of kerosene. The vaporizer and mixing chamber change this kerosene into a combustible gas by mixing it with clean moist air from the air washer. The engine burns this gas and converts it into mechanical energy, causing a rotation of the crank shaft. This power is passed through the clutch and is delivered to the transmission, where the speed of rotation is changed or the direction reversed. The power is then delivered to the worm drive, which further reduces the speed of rotation, and, by means of the rear axle shafts, turns the rear wheels, thus causing the motion of the tractor.

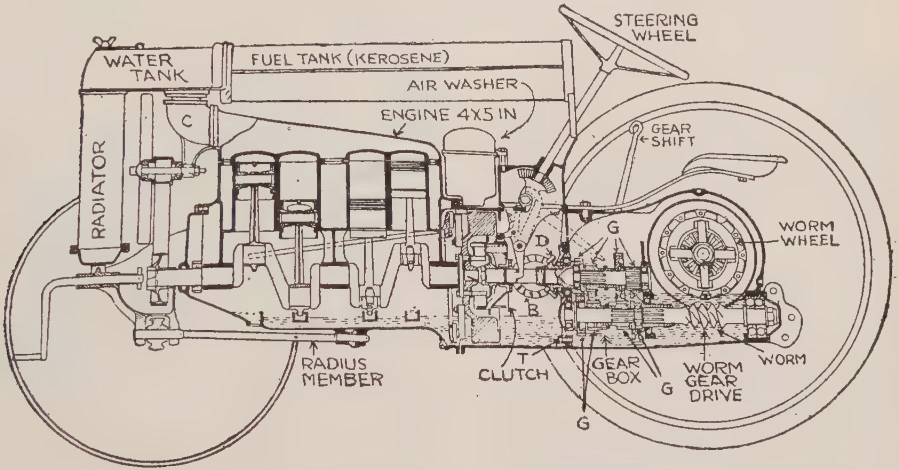

Fig. 16. Sectional view of Fordson tractor. The drawbar cap is shown in the extreme rear.

The crank case, gear box, and axle housing serve as the frame of the machine.

The engine is similar in design to that of the Ford model "T" (see Index under "Ford model T"), the main differences being as follows:

1. The bore and stroke of the engine are greater than in the model "T."
2. The water connections between the radiator and the water jacket are effected with iron connectors instead of with rubber hose, as in the model "T."
3. The fan is larger, runs on ball bearings, and is supported by a bracket from the upper water connector, instead of from the cylinder block, as in the model "T."
4. There is no removable plate in the bottom of the crank case to permit access to the connecting rods, it being necessary to remove the entire crank case for this purpose.

The ignition is similar to that of the Ford model "T" (see Index).

Carburetion is obtained by Holley vaporizer (see page 988).

Transmission is for the purpose of driving the tractor at various speeds according to the class of work to be done. This device also permits the tractor to be reversed. These speed variations are obtained by engaging different sets of gears (G) (Fig. 16).

Clutch: The clutch is inserted between the engine and transmission, and permits the engine to be completely disconnected from the transmission when it is disengaged. When engaged, it first slips a trifle, thus permitting the motion of the engine to be gradually imparted to the transmission and remaining portions of the machine, and consequently no jerk occurs.

The operation of the clutch is as follows (Fig. 16): The gradual "take up" of the load is effected by friction between several disks. The driving disks are fastened to the flywheel by six studs. The driven disks are keyed to the transmission through the clutch drum. When the clutch pedal is allowed to rise, the clutch springs are permitted to press on the clutch drum, thus pressing the disks together and therefore making a connection from the engine to the transmission drive shaft.

Rear axle: The rotation from the transmission is reduced in speed and imparted to the rear wheels by the rear axle. The principal parts are, the worm, the worm wheel (gear), the differential gears and pinions, and the rear axles as shown in Fig. 16. The worm is connected directly to the transmission, and, owing to the engagement of its threads with the teeth of the worm wheel, it causes the latter to rotate. The rotation of the worm wheel can be imparted to either of the rear wheels or to both, in any desired ratio, the parts effecting this result being the differential gears and pinions. Thus it is possible to turn the tractor.

Operating Instructions

Always hitch to the draw-bar cap (Fig. 19), **never to the rear axle housing.**

To operate the tractor, proceed as follows:

1. Fill the radiator with as clean water as it is convenient to get.
2. Lubricate thoroughly (see section on "lubrication" farther on).
3. Fill the air washer with clean, fresh water until it runs out of the filler hole.
4. Fill the fuel tanks with clean fuel that is free from water.
5. For operation of the vaporizer, see page 989.
6. See that the gear shifter is in neutral position (Fig. 17).
7. Lift the spark lever (on the dash) to the third or fourth notch from the bottom.
8. Open the throttle (under the steering wheel) one-third of the way toward the driver.

9. Crank the engine by **lifting upward.**
10. After the engine starts, advance the spark until the engine runs at the maximum speed without knocking.
11. Always release the clutch before attempting to shift the gears. Select the speed desired and shift to this speed immediately. The various gear-shift positions are shown in Fig. 17.

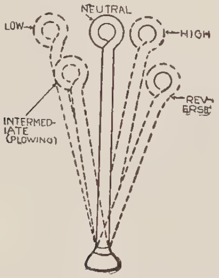

Fig. 17. Gear-shift positions of Fordson Tractor.

12. The speed of the engine is controlled by the throttle. The engine should never be run at speeds greater than 1,000 r.p.m. This speed can be judged by watching the rear wheels.

In **low gear** the rear wheels turn 12 times per minute.

In **intermediate gear** they turn 22 times per minute.

In **high gear** they turn 54 times per minute.

In **reverse** they turn 21 times per minute.

13. To stop the tractor, partly close the throttle; push down on the clutch pedal, shift gears to neutral, release the clutch pedal, turn off the fuel at the sediment bulb, and the engine will stop. In cold weather, it is sometimes a good idea to turn the shifter valve to gasoline; then pull out the choker, and the engine will stop, the cylinders being filled with a rich gasoline mixture, thus facilitating the next start.
14. The radiator can be filled with cold water when the engine is hot, providing the top tank (Fig. 16) is not empty. To prevent freezing of water in cold weather, the following solutions of wood or denatured alcohol should be used:

20 per cent solution freezes at 15° above zero
30 per cent solution freezes at 8° below zero
50 per cent solution freezes at 34° below zero

The fins of the radiator and the outside of the tubes should be kept reasonably clean.

15. The air washer should be flushed out daily through the drain cock on the side.
16. If it is desired **to run the tractor on gasoline** instead of kerosene, **the gasoline should be put into the main fuel tank,** and the exhaust shunt valve (**C**) (Fig. 15, page 990) should be kept at the "off" position.

Lubrication

The engine: The engine is lubricated by the splash system. Heavy, high-grade motor oil should be poured through the strainer in the breather pipe at the left side of the engine until the level in the crank case reaches the upper pet cock at the side of the crank case. When the tractor is being run continuously, the oil should be drained through the drain plug underneath the crank case every week. Flush the case with a quart of kerosene; then refill with motor oil to the level of the upper pet cock. Under no circumstances should the oil be permitted to reach a level below the lower pet cock. Tests should be made with the tractor on level ground.

The transmission and rear axle are both lubricated from the same case. Heat heavy fluid gear oil to about 100° F. With the tractor on level ground, pour this warm oil through the filler hole in the gear-shifter cover until it reaches the level of the filler hole. Plenty of time should be allowed to permit the oil to reach the worm-gear drive. The system holds 3¾ gals.

When the tractor is operated continuously, the oil should be drained every two weeks. This is done through the drain plug underneath the housing. Flush out with a quart of kerosene, and refill.

The commutator (timer): Put a little oil into the commutator twice daily.

The rear-axle roller bearings should be oiled through the plugs with heavy fluid gear-oil weekly. The felt washer at the end of the axle shaft should be replaced when dirty. Remove the rear wheels (the method is explained under "Repairs") below; then pry off the steel cover with a screwdriver, after which the felt can be taken off.

The steering joints and front-axle trunnion should be oiled daily with heavy motor oil.

The grease cups on the steering spindles should be given a few turns daily.

The fan should be oiled weekly with heavy fluid gear-oil.

REPAIRS ON THE FORDSON TRACTOR

Tools for disassembling and assembling various parts of the tractor are essential. The socket type shown in Fig. 18 is an efficient set designed for use on the Fordson tractor.

The Engine

Engine: To **remove the cylinder head,** (1) drain the radiator through the pet cock; (2) shut off the fuel at the sediment bulb and remove the fuel tank; (3) disconnect the wires from the engine and take off the coil box (the timer wires should not be disconnected from the commutator case, but the case should be removed with them); (4) disconnect the cylinder-head from the radiator connector (**C**) (Fig. 16); (5) remove the cylinder-head cap screws, after which the cylinder-head can be lifted off; be careful not to damage the cylinder-head gasket; (6) when **replacing the cylinder head,** clean the surfaces well, turn the engine till Nos. 1 and 4 pistons are at top of stroke, replace the gasket, and pull down the cap screws **tightly.** When the gasket becomes hard, it should be replaced with a new one.

To remove the crankcase: (1) drain the oil from the engine; (2) remove the radius member (Fig. 19); (3) remove the crank-case bolts, and take down the crank case, being careful not to let it fall.

To remove connecting rods and pistons: (1) remove the cylinder head and crank case (see above); (2) disconnect the connecting-rod bearing caps, being careful to note their position (light file marks on the connecting rod and bearing caps will help you); (3) remove the piston with the connecting rod through the top of the cylinder.

To fit new piston rings (see Index under "Fitting piston rings").

Valve timing: Valves have a 5/16″ lift.

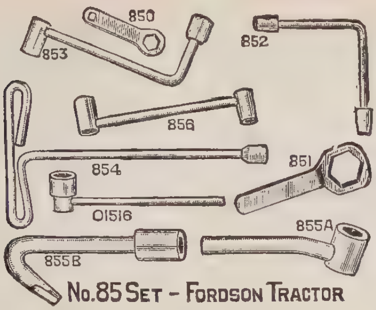

Fig. 18. **Walden No. 85 Fordson tractor socket-wrench set:** (850) wrench for adjusting fan nut and screw; (851) for clutch-shaft nut; (852) for clutch-housing bolt; (853) for crank-shaft cap and main bearing nuts; (854) for gear-shifter plate cap screw; (855**A**) for front-wheel spindle nut; (855**B**) for differential housing; (856) for crank-case bolt and nut.

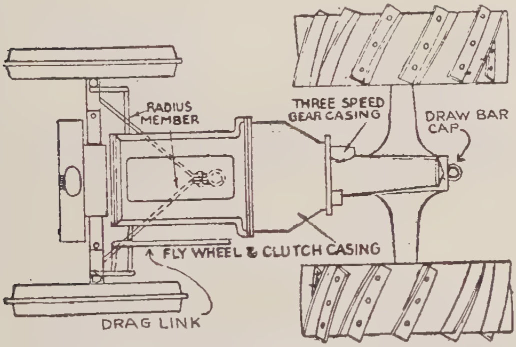

Fig. 19. Top view of Fordson tractor.

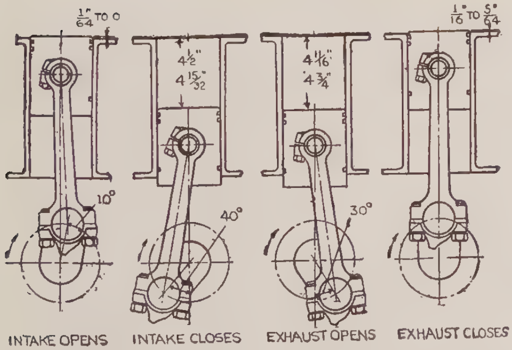

Fig. 20. **Valve-timing diagram,** showing the position of the piston and the crank shaft at the opening and closing of the valves. As in timing the model "T," it is recommended that the valves be timed by the piston travel.

The inlet opens 10° past upper dead center, with the piston 1/64″ above the top of the cylinder; the **inlet closes** 40° past lower dead center, with the piston 4½″ to 4 15/32″ below the top of the cylinder. **The exhaust opens** 30° ahead of lower dead center, with the piston 4 11/16″ to 4¾″ below the top of the cylinder; **the exhaust closes** on upper dead center, with the piston 1/16″ to 5/64″ above the top of the cylinder. **The tappet clearance** is .007″ to .022″.

Grinding valves (see Index under "Grinding valves").

Worn valves or push rods should be replaced with new ones.

Removing carbon (see page 763, under "Removing carbon").

To tighten connecting-rod bearings by removing shims (see page 799).

To tighten the main crank shaft bearings by removing shims (see page 783).

To Remove the Engine from the Transmission

1. Drain the crank case of oil.
2. Drain the water from the radiator and jackets.
3. Shut off the fuel at the sediment bulb, and remove the fuel tank.
4. Remove the air washer and gasoline tank.
5. Disconnect the steering arm from the drag link (Fig. 19).
6. Disconnect the control rods from the vaporizer and commutator.
7. Remove the dash; there are four cap screws holding it to the transmission housing.

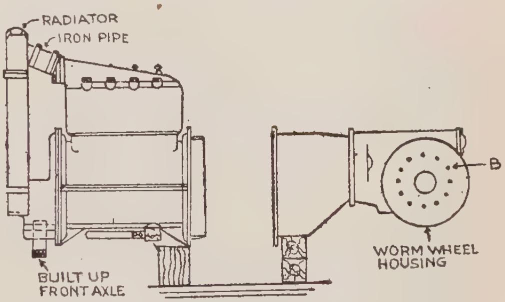

Fig. 21. Showing the method of **removing the engine from the transmission** housing.

8. Block up the transmission housing and the engine, as shown in Fig. 21.

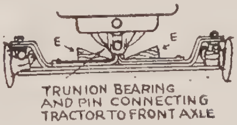

Fig. 22

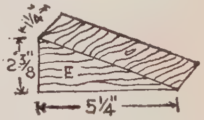

Fig. 23

Figs. 22, 23. Method of **blocking up the engine** before removing it from the transmission housing.

9. Avoid rocking of the engine by placing wedges (Fig. 23) between the front axle and the cylinder front cover, as shown in Fig. 22.
10. Remove the bolts holding the engine to the transmission housing.
11. Pull apart, as shown in Fig. 21.

Gaskets: Where paper gaskets are used, it is best to make new ones before replacing the parts.

Radiator

A small leak may be temporarily repaired with white lead or brown soap, but should be soldered as soon as possible.

To remove: (1) drain off the water; (2) remove the cap screws which hold the radiator to the front cylinder cover; they are underneath the bottom tank; (3) disconnect the fuel-tank strap from the radiator cover; (4) disconnect the radiator from the top tank by removing the four cap screws under the top tank; (5) lift off the radiator.

Fan Belt

To tighten: (1) remove the cotter pin from the nut at the rear of the fan shaft; (2) loosen the nut); (3) the belt can then be tightened by turning the square end of the shaft with a wrench; (4) holding the shaft in this position, tighten the nut with another wrench; (5) replace the cotter pin.

Fuel System

The vaporizer has but one adjustment; that is the needle valve (N) (Fig. 15, page 990). **When the tractor is running, make adjustment as follows:**

1. Retard the spark lever to the fourth notch.
2. Screw up the needle valve (N) until the engine begins to misfire.
3. Gradually unscrew the needle valve until the engine attains maximum speed and no smoke comes from the exhaust.

Dirt in the shifter valve can be removed as follows: (1) remove the shifter-valve cover; (2) set the valve in gasoline position; (3) insert fine wire into the passage.

Dirt in the kerosene spraying nozzle is removed as follows: (1) remove the plug which screws into the float chamber just under nozzle; (2) clean and replace.

Throttle adjustment is obtained by adjusting the screw (see Index).

Ignition System

Repairs on the ignition system are made in a manner similar to those on the Ford model "T" (see Index).

When replacing the coil units on the Ford tractor, use regular tractor coils which are marked on the front of the unit: "Tractor Unit." These coils are equipped with special vibrator points designed for high-speed, heavy duty work. The coils are also fitted with a special composition to withstand the high temperature developed by continuous service. Do not use model "T" coil units on the Tractor.

Clutch

No adjustment is necessary. **If the clutch slips,** the springs (1) (Fig. 24), or the plates (2) and (3) (Fig. 24) should be replaced. **If the clutch fails to release,** the plates are probably bent and should be renewed.

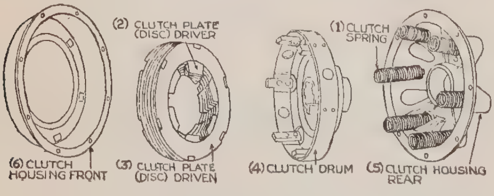

Fig. 24. Clutch assembly of Fordson tractor.

To remove and disassemble clutch: (1) remove the engine from the transmission housing, as described above; (2) remove nut (7) (Fig. 25); (3) pull the clutch from the transmission drive shaft; (4) provide a means of gradually releasing the clutch spring tension, such as a bolt and nut (Fig. 26), or (C) clamps (Fig. 27); (5) disconnect the front from the rear clutch housing by removing the eight bolts which pass through holes (8) (Fig. 26); (6) gradually release the clutch-spring tension by the means provided; (7) remove the housing, as shown in (Fig. 28).

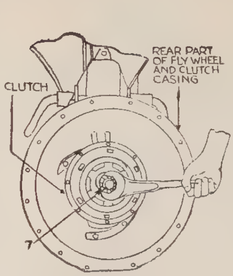

Fig. 25

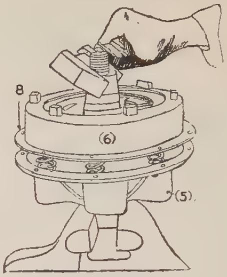

Fig. 26

Fig. 25. Method of removing clutch nut.

Fig. 26. Method of gradually releasing clutch-spring tension.

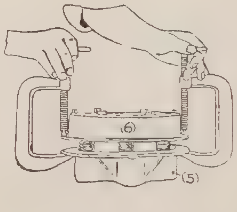

Fig. 27

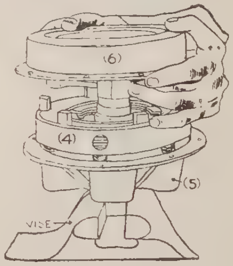

Fig. 28

Fig. 27. Another method of releasing clutch-spring tension.

Fig. 28. Method of removing clutch housing.

Transmission

To remove the transmission gears: (1) remove the engine from the transmission housing, as described above; (2) drain the transmission housing through the plug under the gear-shifter cover; (3) remove the gear-shifter cover from the transmission housing by unscrewing the four cap screws which hold it; (4) remove the clutch, as described above; (5) remove the eight cap screws (T) (Fig. 16); (6) pull on the drive shaft of the transmission, thus removing the transmission plate and the lower transmission shaft in one unit; (7) remove the upper transmission shaft with the gears; (8) when replacing the ball bearings, the stampings on the outer rings must face the ends of the shaft.

Rear Wheels

To remove the rear wheels do the following: On the rear wheel hubs, there are four bolts passing through the wheel bushings. Between each pair of bolts is a **tapped hole.**

1. Jack up the rear wheel.
2. Unscrew the four hub bolts.
3. Screw two of them into the **tapped holes** mentioned.
4. Screw up equally, thus drawing out the bushing until the wheel is free.
5. Pry the bushing off the axle with the hooked end of bar No. 855-B (Fig. 18).
6. When replacing, the four bolts are screwed into their correct positions by drawing them up equally until the wheel is flush with the end of the axle.

Rear Axle

To remove the rear axle: (1) drain the transmission housing through the plug under the gear-shifter cover; (2) remove the rear wheels as described above; (3) remove the twelve cap screws (**B**) (Fig. 21) from each rear axle housing; (4) draw off the axle housings; (5) remove the rear axles and the worm wheel with the differential as one complete unit; (6) take out the bolts which pass through holes (**A**) (Fig. 29); (7) pull the housings apart, thus exposing the parts as shown in Fig. 29.

To remove the differential gear (**B**) (Fig. 29): (1) press the gear toward the wheel end of the shaft until locking ring (**C**) is exposed; (2) remove ring (**C**); (3) press the gear off the differential end of the shaft.

Front Wheels

To remove the front wheels: (1) remove the hub cap; (2) jack up the front axle; (3) remove the cotter pin and nut from the wheel spindle; (4) pull off the wheel; (5) when replacing the wheels, see that the stampings on the outer rings of the roller bearings face each other.

Roller bearings of front wheels: The cups should be a good press fit into the hubs. The cones should be an easy free fit on the spindles, so that they may turn on them. **To adjust the bearings,** draw up the wheel nut until the wheel binds. Then back off one-third or two-thirds of a turn, so that the wheel turns freely but has no end play.

Front Axle

To remove the front axle: (1) jack up the front of the tractor; (2) remove the front wheels as described above; (3) remove the drag link (Fig. 19) from the steering arm; (4) remove the radius member (Fig. 19) from the crank case; (5) remove the front axle trunnion pin (Fig. 22) and the front axle.

To straighten the front axle, do not heat, but straighten cold.

Steering Gear

To tighten the steering gear: (1) remove the sockets from the ball joints at the end of the drag link (Fig. 19); (2) file off these sockets; (3) replace; if the spindle pins are loose, the bushings should be renewed.

Belt Pulley

To install the pulley attachment: (1) block the tractor; (2) jack up the tractor under the right side of the draw-bar cap (Fig. 19); (3) remove the right rear wheel, as described above; (4) remove the foot bracket and see that the tractor is equipped with the transmission drive-shaft spiral bevel gear (**D**) (Fig. 16); (5) place paper gaskets on the pulley housing; (6) insert the pulley attachment in such a manner that the hole in the housing points down, so that the oil drains back into the transmission; (7) tighten up the six cap screws; (8) test the pulley with the hands for slight backlash (play); (9) if there is none, more paper gaskets must be inserted; (10) if there is too much, remove some of the gaskets. Gear (**B**) (Fig. 30) (below) is meshed with gear (**D**) (Fig. 16, page 991). Thus with gear shift in neutral, belt pulley can revolve without driving tractor.

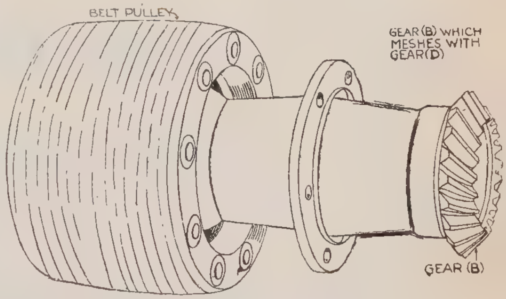

Fig. 30. Belt pulley for Fordson tractor.

Engine Troubles and Causes: Fordson Tractor

Engine fails to start:

1. Gas mixture too lean, or poor grade of gasoline.
2. Water in fuel.
3. Vibrators adjusted too closely.
4. Water or congealed oil in commutator.
5. Magneto contact point obstructed with foreign matter.
6. Gasoline supply shut off.
7. Lack of water in air washer.
8. Water frozen in bottom of gasoline tank.
9. Water on spark plugs or wire terminals.

Engine lacks power:

1. Poor compression on account of leaky valves.
2. Imperfect gas mixture.
3. Spark plugs dirty.
4. Coil vibrator burned or improperly adjusted.
5. Air leak in intake manifold.
6. Weak exhaust valve spring.
7. Too great clearance between valve stem and push rod.
8. Spark plugs dirty or points imperfectly adjusted.
9. Commutator contact imperfect.
10. Burnt out vapor tube or coils (TT Fig. 14, page 989).

Engine overheats:

1. Lack of water.
2. Lack of oil.
3. Fan belt torn, loose, or slipping.
4. Carbon deposit in combustion chamber.
5. Spark retarded too far.
6. Gas mixture too rich or too lean.
7. Water circulation retarded by sediment in radiator.
8. Dirty spark plugs.
9. Lack of water in air washer.

Engine knocks:

1. Carbon deposit on piston heads.
2. Loose connecting-rod bearings.
3. Loose crank-shaft bearings.
4. Loose piston or piston pins.
5. Spark advanced too far.
6. Motor overheated.
7. Gas mixture too rich or too lean.

INSTRUCTION No. 78

MISCELLANEOUS ENGINES: Farm Lighting Plants; Two-Cycle Engines; Diesel Engines; Gas Producers

THE DELCO-LIGHT PLANT

This outfit consists of a gasoline engine of the four-cycle type, together with an electric generator of 32 volts, which is direct driven, as shown below (Fig. 1). A set of batteries (32 volts) is provided. The generator charges the battery in a similar manner to that in which the battery is charged on an automobile. An automatic cut-out is used which disconnects the battery from the generator.

The gasoline engine runs the generator or dynamo which charges the batteries; thus the electric supply for lights, power, etc., is taken from the battery when the engine is not running. The manufacturer is the Delco-Light Co., Dayton, Ohio.

Specifications of the Delco-Light Plant as Shown in Fig. 1

Engine: Air-cooled, single cylinder; Delco-Light battery ignition; simple mixing valve; operates on kerosene, gasoline, or natural gas; self-cranking; stops automatically when battery is charged; splash system of lubrication—one place to oil; height 30″; length, 25″; width, 20″; bore 2½″, and 5″ stroke.

Generator: Direct connected to engine; for 32-volt service; full-load output, 850 watts.

Switchboard: Mounted on generator frame.

Battery (not shown); 160 ampere-hour capacity.

850-watt generating unit only; shipping weight, one crate 425 lbs.

No. 866: 850-watt plant with 160 A.H. battery (glass jar); shipping weight, five crates, 1,273 lbs.

Uses: General farm, school, store, church, and country-home service, with sufficient power to operate motors up to ¾ h.p., when engine is running.

THE TWO-CYCLE ENGINE

The two-cycle type of engine is especially adapted for small-powered launches, where light weight and medium power are the main requisites.

The two-cycle engine is divided into three types: the "two-port," which is adapted for slow speed; the "three-port" high-speed; and the combined "two and three-port," suitable for power work.

The **fuels** generally used are gasoline and kerosene, and on heavy-duty commercial boats a still lower grade of oil is used. On larger heavy-duty engines of this type, the four-cycle principle is generally employed.

The Two-Port Two-Cycle Engine

The action of the two-port two-cycle engine is explained in the illustrations (Figs. 2 and 3).

Fig. 2. **Two-port two-cycle engine.** The **piston** is now at the **bottom** of its stroke. Notice that two actions are taking place: (1) gas is entering the cylinder from the crank case through the "by-pass" port; (2) the combusted gas is passing out of the exhaust port. Thus we have intake and exhaust occurring simultaneously.

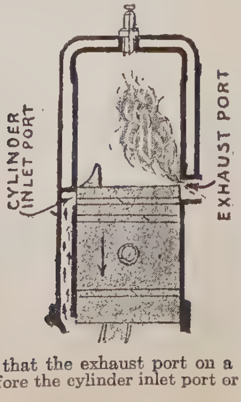

Fig. 3. Note that the exhaust port on a two-cycle engine opens slightly before the cylinder inlet port or "by-pass" opens.

The two-cycle or "valveless" type of engin derives its name from the fact that the gas is le into and out of the cylinder through "port-holes' as they are uncovered by the piston. These port

AIR
MIXING VALVE
CRANK SHAFT

Fig. 5. When a mixing valve is used, the check valve is part of the mixing valve.

When a **carburetor** is **used** with a "two port" type of engine a check valve must be used, as shown in Figs. 2 and 4 A carburetor can be used, however, with a three-port typ without a check valve, as the port is opened and closed b the piston; in fact, this is where the **three-port type** engin differs from the two-port type.

take the place of valves as used on a four-cycle engine.

During **two** movements or strokes of the piston, the four operations of intake, exhaust, compression, and explosion occur during **one** revolution.

On a four-cycle type of engine this would require **four** strokes of the piston or **two** revolutions.

The terms two-cycle and four-cycle are not appropriate. Originally the terms were "two-stroke-cycle" and "four-stroke-cycle," and these were more nearly correct.

Therefore with **two** movements of the piston, one up and one down, or **one** revolution of the crank shaft, four actions take place: (1) intake of gas into the cylinder; (2) exhaust; (3) compression and intake to the crank case; (4) explosion.

When the piston travels **up**, a vacuum is formed in the crank case which causes the gas to be sucked in through the crank-case inlet port or check valve.

When the piston travels **down**, a pressure is formed in the crank case (5 to 9 lbs.), which forces the gas in the crank case through the "by-pass" into the cylinder. A "baffle plate" (D) (Fig. 2) prevents fresh gas from heading toward the exhaust.

Note that when the piston is **down**, the pressure in the crank case forces the check valve of the carburetor to close (Fig. 2). When the piston is going **up**, the vacuum formed in the crank case sucks the check valve open (Fig. 4).

The crank case forms an intermediate reservoir for the gaseous mixture.

MARINE ENGINES

Marine engines are built along the same lines as the automobile engine when of the four-cycle type, but with the addition of a governor on large engines.

The smaller types of marine or motor-boat gasoline engines are frequently of the two-cycle type.

The marine engine is built heavier than the automobile engine because it is run most at full speed or power for long periods of time. However, the modern marine engine is capable of varying speed through the use of the throttle and spark, as in the case of the automobile engine.

The **ignition** for marine engines is similar to the automobile engine, but in many instances the "make-and-break" system, and oscillating type, as well as the K. W. is used.

On the small two-cycle type, the jump spark with vibrator coil and battery is used to a great extent and also the make-and-break system. In fact, the make-and-break system is used quite extensively on the large four-cycle type of marine engine because it is a low-speed engine and of the low-tension type of ignition, and is not affected by dampness, which is the case where high-tension current is employed. If high tension is used, then it must be well insulated, because of dampness.

The **carburetion** is similar, but on some of the larger and heavy-duty types of marine engines a double carburetor, using gasoline to start on and kerosene to run on, is quite often used.

The **clutch** is used between the engine and reverse gear, and employs practically the same principle as is found in an automobile clutch.

A **gearbox** is sometimes employed which gives one speed ahead with a lower ratio than the direct drive. The reverse gear is also employed. Sometimes, however, the propeller itself is made so that the blades will shift at various angles or pitch, (which reverses the direction of propulsion) in place of a speed gear and reverse.

Books on marine engines and motor boats:[1] We recommend the 4 volumes of the *Motor-Boat Handbook* to those interested in marine engines (price $3.00).

STATIONARY GASOLINE ENGINE

This type of internal combustion engine is usually of the four-cycle type. The cylinders are large in diameter, and the stroke is usually larger than the bore. The speed is slow (160 to 600 r.p.m.), but constant.

Fig. 6. **A horizontal engine** (Witte), with a rocker arm for operating the exhaust valve mechanically. The inlet valve is automatic, but note that when the exhaust valve is opened, the bar (1B) closes the inlet tight, although a spring is also provided.

A **governor** is used to keep the speed at a certain number of revolutions, and it is due to the governor action on a stationary engine that you will hear exhausts at uneven intervals.

Governors are divided into two general types: the "hit-and-miss" type, and the "throttling" type.

The "hit-and-miss" principle is generally used with engines using gasoline as fuel, and the "throttling" type, with engines using kerosene or lower grades of fuel.

The reason why the "throttling type" of governor is used with kerosene engines is the fact that kerosene, when used as a fuel, enters the combustion chamber almost in the form of a liquid, while gasoline enters more in the form of gas. The combustion chamber on a kerosene engine, accordingly, must be maintained at a fairly high temperature in order properly to vaporize the fuel, and this temperature should also be fairly uniform.

It is the writer's opinion that the reason trouble is experienced from carbon formation, where it is attempted to burn kerosene in a "hit-and-miss" governor engine, is that the combustion chamber on such engines cools off quite frequently during the time that explosions are cut out. This trouble can, of course, be avoided by using a pre-heater in the fuel line on such engines but this is a makeshift arrangement and not generally satisfactory. The "throttling type" of governor is best, as it comes nearer maintaining a uniform temperature.

On some of the engines using a low-grade fuel, no ignition device is used, as, for instance, the Diesel engine. On others, a hot tube is preheated and serves for ignition. The latter requires complete vaporization of the fuel (all of which is covered in Dyke's *Motor Manual*).

The fuel may be either gasoline, naphtha, kerosene, or any one of the many other petroleum products of low grade, when properly heated. Natural and artificial gas are also used.

Ignition is usually jump spark on small engines, and wipe spark, as described on page 187, which is similar to the "make-and-break," on the larger engines.

---

[1] Can be secured of A. L. Dyke, Granite Bldg., St. Louis, Mo.

The "hit-and-miss" governor action is shown in Fig. 7.

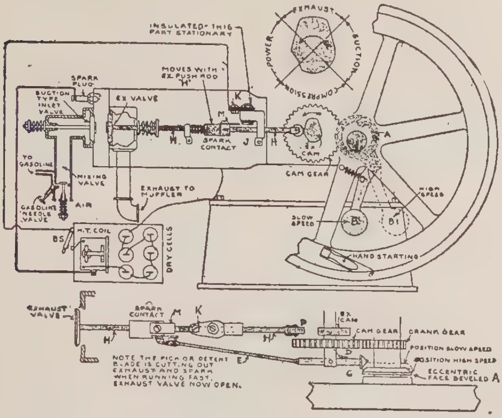

Fig. 7. Illustrating the operation of the "hit-and-miss" governor.

When **the speed of the engine increases** more than that for which the governor is set, the ball (**B**), by centrifugal action, assumes position (**B1**). This causes eccentric sleeve (**A**) to allow pick-blade (**E**) to catch in the notch part of (**M**). This holds open the exhaust valve and also prevents the spark contact (**M**) from coming in contact with (**K**), cutting off the ignition.

When **the speed decreases,** the ball (**B**) assumes a slow-speed position, which causes eccentric (**A**) to move out from the hub of the flywheel and to disconnect the "pick-blade" or "detent-rod" from the notch in (**M**); the engine fires again, and the exhaust valve assumes its regular work until the speed increases again, at which time the same action is repeated. This cutting in and out by the governor accounts for the uneven impulses one notices on a stationary engine.

The throttling type of governor controls the admission of gas into the cylinders instead of cutting off the spark. See Index under "Governor, throttling type."

DIESEL ENGINE

The Diesel engine is used quite extensively for stationary purposes. It is also the type used on submarines. The fuel is a low grade of oil, and ignition is accomplished by air compressed to several hundred pounds pressure, resulting in its temperature being raised sufficiently to ignite the fuel injected into the cylinder.

The fundamental principle is similar to that of the usual four-cycle engine. The main difference is that fuel is injected after the air has been compressed, and ignition is then obtained through the high compression of this air, instead of by an electric spark.

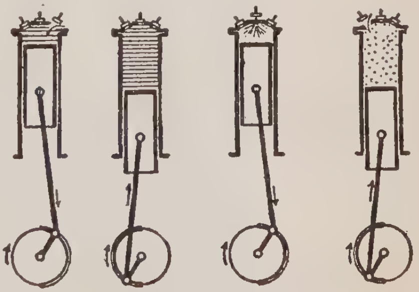
The principle of the "four-cycle" type of Diesel engine may be briefly described as follows: On the first or down stroke of the piston the cylinder is filled with air at the atmospheric temperature and pressure. No fuel is introduced. On the second stroke, the piston travels up and the air, drawn in during the preceding stroke, is compressed to about 500 lbs. per square inch, resulting in its temperature being raised to about 1000° F., or sufficient to ignite any liquid fuel. Then the fuel valve opens and a measured quantity of fuel, usually oil, is injected into the cylinder through an atomizer. The atomized fuel is ignited by the high temperature of the air, and the power stroke follows. On the fourth, or exhaust stroke, the piston travels up and the burned gas is expelled through the exhaust valve. The Diesel engine requires no ignition system, and uses the cheapest of petroleum, crude fuel oils or tar oils.

Diesel Four-Cycle Operation

Stroke 1—Admission or inlet: During this stroke the piston travels downward, and the cylinder is filled with pure air only—at atmospheric temperature and pressure—no fuel being introduced into the cylinder during this stroke.

Stroke 2—Compression: During this stroke the piston travels upward, and the air taken into the cylinder during the preceding stroke is compressed to about 500 lbs. per square inch, resulting in its temperature being raised to about 1,000° F., or sufficient positively to ignite any liquid fuel injected into it. No fuel is introduced into the cylinder until the completion of this stroke.

Stroke 3—Power or working stroke: When the piston has reached the upper end of the compression stroke (or slightly in advance), the fuel valve opens and a measured quantity of fuel oil is gradually injected into the cylinder through the atomizer. This breaks it up into a finely divided spray, the orifices in the atomizer being so proportioned that at full load the admission of fuel is distributed over about 10 per cent of the power or working stroke, the rate of admission being such that there is no appreciable rise of pressure within the cylinder beyond that of compression pressure.



Inlet of air · Compression of air · Combustion and power · Exhaust

Fig. 8. Illustrating the events during four strokes of the cylinder.

The quantity of fuel oil delivered to the atomizer chamber is adjusted to the various load requirements by the action of the governor upon the fuel pump.

The injection air at 750 to 950 lbs. per square inch is furnished by a small two or three-stage compressor, driven from the engine shaft. To prevent the possibility of preignition, this air is thoroughly cooled before being delivered to the atomizer.

When the measured charge of fuel has passed into the cylinder, and during and following combustion, the gases expand and drive the piston downward. When the piston reaches the lower end of the stroke (or slightly in advance), the exhaust valve opens and the remaining pressure is released to the atmosphere.

Stroke 4—Exhaust: During this stroke the exhaust valve remains open, the piston travels upward, and the products of combustion are expelled from the cylinder, completing the cycle.

Brief Explanation of Construction

The general arrangement of the valves and fuel injection apparatus of the Diesel engine, as illustrated in Edward Butler's book on *Carburetors, Vaporizers and Distributing Valves,* is shown in Fig. 9.

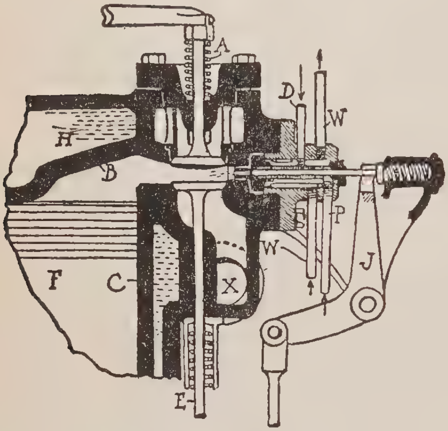


Fig. 9. Section of the Diesel engine. The oil is forced into the cylinder by air pressure.

The cylinder (C) has very little clearance between the top of the piston (F) and the bottom of the combustion chamber (B) at the end of the compression stroke. At this moment the injection valve operated by the lever (J) will be opened, to permit the injection of a charge of fuel forced (during about 20° of the crank revolution) from the supply pipe (P) assisted by an atomizing charge of super-compressed air through the pipe (D). **The cage** containing the injection valve is water-jacketed, water entering and leaving by pipes (W).

The operation of the air-admission valve (A) and the exhaust valve (E) is mechanically controlled in the conventional manner. The movement of the fuel-admission valve is very slight, giving a narrow annular opening for the entry of the oil. Surrounding the valve spindle are a series of brass washers perforated parallel to the spindle by numerous small holes.

The oil is pumped into the space around the valve spindle near its middle, and by capillary action finds its way between the washers and into the perforations.

The air for fuel injection is admitted behind the oil; and because of its high pressure, it blows the oil into the cylinder when the valve opens.

The amount of oil admitted is regulated by the governor, which controls the time of opening of a by-pass connecting the discharge and suction sides of the oil pump. At light loads the oil is pumped to the fuel valve for part only of the admission period, and air alone will enter past the valve for the remainder of the period. (*Motor Age.*)

One manufacturer of the Diesel Engine is the Busch-Sulzer Diesel Engine Co., Second and Utah Sts., St. Louis, Mo.

GAS PRODUCERS

Gas producers are not internal combustion engines, but are **generators** of gas from hard coal, coke, or charcoal.

There are two types, the pressure type and the suction type. The **pressure type** stores the gas into a tank or into the gasometer. The gas is then supplied to any regular type of gas engine as a fuel.

With the **suction type,** the gas is generated in the gas producer, then passes through a washer, and is then drawn into the cylinder of the engine by suction of the piston.

The process of generating gas by means of gas producers consists of passing air, or a mixture of air and steam, through a bed of burning coal, coke, charcoal, or wood contained in a suitable receptacle known as a generator. Dyke's *Motor Manual* explains the gas producer.

INSTRUCTION No. 79

MOTORCYCLES: Engines; Ignition; Carburetors; Transmissions

THE MOTORCYCLE ENGINE

The motorcycle engine is usually a four-cycle type of engine, and is made with one, two, and four cylinders. The air-cooled cylinder is in general use. The "twin type" of cylinder engine shown in the illustration is the most popular, and the cylinders are usually placed 42° to 45° apart.

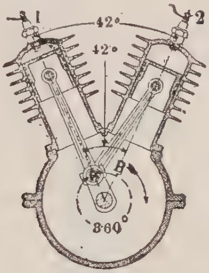

Fig. A

The connecting rods are usually placed on one crank pin. Sometimes there are two crank pins—in this case the firing impulse would differ. The flywheels are usually enclosed in the crank case.

The four-cylinder motorcycle engine is also in use, and is very similar to the automobile engine, but smaller and lighter.

How a Twin-Cylinder Engine Fires

An explanation of how often and the distance apart that the power impulses occur on a twin-cylinder "V"-type of engine, with cylinders placed 42° apart, is given under the illustrations, Figs. 1 to 5.

Indian Twin "V" Motorcycle Engine

Cylinders: Twin, of the V-type, 42° apart, air-cooled, 3⅛″ bore and 3 11/32″ stroke, with a piston displacement of 60.88 cubic inches; horsepower normal rating is 7; actually develops 15 to 18; the **bearings** of the connecting rods and the main crankshaft bearing are of the "roller" type; there are three **rings** to each piston.

Carburetor: Schebler. **Ignition,** Dixie high-tension magneto. Spark plugs are Splitdorf make, ⅞″–18 thread; **lubrication,** oil pump worm-gear driven, geared to the crank shaft.

Valves are the side-valve type, operated by lifter rods. **Valve timing** is correct when gears **(A)** **(B)** **(C)** and **(D)** are placed so that the marks register as shown. The pinion **(A)** is keyed on its shaft and retained by a washer and screw.

Inlet valve action can be understood by referring to Fig. 7. Note that the inlet cam (which is set behind the cam gear) operates against an arm, which operates against the inlet tappet or lift lever.

Exhaust valve action: The same kind of lifting arrangement is provided for the exhaust valve, but the exhaust cam, arm, and lift lever or tappet are placed back, or in rear of the inlet parts.

Fig. B. The Indian twin-cylinder motorcycle engine.

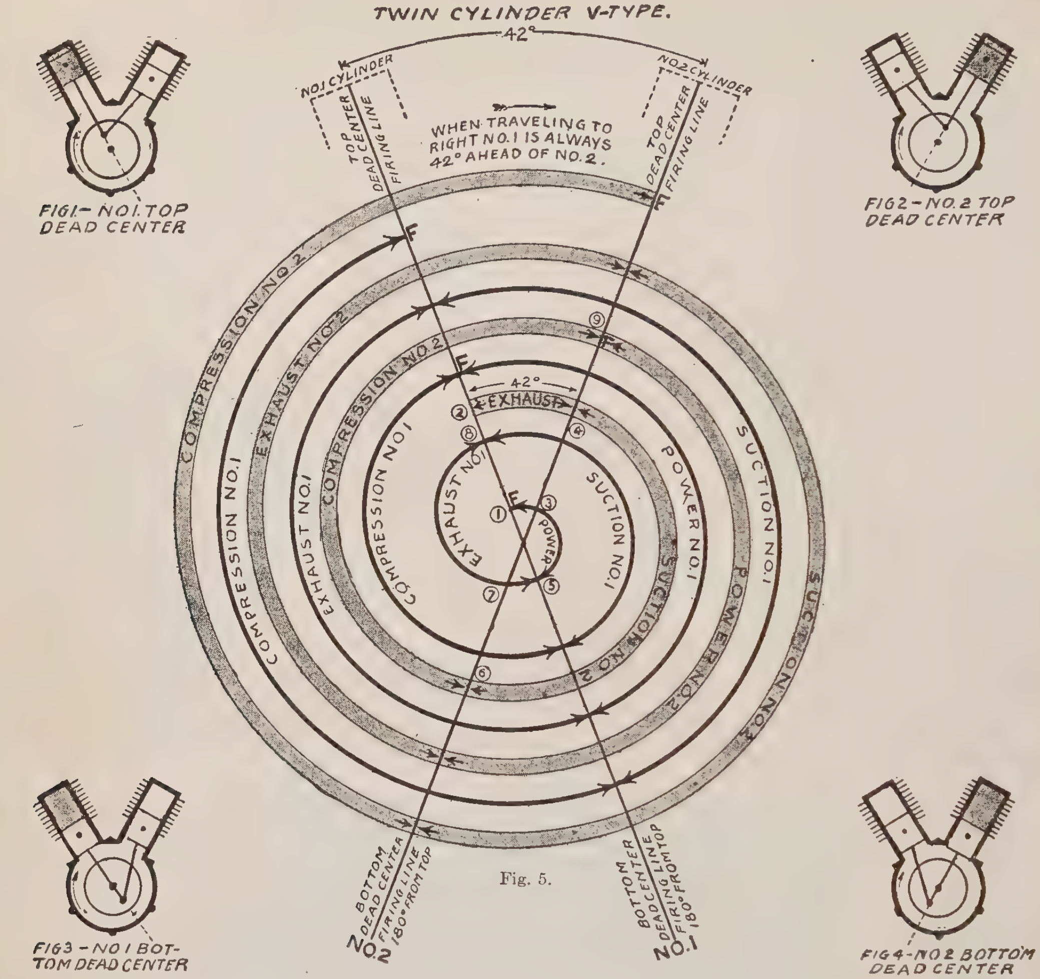

FIG1 – NO1 TOP DEAD CENTER

FIG2 – NO.2 TOP DEAD CENTER

FIG3 – NO 1 BOTTOM DEAD CENTER

FIG4 – NO 2 BOTTOM DEAD CENTER

Figs. 1, 2, 3, 4, 5: How a twin-cylinder engine fires, with cylinders 42° apart.

Fig. 1 illustrates two cylinders placed 42° apart. We will call the cylinder to the left No. 1, and the cylinder to the right No. 2. The bottoms of the connecting rods are together on one crank pin.

Note that No. 1 piston is on top of its stroke and that the connecting rod is straight up and down, in line with the crank pin; in other words, it is on its "firing center" (provided it is on top of the compression stroke, which we assume it to be). Piston No. 2 is not on top of its stroke; its connecting rod where it is attached to the crank pin is 42° away from its firing center. No. 2 has 42° yet to travel to complete its exhaust stroke (see 2 to 4, Fig. 5).

Fig. 2: No. 1 has fired and traveled 42° on its power stroke (see 1 to 3, Fig. 5). No. 2 piston is now on top of its suction stroke (4), and on its dead-center firing line.

Fig. 3: No. 1 has reached the bottom of its firing or power stroke (see 5, Fig. 5), having traveled 180°, or half a revolution. No. 2 is not quite down in its suction stroke, being 42° behind No. 1.

Fig. 4: No. 2 has now reached the bottom of the stroke on suction, having traveled 180°, whereas No. 1 is part of the way up on its exhaust stroke.

Therefore, starting with the firing of No. 1 at (1F), if No. 1 makes a complete revolution—one stroke down on power stroke and one stroke up on exhaust, from 1 to 8—it will have traveled 360°. No. 2, however, will lack 42° of completing its revolution, and will have to travel 42° more than 360° to complete its revolution from 2 to 9.

Therefore, after No. 1 fires, No. 2 must travel 360° + 42°, or 402°, before it fires. Or No. 1 will fire again, 318° after No. 2. fires.

Fig. 5: The black line shows the travel of No. 1, and the shaded line the travel of No. 2. The firing lines of each, or the top and bottom center, are lettered on the illustration.

Start with No. 1 firing at (F) and follow the stroke to the bottom, or a half-revolution; for instance, from 1 to 5 on No. 1 and 4 to 6 on No. 2; each represents a stroke or half-revolution, or 180°.

From 1 to 8 on No. 1 represents a revolution, or 360°.

From 2 to 9 represents 42° more than a revolution on No. 2. From 4 to 9 would represent a revolution on No. 2.

While observing the travel of No. 1, at the same time follow No. 2 and note what it is doing. For instance, when No. 1 is traveling from 1 to 3 on its firing or power stroke, No. 2 is traveling from 2 to 4 on its exhaust stroke, having 42° of its exhaust stroke to complete before it is on its dead center, when it starts on its suction stroke.

—*Continued from page* 1007.

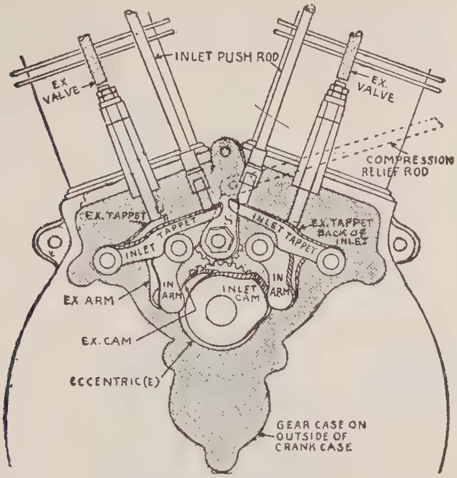

Fig. 7. Valve action.

A **"compression relief,"** or method of opening the exhaust valves to relieve the compression when starting an engine is provided. This is accomplished by a toothed part (**S**) in mesh with a thin eccentric or cam (**E**). When the rod is operated, it causes (**E**) to touch the exhaust rollers on the exhaust arms, which raises the exhaust valves independent of the exhaust cam.

Valve-clearance adjustment is .006″, about the thickness of heavy writing paper, when the engine is hot. Spark-plug gap, .025″.

(**O**) (Fig. **B**) is the oil-pipe connection.

(**R**) is the breather or crank-case vent.

Indian Twin-Opposed Cylinder Motorcycle Engine

Cylinders: two, opposite or 180° apart, instead of 42° as in the "V"-engine; **bore** 2″; **stroke** 2½″; **piston displacement,** 15.70 cubic inches; **horsepower,** normal rating 2¼, develops 4; pistons have two rings; **inlet and exhaust valves,** side by side on top of the cylinders; **timing gears,** in separate housing outside of the crank case; **carburetor,** Indian special; **ignition,** Dixie magneto, driven at engine speed, fixed or set spark. (Hendee Mfg. Co., Chicopee Falls, Mass.)

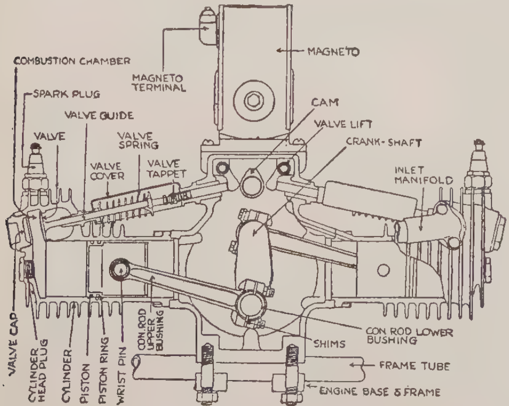

Fig. 8. Indian twin-opposed engine.

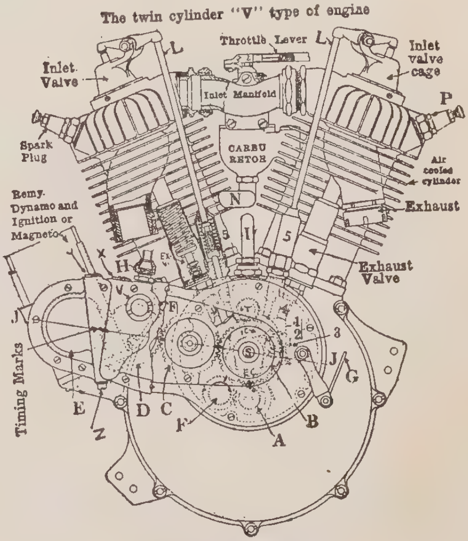
Harley-Davidson Twin "V" Motorcycle Engine

Cylinders set 45°; **valves,** inlet overhead in cage, operated by push rods (**L**); exhaust on the side; **bore** 3 5/16″ x 3½″ stroke; 60.34 cu. in. displacement; **valve clearance,** .004″ between exhaust lifter and valve stem (engine cold), on all single-cylinder models and twin engines prior to 1915. Allow .004″ clearance between inlet and rocker arm and valve stem on all models. On 1916 and 1915 twin engines, allow .004″ for rear cylinder and .006″ for front, and on 1917 to 1920 twin engines, allow .008″ to .010″ for both cylinders.



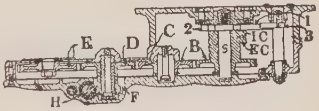


Fig. 9 (upper)
Fig. 10 (lower)

Fig. 9. Side view of H. D. engine.

Fig. 10. Top sectional view of gears and cams; (1) exhaust relief cam; (3) cam on arm of rod (G) (Fig. 9) which operates the relief cam; (EC) exhaust cam; (IC) inlet cam; (2) rollers on rocker arm; (S) cam shaft; (B) cam gear. Other gears correspond with the gears in Fig. 9.

Valve timing, on twin and single-cylinder engines: The exhaust valve should start to open about 9/16″ before bottom center; closes 1/32″ to 3/32″ after top. The inlet valves do not require independent timing. However, the inlet valves start to open 3/16″ before top and close ⅛″ to ⅜″ past top. When timing the ignition, be careful not to use the wrong cam in timing. The small cam is for the front cylinder, and the large cam is for the rear.

When fitting new gears, they should be lined up in accordance with the marks shown in Fig. 9, so that the marks come in a vertical line. (**A**) is the crank-shaft gear; (**B**) the cam gear.

The exhaust compression relief is to relieve compression in the cylinder for easy starting by opening the exhaust valve. When starting, the left-hand handle-bar grip is twisted to the left, which retards ignition, and further turning raises the exhaust valve through rod (**G**) (Fig. 9), which raises the exhaust valve through cams (1) and (3) (Fig. 10).

Crank-case compression relief: A vent (**I**) (Fig. 9) relieves the pressure in the crank case at every revolution. The gear (**F**) operates a rotary relief valve which should open 1/16″ to 3/32″ when the front piston is on top. This valve port opens gradually when the engine is turned in the direction in which it runs, and closes when the piston has reached bottom. This allows a vacuum on the upward stroke, to draw oil and oil vapor to all bearings. A pipe leads to the chain cover, and as it emits a slight amount of oil at each revolution, the chain is oiled.

Oiling system: Oil enters from the oil reservoir through pipe connection (H). It is then carried by a rotary valve pump geared to shaft (F) (Fig. 10), through sight glass (V) into the engine crank case.

If there is **too much oil,** remove screw (X); if oil does not overflow, turn the engine until it does. Replace (X). Then remove the plunger-chamber vent screw (Y) until oil flows in the same manner. Then regulate the oil supply by placing three .010″ washers on the adjusting screw (Z) (Fig. 9). Drain the engine and fill with 1½ pumpfulls of oil with the hand pump. **To increase the oil supply,** add thin washers, one at a time. **To decrease,** remove the washers. When all washers are removed the oil-pump plunger has no stroke at all.

Timing ignition: All twin engines, magneto equipped, fire ¼″ to 5/16″ before top of compression stroke with the spark lever advanced full. The spark occurs when the points are just separating.

All twin electrically equipped engines fire 7/32″ to 9/32″ before top. All single-cylinder engines fire 3/16″ to ¼″ before top.

Berling magneto: The lower cam on the interrupter times for the front cylinder and the upper cam for the rear.

Dixie magneto: No. 2 cam for front, No. 1 cam for rear.

Bosch magneto: Interrupter shoe No. 2 for front, and No. 1 for rear.

Remy generator interrupter: Small cam for front, and large cam for rear. (Harley-Davidson Motor Co., Milwaukee, Wis., Mfrs.)

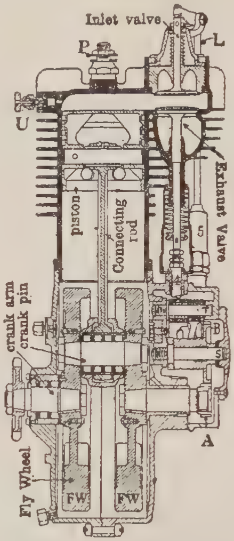

Fig. 11. Sectional view of engine shown in Fig. 9.

MOTORCYCLE CLUTCH AND TRANSMISSION (INDIAN THREE-SPEED AS EXAMPLE)

Operating plan of three-speed Indian motorcycle: The principle of construction and operation of the three-speed gear are identical with that of the two-speed, except that there is an extra set of gears for the intermediate ratio.

When gears (A) and (B) are locked together by dogs (G), the "high ratio" or "high speed" is coupled up.

When gears (B) and (E) are in mesh the "intermediate" or "second speed" ratio is obtained.

And when gears (B) and (C) are connected through the dogs (H), the "low speed" is obtained.

There are two "neutral" positions in this gear set: between the high and intermediate with the gears as shown in the illustration, and between the intermediate and low, with gear (B) on the other side with (E), with the same relative position.

Fig. 13. The Indian twin-type of motorcycle using a neutral counter shaft.

If the machine is equipped with this one-speed device, called a "neutral counter shaft," its purpose is mainly to promote starting without raising the rear wheel. By shifting the small lever underneath the handle bar, the dogs are disengaged, and the drive to the rear is cut out. The clutch is then engaged and the engine started. After the engine is started the clutch is disengaged until the machine is started.

If the three-speed gear box is used instead of a single speed, it is mounted in the same location, but a control lever is placed on the side, as shown at top left of the illustration, instead of the small hand lever. When starting with a two or three-speed the gears are shifted to neutral position and the action is just the same as above. Note the name and location of the parts as lettered.

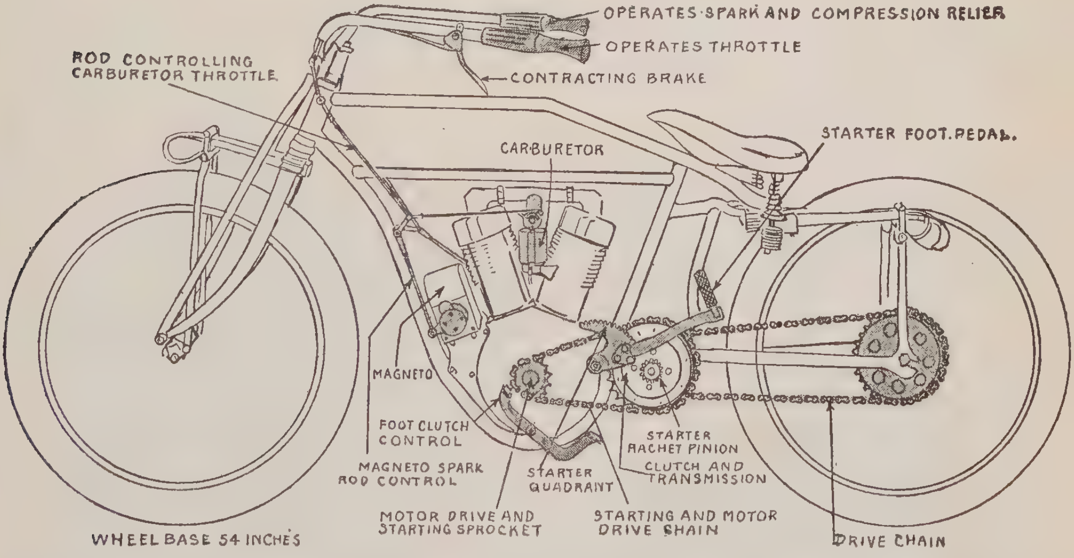

Fig. 14. **The Indian starter:** The down-pressure on the foot lever brings the quadrant into engagement with the pinion on the clutch and turns the engine over three times to each stroke, the clutch being engaged to obtain positive and full crank effect.

This starting of the engine can be done without jacking up the rear wheel, simply by putting the shifting lever into neutral on the three-speed machine and by disengaging the driving cog in the same manner on the single-speed model.

When the starting crank is released on the bottom of the stroke, it is automatically returned to the starting position by a strong coil spring, and when not in use is held in a convenient position by a strong clip. When the starting crank is in normal position, it is fully disengaged from the pinion which revolves with the clutch.

The mechanism consists of a quadrant with a reverse motion and meshes with a ratchet pinion on the clutch shaft. The ratio is three turns of the engine to one stroke of the starter, not taking into account the spinning effect and extra momentum gained.

Note. The models illustrated are the early models. Changes have been made on the later models. The "neutral counter-shaft" has not been used on the Indian since 1917, and wire controls have been used since 1918. The gear-shift lever and clutch pedal arrangement have also been changed. **The reason for showing the older model of motorcycle** is the fact that the older models are those more likely to need repairing, and they clearly explain the principles involved. Write the manufacturers for information on later models.

Continued from page 1010.

Indian Clutch

Construction: The Indian clutch is a multiple-disk dry-plate type. The drive is transmitted through four Raybestos-faced disks which engage with four polished steel disks, and are held in engagement by eight small springs equal distances apart.

This clutch is applied to the one, two, or three-speed transmission.

Operation: Lever (X) (Fig. 12) operates the clutch, and has about 45° travel. When pulled forward, it releases the clutch; when pulled backward, it engages the clutch.

It is connected with the foot pedal, which has a pull-back spring. Pressure on the pedal forward causes the plunger rod (marked by mistake, "shaft driving hub") to come in contact with the screw (W), which under pressure compresses the springs and pulls outward the whole assembly mounted on the inner plate, thus freeing the driving disks.

When the control pedal is released, the pull-back spring causes a reverse action through the mechanism, and again brings the disks into engagement.

To start the three-speed model engine, shift the gears into "neutral" position and have the clutch "in"; start the engine by the pedal. After the engine is started, release the clutch. To start the machine, place the gears in mesh, starting off on "low," and gradually applying the clutch.

MOTORCYCLE MAGNETO (THE DIXIE)

It will be noted that this magneto is similar in every respect to the Dixie magneto explained on page 272, except that a "collector spool" is provided on the drive-shaft end, instead of a distributor. The principle of this arrangement and the method by which two carbon brushes take the high-tension current from the collector spool is shown in Fig. 17. (This is not the exact construction, but it serves to explain the principle.)

14. Shaft nut.
15. Drive key.
16. Magnet.

Timing the Dixie magneto: Usually, the piston is placed on top of compression stroke with the contact breaker retarded, at which point the platinum points of the breaker should just begin to separate. This is taken care of in the meshing of gears as shown in Fig. **B,** page 1007, and varies in different motorcycles. For instance, an earlier setting is sometimes desired.

The distance between the platinum points in the contact-box, when separated, is .020″ or 1/50″.

To remove grease and dirt: Squirt a gunful of gasoline into the spool housing (11) (Fig. 16).

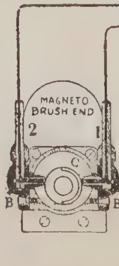

Fig. 17

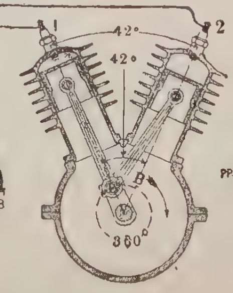

Fig. 18

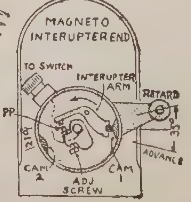

Fig. 19

The carbon brushes should project ¼″ from the brush holders; if the carbon brushes are glazed too much at the ends, rub them with emery paper.

The terminals on the magneto are in right-hand rotation. No. 1 terminal leads to the cylinder which fires first, and usually the rear cylinder.

If a **terminal comes loose** from the terminal to the brush holder, drill out the brass plug, and use ⅝″ cable, twist the copper strands, and insert them in the hole and solder.

A punctured brush holder may be detected by the smell of burned rubber.

Relation of Spark to Piston

On a twin-cylinder "V"-type engine, the firing order is not equal, that is, one cylinder would fire, then the next cylinder to fire would be 360° plus 42°, or 402° after the first. Therefore, the interrupter and brushes carrying the current to the spark plugs must be arranged accordingly.

Note in Fig. 17, that brushes (B1) and (B2) **conduct current to the spark plugs.** (B1) is now on contact, hence cylinder 1 would fire.

Note in Fig. 18, that the cylinders are 42° apart. If cylinder 1 fires now, crank pin (A) will travel a revolution back to (A) again, then 42° more to (B), or 360° and 42°, or 402° in all, before No. 2 fires. No. 1 will again fire, from point (B) to (A), 360° minus 42°, or 318°.

The armature travels at half the speed of the engine crank shaft, and makes a spark every half-revolution. Therefore the armature, with its interrupter and collector ring, would travel 201° when the crank travels 402°, when cylinder No. 1 fires.

When cylinder No. 2 fires, the crank pin on the engine will travel 318° before No. 1 would fire again. Since the magneto armature travels one-half as fast as the engine crank, it would travel from (B2) to (B1), or 159°. Thus we should have an unequal impulse.

It requires two revolutions of the crank to complete the four strokes or four-cycle operation. During these two revolutions **two sparks** are required. The **armature makes two sparks to one revolution.** Therefore it revolves but one revolution to two revolutions of the crank.

The illustrations (Figs. 17, 18, 19) are not of the Dixie magneto, but serve to explain the principle of how the motorcycle twin-type engine fires.

SPLITDORF MAG-DYNAMO, FOR MOTORCYCLE USE

This is a combination of a magneto and a dynamo. The dynamo armature which generates "direct" current is placed above, (I) being the commutator. The magneto armature (U) is a regular armature with wire revolving, generating "alternating" high-tension current, and is placed below. The two are entirely separate and independent.

The fields or magnets are not of the "permanent" type, but are of the "electro" type, excited in the first case by the current in the storage battery, or by the first few revolutions of the generator. The dynamo and magneto are separate and distinct otherwise, but combined in one unit.

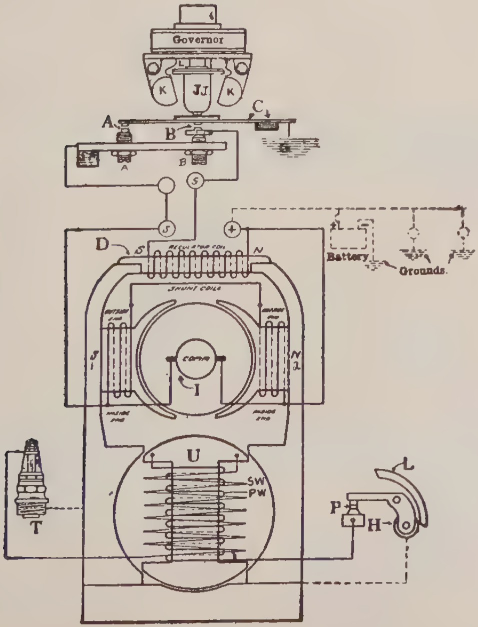

Fig. 20. Splitdorf mag-dynamo.

Magneto Part

The magneto part of the "mag-dynamo" supplies current for ignition. Its armature (U) is a double-wound (SW-secondary—PW-primary) high-tension revolving type. The interrupter parts are shown: (P) platinum points of contact breaker; (L) cam; (H) roller grounded with frame or base; (T) spark plug; (P) points are set at .015″, and spark plugs at .020″ gap.

Dynamo Part

The dynamo generates a "direct" current, which charges a storage battery, and also supplies current for lights. The armature is driven by a gear from the magneto or lower armature. With the battery "floating-on-the-line," the unit has a maximum output of 3 amperes at 7.5 volts at 1,400 r.p.m. of the engine, equal to 30 m.p.h. with average road gear.

Cut-Out Principle

The principle of the automatic cut-out used with the dynamo is as follows:

When the rider gives the starter pedal a downward thrust, as in starting, the mechanical governor part (J) is forced down by centrifugal action of arms (K), which acts upon the spring (C), bringing the main-line contacts (A) together; this allows about 1 or 1½ amperes to flow through the field winding (and armature), magnetizing it so that the lower or ignition armature may produce sufficient current to spark the engine.

If the engine is stiff or hard to turn over, the starting switch is depressed, allowing 4 amperes to go through the shunt fields and armature. The starting switch merely cuts around the contacts (A) so that a strong magneto field is obtained when the rotation of the armature is slow. Of course, when the battery is disabled, a powerful thrust on the starter pedal will rotate the generator armature fast enough to generate sufficient current to magnetize the field enough to furnish a spark at the plugs.

As the speed of the motorcycle increases up to about 30 m.p.h., the charging current also increases to about 3½ amperes. Then through the increased action of the governor spring, a second contact at (B) comes into action. This connects the regulator or bucking coil (D) into the circuit, and magnetizes the soft iron cores (N) and (S), which, you will note, is magnetized in the same way as the field coils. This action bucks the magnetic field of the generator armature and drives the magnetism down to the ignition armature field, weakening the generator field and strengthening the magneto field.

The ignition current is a straight high-tension current from the magneto at all times. When first starting, the magneto field is energized from the battery, and when running, from the generator. Otherwise that is all the connection the ignition or magneto has with the dynamo or generator.

Timing the Magneto on "Mag-Dynamo"

In the Indian, the Thor, and the Merkel, the piston is placed 5/16″ from top of compression stroke with the breaker box advanced. On the **Harley-Davidson** (Dixie magneto), 9/32″; on the **Excelsior,** 13/32″; on the **Pope,** ½″; on the **Dayton,** ⅜.″

Adjustments of Mag-Dynamo

To adjust the cut-out and current control: With the engine idle and all lights turned off, remove the regulator-box cover and adjust the current-control contact screw (A); the correct setting of the contact points should be between .015″ and .025″. This setting will permit the battery to discharge about 1 to 2 amperes. On the other side of the regulator box the setting of the main cut-out contacts can be made as follows: With the engine running slowly, loosen the lock nut and turn the current-control screw (B) several turns to the left. Increase the speed of the engine until the ammeter shows a 3-ampere charge. With the engine running at this speed (approximately 1,200 r.p.m.), turn screw (B) to the right until the ammeter needle drops back approximately to a 2-ampere charge; then set the lock nut.

The fuse used in the circuit is a 15-ampere fuse. The positive pole of the battery is connected to the fuse block, and the negative terminal is grounded.

In case of failure of the battery, three dry cells can be utilized, connected in series with a carbon pole to the fuse block and zinc grounded.

MOTORCYCLE GENERATOR (SPLITDORF DU 1)

On many motorcycles, the Dixie magneto is used, and a separate and distinct dynamo is mounted separately. One type of dynamo is termed the "DU-1" as described below.

The principle of the mechanical cut-out on the "DU-1" Splitdorf motorcycle lighting and battery-charging dynamo is shown in Fig. 21. Note that the centrifugal action of (G) on the armature shaft causes a sleeve at higher speeds to press against the arm (A), which, through hinge (S), makes contact at (B).

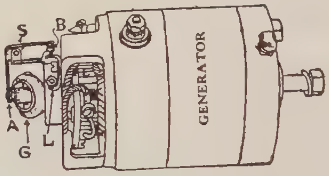

Fig. 21

MOTORCYCLE CARBURETOR (SCHEBLER)

Description: Model "H," ¾″ and 1″; Compensating type; variable fuel feed. The supply of gasoline is controlled by (Z), which raises the gasoline needle valve (I), giving an adjustment on low, intermediate, and high speeds. (C) is the air intake, and can be turned so that warm air can be drawn from the engine.

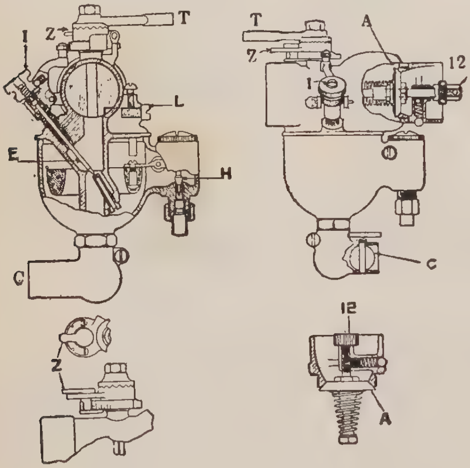

Fig. 22. Schebler motorcycle carburetor.

Low-speed adjustment: See that the leather air valve (A) seats lightly, but firmly. Then turn the knurled button (I) to the right until the needle point (E) sets in the spraying nozzle. Now turn (I) to the left about two turns, and open the low-speed adjusting screw (L) about three turns; then open the throttle about half-way to start the engine. After starting, close the throttle and turn the needle-valve adjusting screw (I) to the right or left until the engine runs smoothly without missing. If with this low speed adjustment, the engine runs too fast, turn the low-speed adjusting screw (L) to the right.

High-speed adjustment: Do not make the adjustment with the engine running idle. The machine should be run in high speed on the road. The throttle and spark should be advanced fully. The adjustment is now made by the pointer (Z), which, as it moves from (1) toward (3), increases the supply of gasoline. Moving the indicator from (3) toward (1) cuts down the flow of gasoline. When the indicator reaches the right point, the engine will run without missing or backfiring.

Starting: The air valve can be locked to assist in starting by pulling out button (12) and giving it a quarter-turn. When the engine starts, release air valve (A) by turning button (12) back.

Extra air port for high speed on the Harley-Davidson carburetor is provided inside the mixing chamber to admit more air at extreme high speed.

To set the float level: Place the float 19/32″ from the top of the bowl to the top of the cork float. The arm can be raised or lowered to meet these conditions.

THE NERA CAR

This machine is mounted on two wheels. A glance at the illustration will give the details.

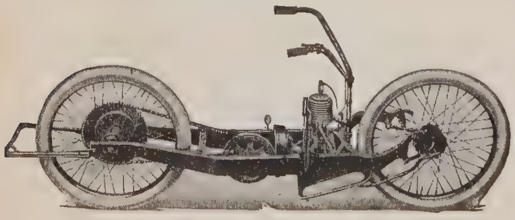

Fig. 23. Side view of Nera Car chassis.

Specifications

Wheel base: 55½ inches.

Length over all: 84 inches.

Frame: Pressed steel chassis, automobile type of construction.

Motor: 2-cycle, 2½ h.p., 2½″ x 2¾″; displacement, 13½ cubic inches.

Transmission: Friction drive to countershaft mounted on SKF bearings; five speeds.

Ignition: High-tension magneto.

Gasoline tank: 2 gallons.

Chain: Roller, ½″ pitch x 5/16″.

Springs: Load carried on barrel-type coil springs.

Saddle: Suspension type of best leather; combination flat and rear coil springs, giving vertical movement in horizontal plane.

Wheels: Wire, 26″ x 3″ with ball bearings; 36 spokes, S.A.E. standard.

Brake: Expanding brake in rear wheel, foot control.

Tires: 26″ x 3″ non-skid.

Speed: 35 miles per hour.

Color: Black.

Weight: Approximately 165 lbs.

Fuel consumption: 85 to 100 miles per gallon.

Non-skid—center of gravity below center line of wheels.

Manufactured by Nera-Car Corpn., 196 South Geddes St., Syracuse, N.Y.

INSTRUCTION No. 80

MISCELLANEOUS CARS: Woods Dual Power Car; Magnetic Gear Shift; Steam Car; Owen Magnetic Car (Electric Transmission). PRINCIPLE OF THE AIRPLANE

WOODS GAS-ELECTRIC CAR

The Woods dual power car: The power plant consists of a small gasoline engine and an electric motor-generator combined into one unit, as illustrated, and mounted on a three-point suspension. The movement of a finger lever on the steering wheel connects the engine to the electric motor-generator, which cranks the engine and develops power which is transmitted through the armature shaft of the electric motor and propeller shaft, direct to the rear axle. See Fig. 1.

ELECTRIC & GASOLINE LEVER BOTH FINGER CONTROL
FOR SPARE TIRE
FOOT BRAKE PEDAL
ELECTRIC MOTOR WHICH IS ALSO A GENERATOR
REVERSE PEDAL
BATTERY OF 24 CELLS 11 PLATES EACH

Fig. 1

The car starts as an electric, by a simple movement of a finger-controlled lever on the steering wheel, which operates the means for connecting the battery to the motor, and increasing the speed, as the lever is advanced.

At any advanced position of the electric lever the first movement of the finger-controlled gasoline lever instantly starts the gasoline motor. As this lever is moved forward, it causes the car to be operated more on the gas, and at a certain point it will run as a straight gasoline car, neither charging nor discharging the battery. With a slight variation of the relative position of the two levers on the steering wheel, the battery may be either charged or discharged at will on any speed from ten miles an hour up to twenty-eight or thirty miles an hour. Electricity is generated and stored in the battery while the car is running.

At any speed above six miles an hour, dynamic breaking may be effected by retarding the electric lever. This causes the electric motor to run as an electric generator driven by the gasoline motor or by the momentum of the car. The power thus generated is used for charging the battery. The same effect may be obtained by a simple movement of the foot-brake pedal, which also acts as a mechanical brake below six miles per hour.

The parts of this car and their location are shown in the illustration, Fig. 1 (Woods Electric Vehicle Co., Chicago, Ill.).

MAGNETIC GEAR SHIFT

This device is used to shift the gears, taking the place of the hand shift lever and selector rods. It is attached to the side of the transmission. The **switch control** is placed under the steering wheel. This system is used on the Premier Car. (Device manufactured by Cutler Hammer Co., Milwaukee, Wis.)

Principle: If you press the switch button 1 (see Fig. 3), you close the circuit of solenoid 1, causing the shaft (**A**) to move to the left.

If you press button 2, you energize solenoid 2, causing the shaft (**A**) to move to the right.

If you press button 3, you energize solenoid 3, causing shaft (**B**) to move to the left. If you press button (**R**), energizing spool (**R**), you bring the reverse gear into mesh.

Pressing neutral button (**N**) and throwing out the clutch, places the gears in "neutral."

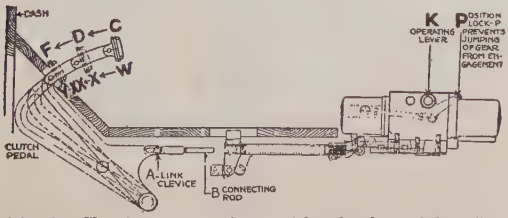

Fig. 2. Showing connections with clutch pedal. (CD) represents travel provided for clutch slippage, and possible throw of clutch pedal for coasting.

Pressing a push botton does not energize one of the solenoids; it merely partially closes the circuit to a certain solenoid, but the circuit is not completely closed until you **throw the clutch pedal down to the floor-board.**

The clutch pedal is so arranged that you can throw out the clutch in the usual manner by **partially** depressing the pedal, but if you push the pedal to the extreme position, you bring the switch (**M**) (Fig. 5) in contact for an instant and permit the electricity to flow to the particular solenoid which was selected when you pressed one of the push buttons.

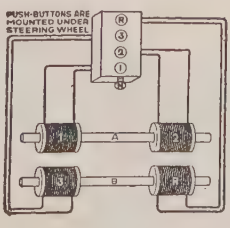

Fig. 3

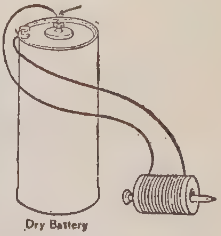

Fig. 4

Fig. 3. Simplified explanation of the **solenoid action.**

Fig. 4. **Principle of a solenoid** simplified: insulated wire is wrapped around the spool (solenoid). If the ends of the wire are connected with the battery the spool sucks up the nail.

The push buttons are therefore known as "selector switches," because they do not actually close the circuit but select in advance the circuit that will be energized when you push the clutch pedal to the extreme position, thereby closing switch (**M**).

A 12-volt battery is used: It is stated an 80 ampere-hour battery will operate the gear shift from 394 to 491 times.

Gear Changes

First speed: To start forward in first speed, push the "selector switch" button No. 1 (Fig. 3) down until it catches. Then depress the clutch pedal as far as it will go and the first-speed gears will instantly mesh. Allow the clutch pedal to return gently. The clutch will engage and the car will move forward in first speed.

Second speed: Press button No. 2 until it catches, and as soon as it is desired to shift the gears from first to second, depress the clutch as before to its extreme position. This brings the second speed gears into mesh. Engage the clutch.

Third speed: Press button No. 3 until it catches. Depress the clutch to its extreme position. Allow the clutch to return to engagement.

Dropping back: In dropping back from one gear to another, the operation is the same, i.e., press the button corresponding to the gear wanted, and when it is desired to shift, simply push the clutch to the extreme limit and the gears will automatically change.

Selection: Should button No. 2 be depressed and should it then be decided that No. 1 is wanted instead, all that is necessary is to press button No. 1. This automatically "kills" No. 2. Similarly, any button that is down is "killed" by pushing any other button. The gears may be selected in any order desired, for example, 1 to 3, 2 to 1, 3 to 1, etc. It is not necessary to press the buttons in numerical order.

Pre-selection: Speed changes may be prepared for at any time in advance of the actual shift by pressing the button corresponding to the gear into which it is next desired to shift.

When the car is stopped, the gears should always be neutralized before the driver leaves his seat, so that when the motor is again started, none of the gears will be in mesh.

Neutralizing: To throw the gears to neutral, press the (**N**) button, and then depress the clutch pedal to the limit. (The neutral button has no catch and does not remain down when it is pressed. Its function is simply to throw out the other buttons in order to break their electrical connections.)

Coasting: The clutch pedal may be thrown out far enough to free the clutch without neutralizing or shifting the gears. The shift takes place only when the pedal is thrown to the extreme position. This arrangement permits disengaging the clutch so that the car can "coast," no action taking place in the gear shift. See Fig. 2.

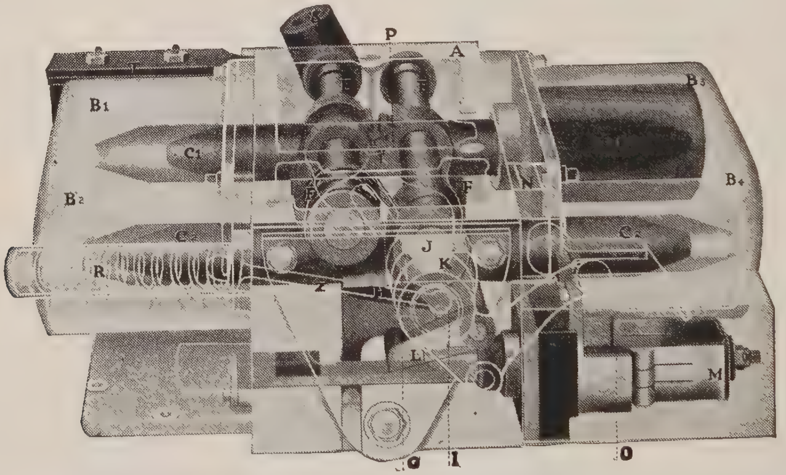

Fig. 5. (**A**) gear-shift housing; (**B-1-2-3-4**) coils; (**C-1-2**) magnet cores; (**E-E**) cam shafts; (**F-F**) neutralizing cams; (**G**) ratchet pawl lever; (**I**) rocker arm; (**J**) operating shafts; (**K**) operating lever; (**L**) pawl operating master switch; (**M**) master switch; (**N**) locking shaft; (**O**) master switch return spring; (**P**) neutralizing return spring; (**Z**) neutralizing return-spring shaft.

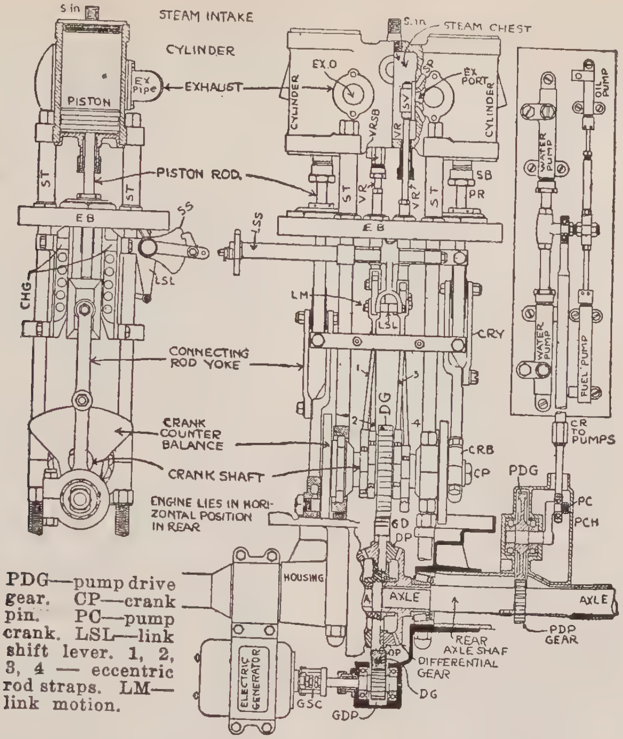
THE STANLEY STEAM CAR

Engine: Double acting, taking steam at each end of the cylinder. Slide valve, built in a unit with the rear axle, and driving through a spur gear on differential (**GD**) (Fig. 6). Crank shaft spur gear (DG) is the drive gear on engine.

The valves which control the admission and exhaust are operated from eccentrics on the crank shaft and through a link motion (**LM**), through (**LSS**) which is connected with left pedal (Fig. 10) and controls the range of motion of the valve.

There are three passages when the valve is open for a large part of the stroke. This admits steam at boiler pressure and shuts the valve a certain distance before the piston reaches the bottom of its stroke. For the rest of the traveling the piston is driven by the expansion of the steam. Pressing the pedal (T) (Fig. 10) forward until it catches or hooks up causes the valve to close earlier. This means that less steam is taken from the boiler and the piston is driven a longer distance by the expansion. This, of course, is more economical of steam and is the condition for normal running.

The longer valve opening is used for starting, and practically for nothing else. With the pedal pressed forward, the operation of the valve is reversed so that the engine will run backwards, this giving the reverse motion.



PDG—pump drive gear. CP—crank pin. PC—pump crank. LSL—link shift lever. 1, 2, 3, 4 — eccentric rod straps. LM—link motion.

Fig. 6. **Stanley engine, rear axle, and pump gear.** The pumps are really mounted forward on the chassis, and are driven by a crank off the rear axle. The electric generator is also rear-axle driven.

After leaving the engine, the steam goes to feed the water heater, thence to the top of the radiator, upon passing through which it condenses into water and this water flows back to the main tank. Differing load and road conditions entail the loss of some steam, and it is this loss which has to be made up by refilling the water tank. However, sufficient water can be carried for 200 to 250 miles of ordinary running, or, in other words, it takes this amount of ordinary running before the slight loss of steam is equivalent to the whole tank full of water, which is about 20 gallons, and is placed underneath the car, below the frame.

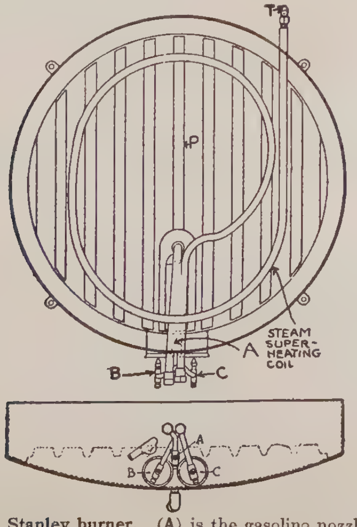


Fig. 7. **Stanley burner. (A)** is the gasoline nozzle for the pilot light and **(B)** and **(C)** the two main burner nozzles for coal oil or main fuel.

Boiler: Fire tube type, the flues being welded by the acetylene process to the bottom head.

Burner: When we want more power from the gas car the throttle is opened. When we want more power from a steam car the burner must supply more heat, thus generating a higher pressure of steam.

How kerosene is used: The kerosene under pressure is first led through a long coil placed on top of the boiler, where the exhaust gases of combustion yield up part of their waste heat, by preheating the kerosene. From this top or heating coil the kerosene passes by way of the automatic control and main burner valve to the vaporizer (located in the fire). Here the hot kerosene is transferred into a true gas, and after being mixed with a definite amount of air is burned with the blue "Bunsen" flame.

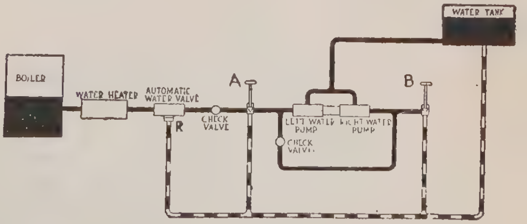

Fig. 8. **Diagram of water system of Stanley steam car.** Water is pumped toward the boiler by one or two pumps, according to the positions of the hand valves **(A)** and **(B)**. After reaching a proper level in the boiler, the release valve **(R)** is opened and the water then goes back to the main tank, whether the pumps are both working or not. In practice, the left pump always is in use subject to the automatic control, and the right pump is hardly ever called into service, but doubles the supply for emergency use.

Uniform water level: When the water reaches a certain height, it is forced to return to the supply tank by an automatic by-pass, thermostatically operated.

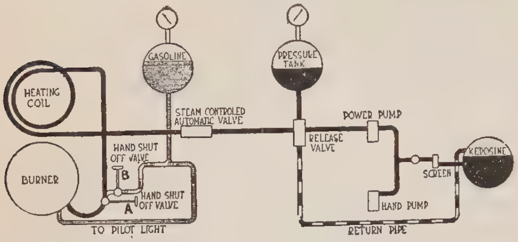

Fig. 9. **Diagram of fuel system of Stanley steam car.** The gasoline only supplies the pilot light, which never goes out, and the consumption is small, so the size of the tank is exaggerated in the cut. Kerosene, the operating fuel, is carried in the rear tank and pumped to the pressure tank from which the burner takes its supply. When the steam pressure reaches a predetermined point, the supply of fuel is cut off and the kerosene pumped is allowed to go back to the main tank. The heavy black line in the cut indicates the kerosene supply, the broken black line the return lines for surplus, and the grey lining, gasoline.

Fig. 10. **Control of car:** The left pedal gives the two valve positions for forward running and the reverse. (**T**) is pressed forward half-way after starting and left there. (**F**) is the reverse pedal, and is pushed full forward when the car is reversed. The right pedal operates the service brake, the lever, the emergency brake. The throttle is the only control used while running. A little lever, partly concealed by the throttle lever, is for shutting off the fuel when making a long stop. When starting from dead cold, the valve turning the gasoline into the main burner is used. On the dash the left gauge shows the fuel pressure and is seldom looked at. The right gauge shows the steam pressure. In the center is the water glass that is carried only as an emergency indicator in the event of any trouble in the water-feed system. (The Stanley Steam Car Co., Newton, Mass., is the manufacturer.)

Questions Answered Relative to the Stanley Steam Car

Q. 1: Where is the engine located?

Ans.: The engine is located on the rear axle and supported from the rear Axel differential housing. It is swung at the other end, from the car frame, by means of a spring strap hanger.

Q. 2: How does the engine drive the rear axle?

Ans.: The engine frame, made up of four members, is carried through the differential housing, turning in an oscillating block at that point. Thus the engine and rear axle become a unit. The gear teeth of the engine's main drive mesh with those of the differential.

Q. 3: What is the ratio of the gearing?

Ans.: This depends upon the size, power, and type of car employed. In the older models it is 2:1, and in the later models 1½:1.

Q. 4: Where is the boiler located?

Ans.: The boiler is located in front of the dash, underneath the hood and behind the condenser, which is also a radiator.

Q. 5: What steam pressure is usually carried?

Ans.: All stock cars, regardless of model, operate on 600 lbs. pressure normally. However, for speed purposes this pressure is run up as high as 1,200 lbs. to 1,500 lbs.

Q. 6: What is the average time required to raise sufficient steam pressure when cold?

Ans.: The initial time of steaming a car when cold will take approximately fifteen minutes. This includes filling of the tanks and boiler, as well as the raising of steam pressure.

Q. 7: What time is required if the car has stood awhile, after having been used?

Ans.: No time whatever is required for raising the running pressure, inasmuch as that pressure has been maintained.

Q. 8: What is the fuel consumption?

Ans.: One of the Stanley five-passenger, big touring cars was run for three consecutive months, making an average of twelve miles per gallon of coal oil. On long runs, this figure is increased as high as sixteen or seventeen miles per gallon of coal oil.

Q. 9: How are the various speeds controlled?

Ans.: From zero to the world's record is obtained by the opening of the throttle, the handle of which is located on the steering wheel. There is no other movement on the part of the operator for increasing or retarding his speed, other than the throttle.

Q. 10: What is the water capacity and consumption?

Ans.: The water capacity is 20 gallons carried in a tank beneath the car frame and filled through a radiator. This capacity is sufficient for a day's run. We have known it to go as high as 350 miles.

Q. 11: Mention the control levers, valves, etc.

Ans.: When starting out with a car, a valve is opened which places the car under automatic control from that time on. When brought to a stop, this valve is closed. The operating controls are the throttle, the service and emergency brakes, and reverse.

Q. 12: Where are the control parts located?

Ans.: The throttle subimposes on the steering wheel. The foot brake is in the usual position. Reverse is a foot brake. The emergency is a handle brake, located on the side of the car.

Q. 13: What are the advantages of a steam car?

Ans.: Entire lack of vibration; freedom from gear shifting; absence of clutch; absolute flexibility; more power per weight than is possible in gasoline cars; a car that cannot freeze up in winter weather; simplicity of controls, but 32 moving parts, counting the wheels; low cost of upkeep; greater tire mileage; small depreciation factor; no smoke or steam visible in cold weather.

Q. 14: What are its disadvantages:

Ans.: These have in later models been overcome, but formerly they were: shape of hood; necessity for firing up; likelihood of freezing; necessity of taking on water every fifty miles (before the condensing system was used); steam in the street.

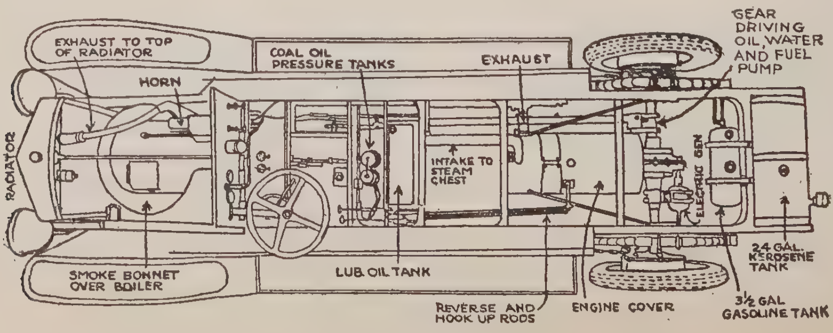

Fig. 11. Plan view of the Stanley steamer.

THE DOBLE STEAM CAR

How the Doble Differs from the Stanley

1. The Doble boiler is of the water tube type. The Stanley boiler is of the fire tube type.
2. The Doble boiler consists of 28 sections, placed in an insulated casing. The Stanley boiler is in reality a big drum standing over the burners.

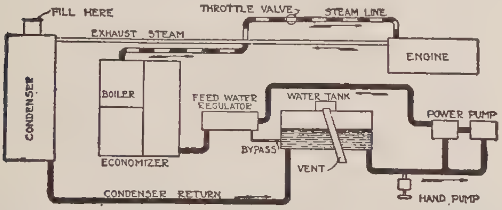

Fig. 12. **Water and steam piping diagram of the Doble steam car.** The cycle of operations is as follows: Water put into the condenser flows to the water tank by gravity. It is pumped by a power pump through the regulator and economizer into the boiler, where it is changed to steam. Steam from the boiler passes through the throttle into the engine, thence to the condenser, where it is reduced to water again.

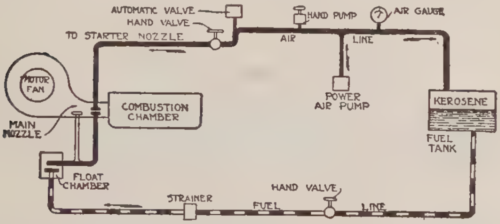

Fig. 13. **Air and fuel piping:** Air pressure of 2 lbs. per square inch is maintained in the fuel tank. The blower motor is started through a switch, after which speed is regulated automatically by the steam pressure.

3. The Doble has no pilot light (the mixture is ignited by electric spark). The Stanley has only a pilot light for ignition.
4. The Doble uses kerosene for both starting and running. The Stanley uses gasoline for starting, kerosene for running.
5. The Doble slide valve is used only for admission of steam to the engine cylinder. The Stanley slide valve regulates both admission and exhaust.
6. In the Doble the exhaust steam goes direct to the radiator. In the Stanley, the exhaust passes through a feed water heater before it goes to the radiator.

Features of the Doble

Sectional boiler: 20 sections used for generating steam and 8 sections used for feed water heater or economizer.

Absence of pilot light: This is a radical departure from the usual construction.

Kerosene for starting, as well as for running.

Wide pistons: Necessary on account of the pistons having to open and close the exhaust port (similar to a 2-cycle gasoline engine). This is termed the uniflow principle.

Absence of eccentrics: The valve gear is a modified form of the "Joy valve gear" in which modification the "correcting" and "anchor links" are eliminated, thus simplifying the construction.

Final drive (gear ratio): Almost 1 to 1, viz., 47 teeth in the drive gear and 49 in the differential.

A condenser is provided so that the steam is reconverted into water, and is used over and over again.

Lubricating oil is mixed with the water for lubrication of the cylinders. (Doble-Detroit Steam Motor Car Co., Detroit, Mich., manufacturers.)

Other steam car manufacturers: Gearless Steam Auto Mfg. Co., 635 Symes Bldg., Denver, Colo.

OWEN MAGNETIC CAR (ELECTRIC TRANSMISSION)

The Owen Magnetic makes use of an actual electric transmission, known as the Entz. The arrangement of this system permits the changing of all speeds by a small lever similar to a spark lever mounted on the steering wheels. The **difference between this and other gasoline cars** lies in the magnetic transmission.

Elementary Principle

Refer to Fig. 14: (A) shows a magnet with a "keeper" at bottom, familiar to everyone. (B) is a magnet and pedestal with a hand crank to revolve it.

(C) is a piece of steel on a pedestal placed within the magnet on the same line of travel. It will be apparent that as the magnet is revolved by turning the crank, it will attract the piece of steel which will revolve with it.

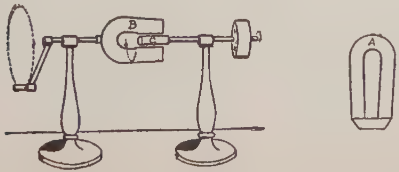

Fig. 14

Refer to Fig. 15: (B) is now revolved by the gasoline engine instead of the hand crank, taking the place of the flywheel, and revolves at engine speed regulated by the throttle. To describe it, we will now call (B) a revolving field.

(C) is now part of the propeller shaft, and to describe this, we will now call (C) an armature. When the car is running in "high speed," (C) follows (B), because it is magnetically locked, but it will be noted that we are **driving through an air space or gap,** there being no mechanical connection at any time between the rear axle and the gas engine, but only magnetism transmitting the torque of the gas engine to the rear axle.

When arriving at a grade which is too steep to climb on "high," we should now stall our gas engine unless we applied a form of speed reduction.

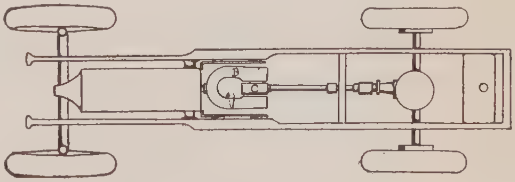

Fig. 15

Refer to Fig. 16: The conventional electric motor (**D**), as shown, gives us the reductions needed in the following manner:

We now drive through what is in effect a slipping clutch, and it is apparent that if it were possible to use the power that is lost in heat through the friction of the slipping clutch in the gear type of transmission car, all the power of the engine would be transmitted to the rear wheels and there would be no use for a gear box.

The magnetic transmission gives us this result, as we now find that (C) is trying to keep up with (B), but as (B) and (C) now have ceased to be magnetically locked, because we have changed the position of the control lever on the steering wheel, and are therefore slipping, the difference in their relative speeds generates electricity which is led to (D).

Armature (E), being of the same form as (C) and on the same propeller shaft, takes the electricity generated by the slip, and acts as a power booster on the propeller shaft, giving us innumerable speed reductions, wonderful flexibility, and absolute silence at all speeds.

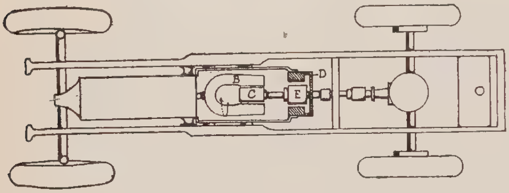

Fig. 16

The large horseshoe magnet (B) (Fig. 16) is revolved by the engine. The magnetic lines of force create a drag on the armature (C) which carries the armature with it. By elaborating on the construction as shown, the slip energy created by the difference in rotating speeds of magnet (B) and armature (C) is converted into potential electric force and carried to the motor whose field coils are shown as (D) and armature (E).

Control Lever Positions

Charging: Car stationary, engine running. Generator charging starting and lighting battery; seldom necessary, as battery is automatically charged on high-speed position when the car is in motion.

Starting: Current from the starting battery operates the generator as a motor for the starting engine. When the engine has started, bring the lever to neutral position.

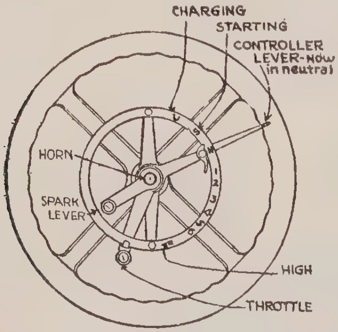

Fig. 17. Control lever positions of Owen Magnetic Car.

Neutral: Car stationary, engine running. The clutch generator circuit is open, and the motor is short-circuited on a resistance. Bring the lever to first position.

First position: Generator producing light clutching effect and maximum current for electric motor. The result is a maximum difference between engine speed and car speed, producing greatest torque or pulling power.

Second position: The clutching effect of the generator is increased and the supply of current to the motor is decreased. Result: the car speed is increased.

Third position: The clutching effect of the generator is further increased and more of the driving power is transmitted. The motor does correspondingly less work. Result: an increase in car speed.

Fourth position: The generator continues to transmit more and more of the driving power, the work of the motor gradually decreases. Result: car speed increases.

Fifth position: The same general action. The generator is carrying nearly all the load, while the motor is practically idling.

High: On this position clutching effect of the generator has increased nearly to the locking point, transmitting all the driving power. The motor no longer assists, but operates only as a generator to charge the starting and lighting battery.

The gear ratio on the Owen magnetic car, 7-passenger, is 4½ to 1, and on the 5-passenger car, 3½ to 1.

Principle of Construction

In place of the flywheel, clutch, gearset, starting and lighting system, and their auxiliary parts, two direct-current dynamo machines and a drum controller have been substituted.

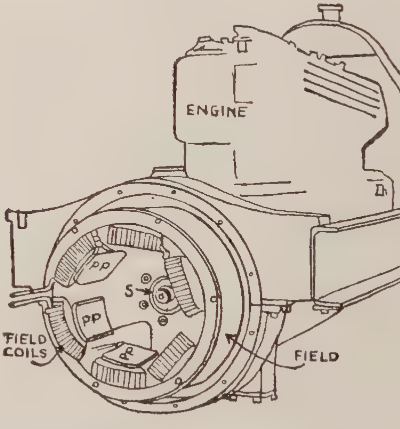

Fig. 18. Field coils, etc., of the electric transmission system forming the flywheel of the gasoline engine, as mounted on the Owen magnetic car.

Clutch generator: One of the dynamo machines has its field magnet frame directly connected to the engine crank shaft, taking the place of the ordinary flywheel (Fig. 18). The armature of this machine is mounted on a large, hollow shaft, which is directly connected to the propeller shaft (Fig. 19). This machine is called the "clutch generator," as it acts both as a clutch and as a generator. There is no mechanical connection between the engine and the rear axle; it is connected through an "air gap," which is entirely a **magnetic** connection.

The motor: The second dynamo machine has its armature mounted on the same hollow shaft as the first, and its field magnets are stationary; it is called the "motor," as it is generally used as a motor to help drive the propeller shaft, and to boost the effort of the engine as transmitted through the clutch generator, which, like any clutch, can transmit only the engine effort or torque.

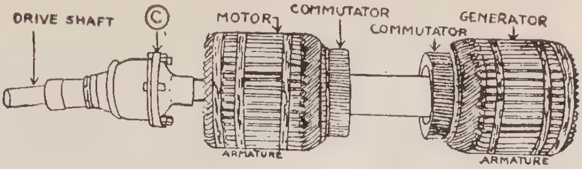

Fig. 19. Armature of motor and generator attached to the propeller shaft, as on the Owen magnetic car.

The clutch generator is used as a clutch alone, on the **high speed,** when it is short-circuited upon itself, and a small speed difference between armature and field, or a small slip, is necessary to establish the current in its windings which energizes it and causes it to act as a clutch.

On the **high-speed** position the **motor** plays no part in the transmission of power, but is used as a charging generator for the storage battery, which later is used for cranking the engine and for the electric lights.

The electric motor aids propulsion. On all power control positions other than the high, the motor helps turn the propeller shaft, by taking current from the clutch generator in which circuit it is included. At these times the slip in the clutch generator is greater than is needed to energize it as a clutch, and the **additional slip produces the current required for the motor,** which it utilizes for giving additional turning effort to the propeller shaft.

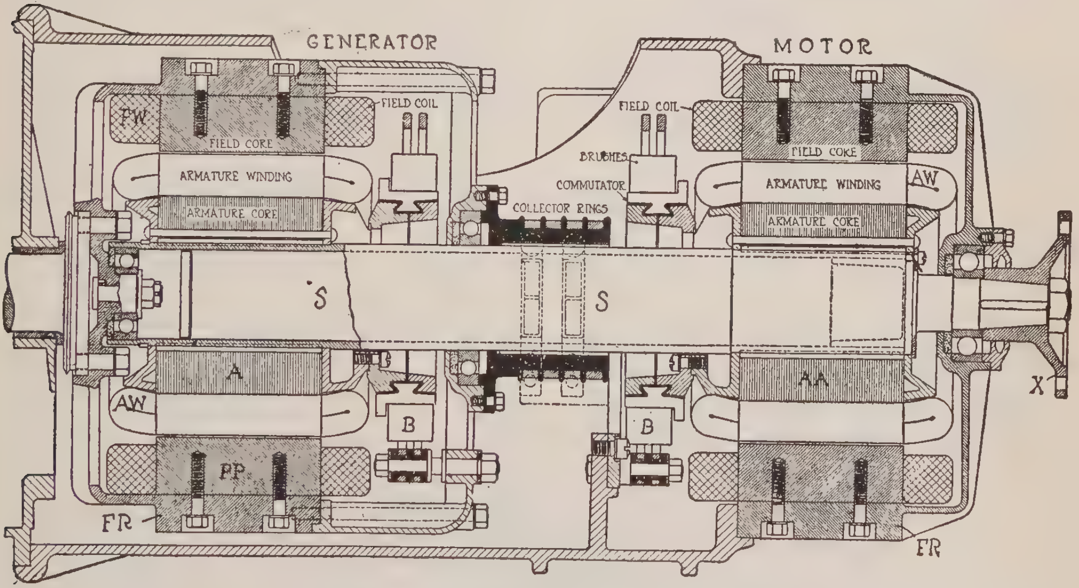

Fig. 20. **Section through Owen-Entz electric transmission.** Generator field cores and coils form the gasoline engine flywheel and the collector rings shown are for the purpose of connecting the field-current of the generator to the various circuits. The brushes of the generator revolve with the field. The two armatures are identical, and both are keyed to the hollow shaft which is attached to the propeller shaft and has no connection with the gasoline engine. (*Motor Age.*)

The different graduations of speed and torque are controlled by the relative strength of the generator and motor field. The weaker the generator field compared to the motor field, the greater the slip, and the more electrical energy goes to the motor for producing greater torque.

Besides the positions of power control, there is a neutral position in which the clutching effect is cut out, but the motor is so connected, through a resistance, as to act as an electric brake, in which case it becomes a generator, taking power to drive it, and so braking the car.

This brake is most effective when the speed is highest, and is ineffective below 15 m.p.h.; it will hold the car on any mountain grade to 20 m.p.h. without wear of any parts, and can be applied with the car going 60 m.p.h. It cannot hold the wheels, and there is little danger of skidding, as the braking effort disappears at speeds below 15 m.p.h.

Manufacturers of this car are the Owen Magnetic Motor Car Corporation, Wilkes-Barre, Pa.

Parts of Owen-Entz Electric Transmission as Shown in Fig. 20

FW—Field windings
FR—Field rings (the fields FR may revolve without any motion of A).
S—Continuous shaft.
X—Coupling connected to the drive shaft.
PP—Pole pieces.

FUNDAMENTAL PRINCIPLE OF AN AIRPLANE

There are two essential factors necessary in order that the airplane, a heavier-than-air machine, rise from the ground. They are **thrust** and **lift.**

There are two factors which offer resistance to the airplane rising from the ground, they are known as **gravity** (resistance downwards) and **drift**[1] resistance horizontally, also known as "head-resistance").

The aerial screw or propeller produces the thrust through the air, which overcomes the resistance or drift. The **lift increases** as the speed of the thrust increases, therefore **gravity** is overcome and result is the wings have a lifting effect, produced as will be explained.

It is well to note that, for an airplane to be supported in the air, it is essential that it be kept in motion through the air and not by the motion of the air past the airplane stationary. In other words, the mass of air engaged, the velocity, and force with which the wing surfaces engage the air, is the theory advanced for the support of the plane in the air.

How this lifting effect is brought about, is explained as follows:

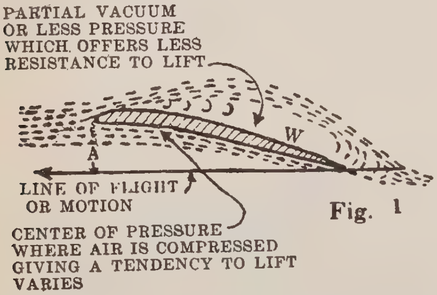

Fig. 1

Supporting and lifting effect under wing: The wing surface is (W) (Fig. 1). The horizontal line we will call the direction of line-of-flight-or-motion." The dotted lines represent the wind or air current, and at another point, say one-third of the way back from the front or leading edge of the wing tip, is the "center-of-pressure," which varies. As the bottom of the wing meets the air, it results in the air striking the under part of the wing, when it is compressed, causing the compressed air to push[2] **up** against the under surface of the wing. The air is gradually diverged downward, thereby giving the wing its supporting effect.

Lifting effect above wing: Over the upper surface of the wing the opposite action is taking place.

Instead of pressure above the wing, the theory is that a **partial vacuum** is created by the air striking the forward edge of the wing and being deflected upwards and over a greater part of the wing surface, as shown in Fig. 1. In other words, there is very **slight** air pressure above. The result is that if the pressure below the wing is greater than above it, and a partial vacuum is created above the wing, the mass of air engaged under the wing by motion produced by the thrust of the propeller, will cause the wing to have a **lifting** effect. This is the fundamental principle of flight.

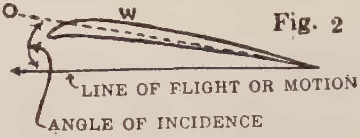

Fig. 2

The angle between this line (O) (Fig. 2) and the line-of-motion is termed the **"angle of incidence,"** and right here, together with the curve or camber of the wing, is what governs the lifting capabilities of an airplane, of course assuming that the thrust is equal.

Parts of an Airplane (Fig. 3)

1. **Propeller** or aerial screw.
3. **Radiator.**
5. **Cock-pits.**
6. **Fixed horizontal stabilizers** to buoy up the tail when flying, as the rear of the machine has a tendency to drop tail down when the wings at the front are at an extreme angle to the wind.
7. **Elevators** for ascending or descending; controlled from the cock-pit. Elevator **up** causes the machine to ascend, and **down,** to descend.
8. **Rudder,** controlling the direction or turning. The rudder is hinged and controlled from the cock-pit.
9. **Ailerons** produce side or lateral tilt. Used to balance the machine if inclined sidewise.
10. **Wing surface** or aerofoil.
11. **Body: Fusilage** is the frame work, separate from the wings. Chassis or landing gear are wheels underneath (not shown).

---

[1] Drift also refers to resistance offered by the shape of wings, struts, etc., or any other factors which would have a tendency to oppose lift.

[2] The air must meet the wing surface at such an angle that a downward velocity be given to it after the plane has passed over it. The actual velocity required will depend upon the weight to be carried and the supporting surface that is used.

The machine will slightly "nose-down" when the power of the propeller or thrust is off. If nosed-down too much, descent will be too rapid; thus elevators are then used and the machine glides to a landing.

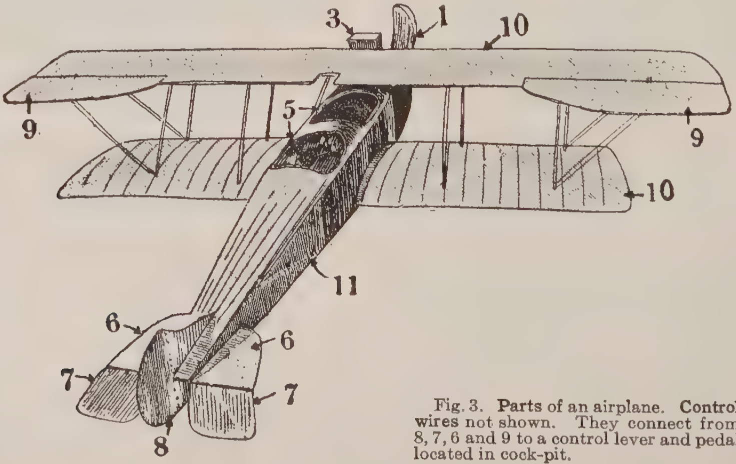

Fig. 3. **Parts of an airplane. Control wires** not shown. They connect from 8, 7, 6 and 9 to a control lever and pedal located in cock-pit.

INSTRUCTION No. 81

REMODELING OLD CARS: Speeding up Old Cars; Redesigning and Speeding up a Ford; How to Make a Motor Sled

DESIGNS FOR REMODELING OLD CARS

The following suggestions and illustrations are from *Motor Age*. Details as to construction are not given.

The different methods employed are shown in the dotted lines. For instance, in the Buick model "30," the idea is shown whereby bucket seats are installed and a cowl is built around the seats. The gear ratio is changed to 2¾ to 1.

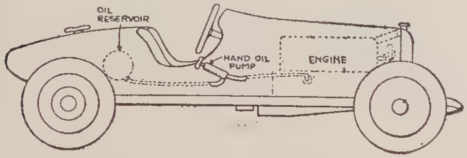

Fig. 1. Suggested method of connecting oil pump on side of racer body with oil tank in rear and motor crank case.

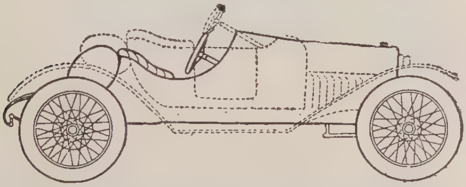

Fig. 2. Sketch showing how a model "30" Buick may be stripped down into a speedster.

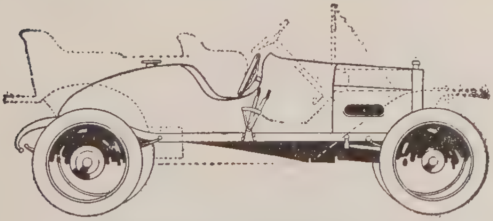

Fig. 3. Speedster body for model "19" Haynes.

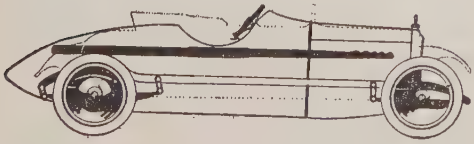

Fig. 4. Mercer with body similar to Mulford's Frontenac.

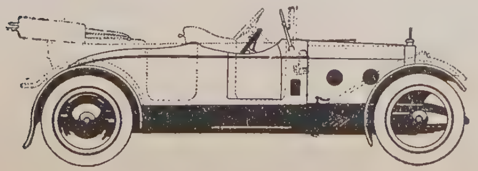

Fig. 5. Suggestion for roadster design for early Pierce-Arrow.

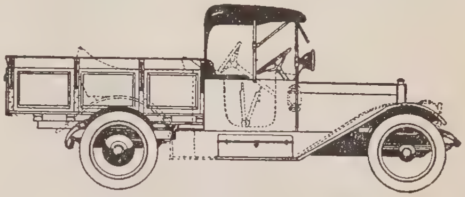

Fig. 6. How a farm truck might be made from an old Winton.

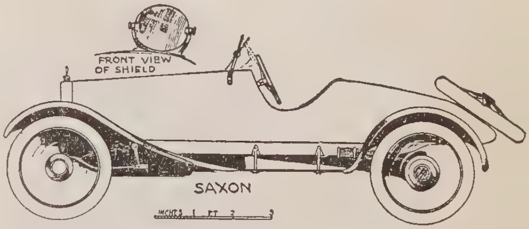

Fig. 7. Speedster body on Saxon "six" designed after ideas of *Motor Age* reader.

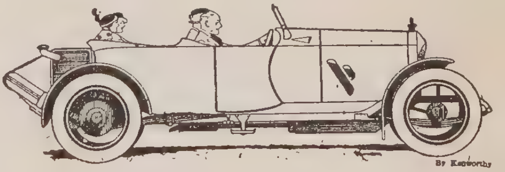

Fig. 8. An exclusive *Motor Age* design for a four-passenger touring roadster.

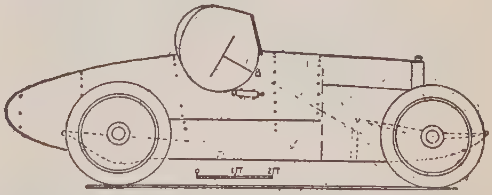

Fig. 9. Diagram showing how a *Motor Age* reader rebuilt an early model car.

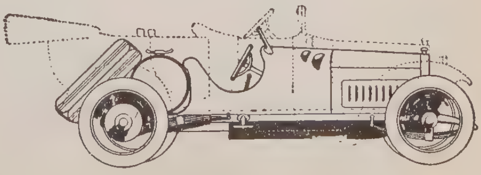

Fig. 9A. Speedster body for early model Cadillac "eight," with cantilever springs to reduce overall height.

REDESIGNING AND SPEEDING UP OLD CARS

Generally speaking, the replacing of the old body with a raceabout type is the most important consideration in rejuvenating an old body, but usually the steering column has to be lowered and sometimes a leaf removed from each of the springs to make up for the lighter body, although this latter is not essential by any means. All too often, old cars have springs that are too weak for the heavy bodies with which they were originally burdened, and these prove just about right for the lighter bodies.

Changes in the valve timing are often made to assist in the speed possibilities, and sometimes different axle gears are used so as to raise the ratio between engine and wheels. It must be borne in mind, however, that many chassis and engine changes of this kind will work to the disadvantage of the car for slow running. They will serve to make the machine faster, but they hamper the engine's ability at low-throttle running. In other words, it will not have the proper flexibility on high gear.

The body being the first consideration in making a speedster, it might be well to take up some of the possible designs. For Fords the combinations offered by concerns making a business of this kind of work are indeed attractive. You can get a complete outfit of radiator, hood, floor boards, rear gasoline tank, and body in the neighborhood of $100, and it is surprising what a difference these make. Other concerns make a specialty of the body proper, exclusive of radiators, hoods, tanks, etc., and it is also possible to get bucket seats alone, so that, with a little ingenuity, quite a presentable racy roadster can result from combinations with old chassis.

Dressing up the cars: The illustrations shown here are suggestions as to how to dress up the chassis in several ways. Many of the most attractive of the types that have come to our attention have been made by enthusiasts, with the assistance of a tinner or other tradesman of similar experience. The usual form of racing roadster is shown in Fig. 10.

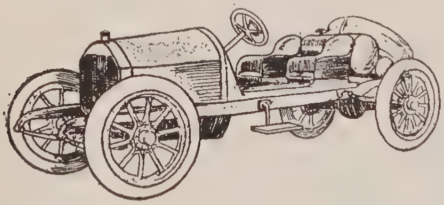

Fig. 10. Usual form of racy roadster with bucket seats.

This has bucket seats that are attached directly to the floor, with gasoline and oil tanks and tires carried at the rear in a way that adds to the appearance. The dash is sloped slightly, and the steering wheel brought down, so as to make steering easy with the seats in this low position. Sometimes running boards and mudguards are entirely eliminated, as shown, with steps at the side to assist in getting into the car, while often the owner prefers to have the mudguards as a matter of protection. They retard the speed a little where fast driving is the thing most sought, but it is a question if they do not also add to the appearance. Usually the hood is sloped somewhat as an added feature. Undoubtedly a high, narrow radiator also does its part in improving the looks, but this is carrying the alterations to an extreme.

Wind resistance is quite a factor in hampering the speed of a car, far more of a factor, in fact, than most motorists realize. To attain greatest speed, the head resistance, by which is meant the surface against which the wind strikes, must be made as small as possible, and the body must be so smooth along its length that there are no obstructions against which the wind can strike and thus form eddies. In other words, the air should be allowed to slide along the body without having to come in contact with lamps or other obstructions.

Getting streamline effect: This is the streamline idea, and in order to carry it out best, the radiator should be as narrow as consistent with proper cooling, the hood should slope, and the rear should taper. If a taper tail is fitted, this forms the most perfect form of body, so far as wind resistance is concerned, providing the rest of the body conforms with it. Tires and gasoline tanks obstruct the air, and wherever possible they should be placed within the tail, if one is fitted. It is not always easy to keep some parts from offering wind resistance, for generally the spare tires have to be carried outside. Two body designs that carry out the wind-resistance reduction theory very well are shown in Figs. 11 and 12.

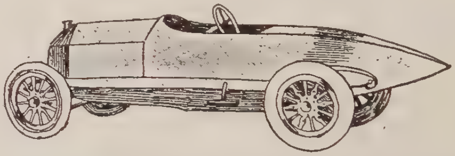

Fig. 11. Type of body designed for minimum wind resistance.

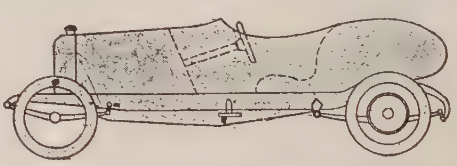

Fig. 12. A suggested body design for class and wind-resistance-lowering.

Thus, even if the engine and gear ratio are not altered at all, more speed is obtainable by cutting down the wind resistance and fitting the lighter body. Usually from 10 to 15 miles per hour are added to the possibilities of the vehicle by these changes alone, and sometimes, with the engine specially tuned for speed work, though timing and valves are not altered, it is possible to get even more. The reduction in wind retardation, however, permits of raising the gear ratio sometimes where it would not be practicable to do so otherwise. Often if a car is fitted with a standard ratio of 4 to 1, say, this can be raised to 3 to 1, if the other factors have first been changed.

One of the mechanical points that can be changed is **the carburetor setting,** adjusting it so that while it may not allow the engine to throttle down so well, it works better at the higher speeds. Usually this is the result of making the mixture leaner, and it ordinarily has the added advantage of preventing the engine from getting so hot.

The magneto or other ignition apparatus can also be altered to conform to the higher speeds, this usually being a matter of setting the timing ahead a slight amount, the exact extent of which depends entirely upon the engine.

More power, and consequently more speed, is often obtainable by reducing the vibration through accurately balancing the pistons. In other words, a set of pistons each of exactly the same weight should be used if possible. Often speed bugs have gone so far as to drill the connecting-rods in order to lighten these reciprocating parts as much as possible, but this ordinarily is not advisable, for the rods are undoubtedly weakened thereby, and not being designed for such treatment, they often will not stand the strain (determined by the amount of stock in the rods).

Extra lubrication is often advisable where the owner wishes to maintain excessively high speeds for any length of time. This can be attained very simply by rigging up an auxiliary supply that will feed directly into the crank case. An easy scheme to employ is shown in Fig. 13. A hand pump is pivoted to the floor of the car as indicated, and an air line runs from it to the top of the oil tank at the rear. The delivery pipe from the oil tank to the crank case runs from the lower side of the tank, and thus the air pressure, coming from the hand pump, forces the excess oil to the engine.

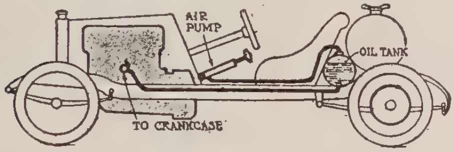

Fig. 13. One way to fit an auxiliary oil system when the tank is at the rear.

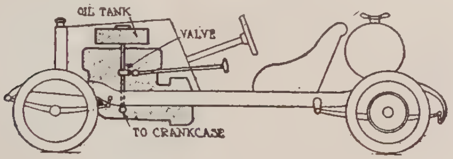

Fig. 14. Extra oil tank at top of motor, supply from which is controlled by a valve.

Sometimes an auxiliary oil tank is fitted to the engine and under the hood, if there is room. There is a pipe connecting from the bottom of this to the crank case, and a valve is interposed in the pipe to allow of controlling the oil from the seat by means of a rod.

Such auxiliary devices as these and the altering of the cam shaft and valves are extremes to which the average man cannot go, although they are conducive to surprising results where intelligently carried out. (*Motor Age.*)

Racing-Car Exhaust Effect

The low rumble in the exhaust of a racing car is due generally to the design and construction of the engine. One method of obtaining this effect is to magnify the sound as in Fig. 15.

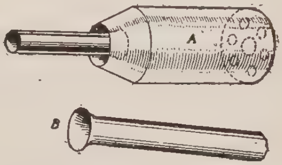

Fig. 15. Noise-amplifying exhaust to give racer sound to small engines.

This shows a large sheet-steel cylinder, (**A**), fitted with a conical-shaped head into which the exhaust pipe is led as shown. The end of the exhaust pipe should be flared, as shown at (**B**). The rear end of the cylinder (**A**) is covered with a metal cap into which several holes have been made.

We have seen this arrangement used very successfully on a small high-speed engine, the exhaust of which sounded like a high-powered racing car. Many of the racing cars give out a metallic-sounding exhaust because the exhaust pipes and headers are made of thin metal. This thin metal will vibrate under the periodic exhaust impulses and set up a peculiar ring of its own. Of course, the thinner the exhaust pipe, the better will be its radiating effect.

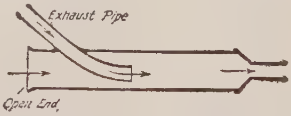

Fig. 16. To increase efficiency of exhaust for racing a method is to run pipes, with gradual bends from each exhaust port, to an expansion chamber. The pipe leading from expansion chamber to the rear should have a gradually increasing diameter to permit gases to expand as they cool.

SPEEDING UP A FORD[1]

As I have helped in rebuilding several Fords that turned out exceptionally fast for the money invested in the job, I believe that I have gained some experience that may be of value to others, so will set down what I have learned, and it may be taken for what it is worth.

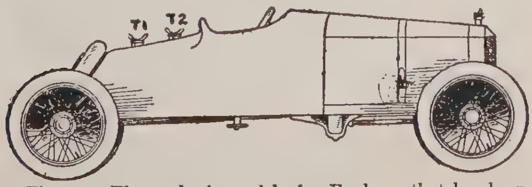

Fig. 17. The author's model of a Ford car that has been made fast.

There have been a few jobs turned out that ran into the thousands, you might say, and that were Fords in name only when finished. Of these I shall have little to say, taking it for granted that what is wanted is something that is within the ordinary man's reach, both in a pecuniary way and, if he delights in doing his own work, in a mechanical way.

Division of Work

The work naturally divides itself into two parts, the engine and chassis, or the running gear. I will discuss the engine first, it being the most important part.

Engine

The engine, as it comes from the factory, has bored cylinders, and as it is impossible, especially in a commercial way, to bore a perfectly true cylinder, the first thing you should do is to have your cylinders reground by a competent machinist, one who makes a specialty of this sort of work. Then you have a set of cylinders that are in line, have equal bore all the way through, and are as near round as it is possible to make them.

---

[1] From *Motor Age*, by Mr. E. B. Williams.

The pistons I have used were cast of aluminum alloy, of course, and were equipped with non-leaking rings. Whatever make is purchased, or if you have them made to order, see to the following things: There should be a rib or "reinforced run" from the piston-pin boss up to the piston head on the inside. Also several ribs should be cast across the inside of the head. This both stiffens the piston and helps in carrying away the heat from the explosions. If you have the pistons made to order, it is advisable to have them cast and machined for two rings rather than three. This cuts down ring friction, lightens the part, and will hold compression as well as three or more rings, if properly fitted.

In fitting the piston, plenty of clearance must be given—from .007″ to .008″ at the top being about right. This may seem excessive, but remember that the expansion of aluminum is much greater than of cast iron.

This large clearance may lead to oil pumping and foul plugs, and so I have always turned and drilled an oil groove in each piston just below the lower ring groove, as shown in Fig. 19. The grooves are about 1/16″ deep and 3/16″ wide, having the lower corner rounded off. There are eight ⅛″ holes drilled through the groove at equal distances around the piston, slanting down toward the inside. The top corner of the ring should also be slightly rounded.

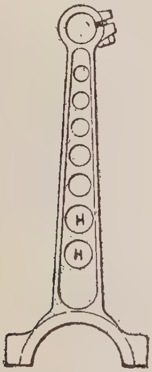

Fig. 18

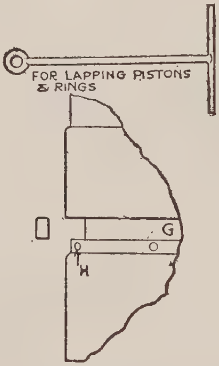

Fig. 19

Fig. 18. The connecting rod has been lightened by dressing with a file and drilling holes through the inside web.

Fig. 19. The tool at the top can be used for lapping the pistons and rings. At the bottom is illustrated the preparation of the piston and ring to prevent oil going into the cylinder.

As the piston goes up, the rounded edge of the ring and the groove tend to slide over the film of oil on the cylinder wall, while in going down, the sharp lower edge of the ring scrapes the oil in the grooves and it runs through the holes to the inside of the piston, and thus back to the crank case.

Lapping Rings to Fit

The rings should be of some good non-leaking type, or at least be step cut. Fit them in the cylinder with a gap of about .004″, then lap them to a fit. In lapping them in, they should be placed on an old piston (cast iron is best), and worked back and forth in the cylinder, keeping the cylinder walls well covered with a mixture of exceedingly fine carborundum, or some other abrasive, and oil. As the piston is moved back and forth, give it also a slight rotating movement. I have used a tool similar to the one shown in Fig. 19 for this purpose. The wrist pin goes through the hole shown.

This is a long tedious job, but you will be well repaid if it is properly done. It takes from 1,500 to 2,000 miles to wear in a set of rings under running conditions. Be sure to get all the abrasive from the cylinder walls and rings after the lapping is finished, or it will continue after the engine is running.

Treatment of Connecting Rods

You can **lighten the connecting rods** considerably by dressing them up with a file and drilling several holes through the inside web. This does not dangerously weaken them, judging from my experience. Do not drill any holes in the last inch toward the bottom, as this is where the most strain comes, and anyway, this part of the rod is more of a rotating than a reciprocating mass. In one car the rods were chucked up and the lower ends turned out and bearings (made of Kelly metal) were cast, turned to fit and installed. After 2,500 miles of driving, most of it at high speed, the engine was torn down and these bearings showed practically no wear. This metal, if used, must be fitted with plenty of clearance.

Large Valves Are Better

You will secure better results if the valve ports and pockets are turned out and larger valves are used. No trouble is liable to be encountered in boring the seats and ports from the top, but when going in from the side the tool will sometimes break through, and you will have to have the hole welded. It is best to do this before regrinding the block, as the heat, if welding is necessary, will warp the walls surrounding the weld. The ports can be enlarged 3/16″, and this is necessary if you expect good results. I have used tungsten steel valves, giving the stems plenty of clearance.

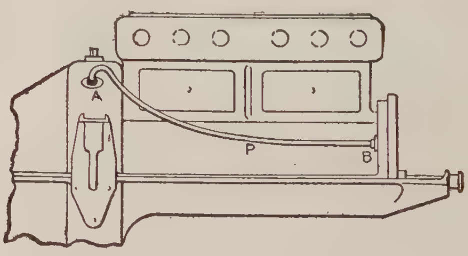

Fig. 20. One auxiliary oil system.

The valve springs must be stiffened considerably, either by installing heavier springs, or by placing spacers between the upper ends of the springs and the cylinder casting.

It is good practice to install adjusters, using the kind that screws into the valve push rod, it being necessary to anneal, drill, and tap the rod. While you are about it, drill the length of rod to the head, but not through. This lightens the part and cuts down inertia, thus helping the valve to close more quickly.

Cam Shaft

At this stage we come to the cam shaft, which should be of the high-speed type if you can afford it, several different makes being on the market. I have secured good results with shafts taken from Ford cars of early vintage. You will find them considerably different from the new type. If the regular shafts are used, do not try changing the timing, as one tooth on the coarse-pitched timing gears of the Ford throws the timing out too much.

Remove Magnets

Leave out the magneto armature coil assembly, and remove the magnets from the flywheel, screwing back the brass screws and brass magnet supports only. It will be necessary to shorten the screws a little. They will kick up almost as much oil as the magnets, and considerable drag will be removed.

Crank Shaft

Now see that the crank shaft is perfectly true; then assemble the crank shaft and gearset and try out in the lathe, first seeing that the bushing in the driving-plate assembly is a good fit on the gearset shaft. If there is any wobble, it will probably mean turning up both sides of the gearset-shaft flange and the back side of the crank-shaft flange. Now reassemble, and turn up the flywheel if necessary to make it run true. Take out the assembly and try on two perfectly level knife-edge testing bars for balance. If one side of the flywheel turns down, take out the material on that side until the wheel stays where you turn it. This may seem a lot of trouble, but it is essential that these parts be true and in perfect balance.

Gearset May Affect Bearings

The power and added strain at high engine speeds will sometimes cause the gearset to whip out the babbitt bearing at the rear in what is called the front ball cap. This will in turn loosen up the rear main bearing. I have found it advisable to turn out the ball cap and equip it with a bronze bushing, fitting it rather loose on the gearset driving-plate, assembly shaft to give lots of room for oil.

Lubrication

It is good practice to fit some auxiliary oiling system besides the gravity one with which the Ford is equipped. If money is no object, a force-feed system can be installed, which should have leads running to all four cylinders, being tapped through the walls on each side near the bottom of the cylinders, and also a large lead running to the front of the crank case. I have secured good results by cutting a ⅞″ hole near the top of the gearset case on the right side, and running a piece of brass or steel tubing, also ⅞″, to empty into the timing-gear case as shown in Fig. 20. The front end need be only a snug fit in the case, but the rear end must have a flange which can be bolted to the gearset cover, using a gasket between. A sheet-iron partition can be installed just back of No. 4 cylinder. This can be made as high as it is desired to carry the oil level under the connecting rods. Of course, every car intended for long distance should also have a hand oil pump convenient to the driver which will force oil from the reserve oil tank to the front of the engine.

High-Tension Magneto not Used

While I believe a good high-tension magneto to be the best ignition on earth, I have discarded it in Ford work on account of the additional power needed for driving. Turning a magneto armature over at two or three thousand revolutions a minute requires more power than is generally thought, in my estimation. I have used a battery-distributor system because it is light, is easily driven, and works on the open-circuit idea, thus requiring only four or five dry cells for current.

Cooling

Some additional cooling is needed. I have found the large "V" honeycomb type of radiator to be best. You will find that it will probably be unnecessary to use a fan with one of these. If you are building a streamline body, it will be better to have some radiator maker build one of the tall narrow kind to order, or you may purchase a stock radiator. If it is necessary to use the original radiator, have a good tinsmith build on an extra tank to the top, either back under the hood, or point it and extend it out in front. Anyway, the original equipment must be improved upon for fast work.

Carburetion

For a carburetor I recommend a 1¼″ type, with a 1¼″ built-up steel-tubing manifold. The one illustrated in Fig. 21 has given good results. No cast manifold is efficient, as the rough surface inside, with possible fins and irregular turns, seriously hampers the flow of gas.

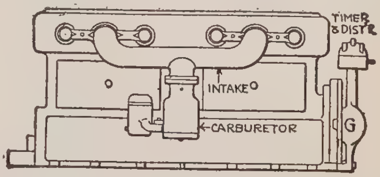

Fig. 21. Ford block showing installation of built-up manifold, carburetor, and ignition apparatus.

Air Pressure on Gasoline Tank

It will be necessary to use air pressure on your gas supply, as the carburetor should be set high, thus shortening the manifold.

Inlet and Exhaust Manifold

Each end of the intake manifold has a collar brazed or welded about 3/16″ from the end; so also the exhaust pipes, which are of steel tubing and run straight out through the hood. A copper-asbestos gasket is slipped over the end of the manifold and makes a tight fit between the collar and the cylinder casting. The manifolds are held on by crows' feet, which slip over the original studs and bear against the outside of the collars.

Running Gear

When we come to the running gear, we have two things to consider: If the car is to be used for fast track work only, by all means lower it. But if you want it for other work too, you will probably have to leave it up in the air, and sacrifice some efficiency.

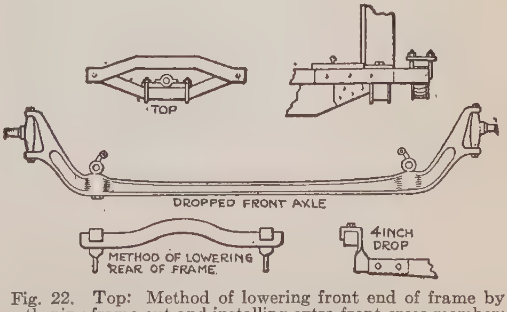

Fig. 22. Top: Method of lowering front end of frame by lengthening frame out and installing extra front cross-member; center: dropped front axle; bottom: method of lowering rear end of frame 4 in.

The best way to lower the front end, to my notion, is to have a new axle made similar to the one illustrated (page 1027, Fig. 22). It leaves your frame strong and rigid, and an added advantage is that your radius rods are still in a straight line.

The rear end of the frame can be lowered by cutting off the side members just in front of the rear cross-member, and using steel forgings as shown in Fig. 22.

The front end, if a cheaper construction is desired, may be lowered as shown in Fig. 22, by riveting pieces of channel iron on the sides of the frame, letting them stick out in front about 5 inches.

An extra cross-member, similar to the regular Ford front cross-member, but with a high instead of a low center, is riveted across the front to the two new side-extensions. This sets your front axle ahead enough to clear the radiator, and the amount of frame drop depends on the shape of your new cross-members (as can readily be seen) which carry the spring. With this method it will be necessary to lengthen out your radius rods and the starting crank.

Assembly Should Be Kept Rigid

In tilting the steering post, it is desirable to keep the assembly as rigid as possible. Have it bolted to the dash securely, blocking behind the dash plate with a wedge-shaped piece of hardwood shaped to fit the space caused by lowering. It will be necessary to drill a new hole in the side of the frame for bolting down the bracket. You can block under the bracket where it tips from the frame with steel washers before bolting.

Steering

The steering-gear connecting rod and the spindle-arm connecting rod should both be stiffened. An easy way to do this is to place a piece of small channel iron or steel tubing alongside the rod and bind the two together with several layers of tape, taping the whole length of the rods, and then shellacing the whole job. This is cheap, easy to do, and makes a permanent job.

Axle

See that the axle tips (casters) **toward the back of the car at the top.** The nearer vertical the axle is set, the harder it is to steer, and when the top of the axle gets ahead of the bottom, it is almost impossible to keep the car in the road.

A good gear ratio for a car put up like this one is about 2 4/7 to 1. While I have always made my own special gears, several concerns are making and advertising them. Some makes sell for $15.

While you have the rear end down, see that the **differential gears** are a good fit on the inside ends of the axles. These sometimes get loose and tear the key seats out of the axle.

The rear hub brakes on the Ford were only intended for holding the car when standing still, and if used when running, they do not last long, and are not very efficient at that. The best brakes I have used so far were secured from Los Angeles, Cal., costing $16 per set. They have large drums and external contracting bands lined with raybestos.

Be sure to see that the **transmission bands** are a perfect fit on the drums and are not adjusted too tight. They can set up quite a drag if not properly set.

Speed thus Obtained

I had one of these cars do 68 m.p.h., and another one equipped with wire wheels 71 m.p.h. Of course, if economy is no object, a new cylinder head with overhead valves and cam shaft, wire wheels, etc., can be added, the stroke lengthened, and in this way a few miles per hour can be gained, but for the man of moderate means the foregoing described car will go fast enough and furnish lots of pleasure in the building.

Cost

The job I have described will run from $200 to $350, depending on how much of the work the builder is able to do himself.

I have not taken up **the construction of the body,** as that depends upon the taste or ability of the man who is building the car, and also upon the use to which it is to be put.

For racing, a pair of bucket seats and a gas and oil tank bolted to the frame will get by very well, but they are not comfortable or very clean. The body shown on page 1031 is good, being neat in appearance; it can be made comfortable, and offers little resistance to the wind. While it is not drawn to scale, the proportions are near enough right to give the idea. There is a gas and oil tank in the rear compartment, with the spare being slung on the extreme rear. This body should cost you about $150 at the average body builders.

Don't forget your **hood straps,** and have them very substantial.

ANOTHER EXAMPLE OF INCREASING THE SPEED OF A FORD[1]

Cylinders

If the car has been driven over two or three years, it will be probably advisable to have the cylinders rebored to the Ford standard of 1/32″ oversize. While this will add only about one-half horsepower to the engine, on account of the larger bore, the fact that the cylinder casting will have aged sufficiently to attain its permanent set will have more influence on the power of the engine than is often supposed.

Compression[2]

It is, perhaps, not generally known that the cylinder heads on the Ford cars have not always been the same. The **cylinder heads** used a few years ago were not as deep as those used on the latest models. To obtain higher compression (which is necessary for high-speed work), it will be well to secure one of these old-style cylinder heads. They can be identified by comparing them with cylinders of the latest type, using a depth gauge as shown in Fig. 23.

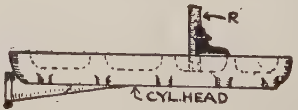

Fig. 23. Measuring depth of cylinder head.

---

[1] From *Fordowner*, by Mr. Murray Fahnestock.

[2] In different Ford races there was not a car in which attempts had been made to increase compression by reducing compression space, and cast-iron pistons seemed to predominate. Gear ratios used were from 2¾ to 3 to 1. For long races radiators were fitted with tanks for extra water capacity.

These high-compression cylinder heads give more power, but they are harder on the bearings and make the engine more liable to knock, so that many owners are very glad to trade them for cylinder heads of the latest type, if the difference is pointed out to them.

It is true that different compressions affect the power of explosions, and that an **uneven compression ratio in different cylinders will, consequently, cause an engine to jerk.** If the compression is excessively high, it can keep the spark from jumping the gap in the plug.

If the old-style cylinder head cannot be obtained, it is possible to plane off about one-eighth inch from the bottom of the cylinder head and thus increase the compression of the engine to about 70 lbs. to the square inch. The work must be carefully done, so that a true surface is obtained, or water leaks and loss of compression will result. Good gaskets should be used between the cylinder head and the cylinder blocks, so that no compression will escape. By the use of Prussian blue and a scraper, it is possible to fit the cylinder head to the cylinder block without the use of a gasket, thus reducing the compression space about 1/32″.

Unless the compression is the same, the engine will not be in good balance, and loss of power will result. The power lost when one cylinder does not fire is far more than one-quarter, and this is due largely to a loss of balance.

Valve Springs

One of the most important features necessary to obtain increased power is good valve action. Valve springs are cheap, and it pays to install a new set of valve springs occasionally, even if the old ones do not seem to be worn out. Lively springs close the valves promptly and this is especially necessary if the engine is to be run at high speeds. If it is to be used for racing and the last ounce of power is desired, it may be advisable to use special valve springs that are stronger than the regular type, but which are more apt to break the valves and are more noisy.

It is, of course, understood that the engine will be kept free of carbon and the valves ground frequently, if used for speed work.

Valves and Cam Shaft[1]

In order to obtain the highest possible speed, it is necessary that the valves be timed differently from what is standard practice. For racing, it is necessary that the valves be given a greater lift, that is, that they open farther, and that the cams be so designed that the valves be opened and closed more quickly. Now these quick-action valve cams cause greater wear and tear and make more noise. It is also true that the engine will not run smoothly on high gear at speeds of less than 20 miles an hour, so these special cam shafts are only of value when the car is used for racing only.

For use as a speedster, on average roads, the regular cam shaft is probably the best. It is easy to set the timing gears one tooth ahead and so to open the valves earlier, but this also means that they close earlier, and so little is gained by this practice.

It is sometimes asserted that the speed of the Ford engine is purposely limited by the small size of the ports or valve openings. This is probably done so that careless drivers will not run the engine too fast, but if it is intelligently handled, it is true that greater power can be obtained by enlarging the ports or valve seats. A wide seating for the valves is not necessary and tends to restrict the flow of the gases. One thirty-second of an inch is wide enough, but requires more frequent grinding and valve adjustment than a wider seating, as it wears more quickly under the hammering action of the valves. Fig. 24 shows how the valve ports may be bored out larger, but great care should be taken not to break through the sides of the water jackets, as the walls are not always uniform in thickness, due to the displacement of the cores when the castings are made.

Muffler and Carburetion

Getting a large charge of fresh gas in the cylinders for each explosion is one of the essentials of maximum power. Of equal importance is the necessity of getting the old burned gases out quickly. For this reason, a muffler is often omitted from racing cars, although a car cannot lawfully be operated without a muffler on the roads of many states. However, a cutout is easily attached, and if used in moderation, serves the purpose very well. If no muffler is used, the end of the long exhaust pipe should be somewhat flattened, so that the sound waves will be somewhat broken up as they emerge. A number of small holes, and diagonal saw cuts will also aid in giving a free exhaust without undue noise. Or, it is possible to remove one of the baffle tubes from the muffler, or to bore additional holes in the muffler tubes, so that a comparatively free exhaust is secured without losing the muffling qualities altogether.

Carburetion: To obtain the maximum speed from the engine, a larger carburetor, say the 1¼″ size, can be used. This will not be economical of gasoline, and the engine will not run as smoothly at low speeds, but with a larger carburetor and a larger intake manifold, which should be smooth inside, the engine can draw in fuller charges at high speed.

Pistons and Piston Rings

The piston rings certainly create friction as they rub against the cylinder walls, and if the top ring is so well fitted that no compression will escape past it, the two lower rings are unnecessary, as they cannot stop any gases that do not reach them. Some owners prefer to fit special or patented piston rings at the top of each piston and claim that it makes the engine run more freely. However, if only one ring is used, greater care must be taken to keep that one ring in good condition.

If the rings are fitted on an old piston, they may be lapped in by using emery, and a more perfect fit will be obtained, and then they may be placed on the new pistons for actual use. If lapped on the new pistons, the grooves (for the rings) in the pistons are apt to be worn.

Pistons: For high-speed driving it is necessary that the pistons should be rather a loose fit in the cylinders, as otherwise they are apt to seize when the inevitable expansion due to heat occurs. This does not mean that it is not necessary to rebore cylinders or to fit new pistons on old cars, for in such cases the cylinders and pistons are apt to be worn oval, due to the thrust of the connecting rod and so do not have the proper clearance all around.

Obtaining Balance of Engine

Light pistons are certainly an advantage, and the use of aluminum has much to recommend it, especially if new pistons are to be fitted in any case, as then the additional cost will not be so much. In case the cast-iron pistons are used, they can be greatly lightened by careful drilling, care being taken not to weaken them too much. Most of the holes should be drilled near the ends of the piston pins, for if drilled on the sides, where the thrust occurs, they permit the oil to be squeezed out and thus to spoil the lubrication where it is most needed.

---

[1] Sometimes the inlet valve is made to open slightly earlier for speed work. In this case the engine will not idle down very well.

Light reciprocating parts are the secret of high speed and power. If we consider structural iron work, we shall notice that beams are made very heavy along the edges where the strain occurs, and often the center is only a light lattice of thin steel strips (see Fig. 18, page 1026, for a drilled rod).

It is possible to balance the rotating masses of the engine, but it is not practicable to balance the reciprocating weights, except to a small extent. But by making the parts lighter, the unbalanced forces and power-absorbing vibrations are greatly reduced. It is more important to lighten the connecting rod at the piston end than at the crank-shaft end, because the piston end of the connecting rod has a reciprocating motion, while the big end bearing has a rotary motion.

Connecting rods: It is also important that the four connecting rods be of equal weight and that the four pistons have the same weight, so that they will tend to balance each other and to reduce vibration.

The **alignment of the connecting-rod bearings** is important. This can best be tested in special jigs which are part of the equipment of every branch of the Ford Motor Co. If one wishes to align these bearings, the piston pin can be placed in one end of the connecting rod, and a cylindrical pin, the size of the crank pin, placed in the other end of the connecting rod, and two steel squares used to make sure that the two bearings are in perfect alignment with each other (Fig. 25). This tests the alignment in one direction only and to test them in the other plane, it will be necessary to use the same tools and a perfectly flat surface, so that the distances from the pins to the plane surface can be measured and made equal on each side. See Index under "Alignment of pistons and connecting rods."

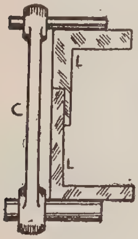

Fig. 25

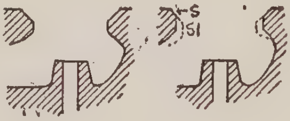

Fig. 24

Fig. 24. Increasing the port opening.
Fig. 25. Alignment of connecting rod.

Crank shaft: It is important that the crank shaft be in good running balance, which is different from being in balance when at rest. It can be tested by revolving the crank shaft at different rates of speed, between centers. The bearings of the crank shaft are also important, and, after they have been scraped to a good fit, the engine should be driven by an outside source of power until the bearings fit perfectly.

Flywheel: It hardly pays to reduce the weight of the flywheel, especially if the power of the engine is increased and a higher compression is used, but the flywheel alignment can be tested by holding a steel pointer near it when the engine is running, for a wobbly flywheel involves a loss of power.

Ignition and Lubrication

Ignition: For ordinary road use, the Ford ignition system will furnish about all the sparks required, but to obtain the very highest speeds, the more accurately timed sparks of the high-tension magneto are an advantage. If the Ford ignition system is used for high-speed work, the magnets and magneto-coil assemblies should be of the latest type and the vibrators should be adjusted more tightly, so that there will be less lag in the ignition. The spark can be advanced by bending the rod from the lower end of the steering column to the timer. It is also well to be sure that the timer is in good condition and that the spring holding the roller against the segments is strong and quick-acting. It may be even an advantage to fasten an additional spring beside the one already in place.

Lubrication: Adequate lubrication plays an important part in the maintenance of high engine speeds. A good quality of thin oil, which does not burn easily, should be used. Heavy oils exert a constant drag, and are not needed, if the engine is in good mechanical order. Oil holes can be drilled in the connecting-rod bearings and larger oil grooves can be cut in the bearings. It is also well to fit a much larger oil pipe and oil funnel. The oil pipe can be drilled with holes opposite each connecting rod, so as to supply a good oil bath.

RACING TYPE OF BODY

An example of a racing type of body for the Ford is shown below, together with dimensions.

As previously stated, one way of increasing the speed of the Ford car is by reducing the wind resistance, by taking off the top, mudguards, and windshield, and also, by the use of special racing bodies.

The radiator is designed especially for racing, and is high and narrow, thus reducing the wind resistance and improving the appearance. The radiating surface is of the patented bridge fin type, and the construction is of copper throughout.

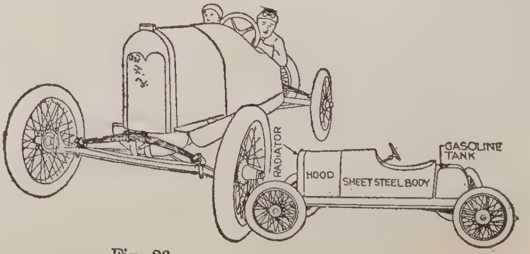

Fig. 26

Fig. 27

Figs. 26, 27. Front and side view of a racing type of body.

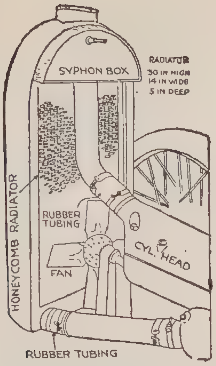

Fig. 28. The radiator is long and narrow: 30″ high; 14″ wide; and 5″ deep. Water capacity is 4½ gallons, including a tank at the top of the radiator.

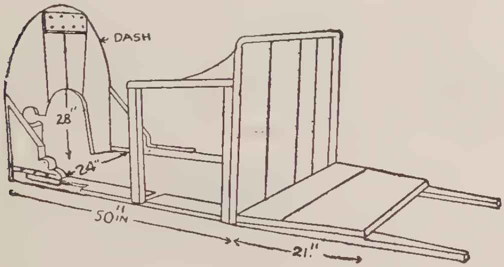

Fig. 29. The wood skeleton of frame of the body.

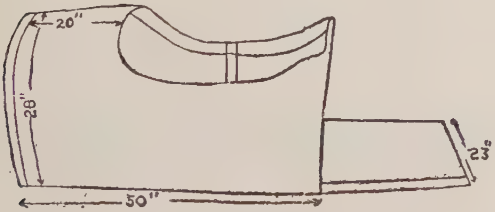

Fig. 30. Side view of metal body (18-gauge pressed steel) which is fitted over the wood skeleton (Fig. 29).

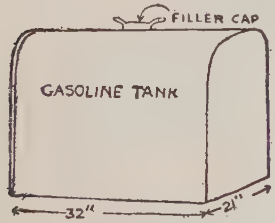

Fig. 31

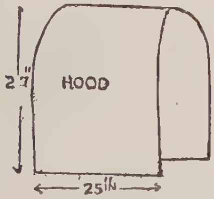

Fig. 32

Fig. 31. The gasoline tank of 35-gallon capacity which is made of 18-gauge steel with splash plates inside, anchored by steel straps. A large polished aluminum filler cap adds considerably to the appearance.

Fig. 32. Hood made of 18-gauge steel.

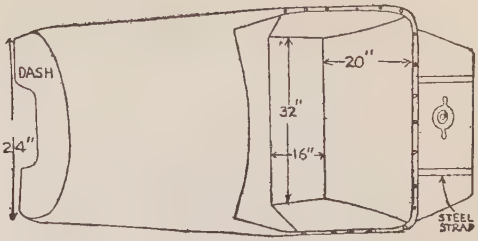

Fig. 33. Top view of body with gasoline tank in rear.

Fig. 34. **Bucket type of racing seats for the roadster, or** speedster. The shell is heavy gauge steel, attached and braced to wooden seat bottoms, and upholstered with substantial imitation leather, known as mule skin. (Can be secured of Am. Auto Accessories Co., Cincinnati, Ohio, Lehman Mfg. Co., Cannelton, Ind., and Laurel Motor Corpn., Anderson, Ind.)

Racing Parts for Ford

A concern that makes a specialty of supplying parts for speeding up Fords for racing, etc., is the Laurel Motors Corpn., Anderson, Ind. They supply such parts as enumerated below:

Racing gears.
Racing radiators.
Racing carburetors.
Racing magnetos.
Steering gears; worm and gear type.
Cam shafts for high speed (see page 1033).
Counter-balances.
Parts for underslung chassis, etc.
Pistons: light weight.
Cylinder heads with 16 valves, etc.

MISCELLANEOUS SUGGESTIONS OR SPEED POINTERS[1]

Oiling a Ford for Speed

The oil reservoir (R) is placed at any convenient point from which oil is pumped by a **hand oil pump** (P) to the crank case (E) (Fig. 35). From here it is pumped by a small **piston oil pump** to the oil gage (G) on the dash; thence to the timing gears (T).

The oil pump is placed opposite the No. 4 exhaust cam by drilling a hole large enough to permit head (A) to pass through.

The pump parts are made of brass tube (B) screwed to flange (C) having four holes for cap screws. The crank case is tapped, and leather gaskets are inserted between. The piston of the pump is made of steel. Bushing (D) is fitted into (B) to which the remaining part of the pump is screwed. Check valves and parts are shown in the illustrations, Fig. 35.

---

[1] This matter is collected from various authoritative sources. The writer has not personally tried out any of the devices.

The oil pipes are ¼″ copper tubing, using solderless connections. At (F) the pet cock is removed and a fitting is screwed into its place. Tubing (G) leads from this to the lower part of the oil pump. A hole is drilled at (T) and tapped to take the connection. (*Motor Age.*)

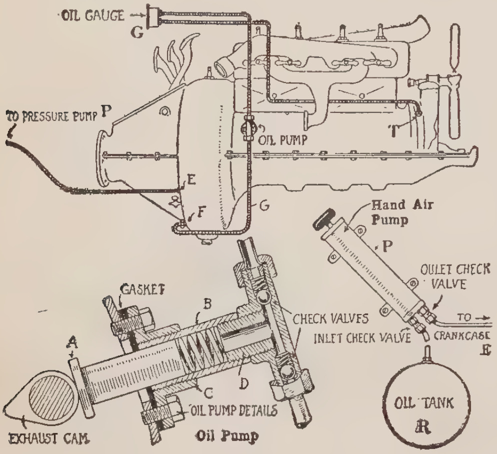

Fig. 35

Auxiliary Oiling (Another Example)

The present oil system in the Ford engine, while suitable for all ordinary purposes, is inadequate for high speed. The oil rotating with the flywheel is caught in a small funnel and is carried through a ⅜″ tubing to the timing-gears, flowing to the engine case, where it lubricates the moving parts of the engine. This funnel can hold only a certain amount of oil, and at any speed the tube can handle only a ⅜″ stream.

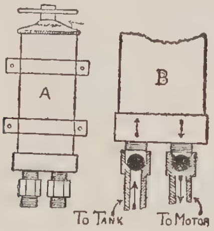

Fig. 36. Home made oil pump.

The funnel should be made larger, the long way, and higher to increase the weight there, and the tube should be replaced with one 7/16″ in diameter.

An auxiliary pump is frequently connected to the engine, as shown (Fig. 36). An old tire pump can be converted into a pump as follows:

An old tire pump is cut off about six inches below the handle. A metal handle is substituted for the wooden one, as shown in the drawing. The bottom of the pump is removed and carefully soldered, and the air outlet is soldered up. Two check valves, requiring no solder, are fitted to the bottom of the pump by drilling and tapping. The valves are, of course, inserted so that they will act in opposite directions. The valve allowing the oil to enter the engine allows the oil to be forced out of the pump, but will not allow it to re-enter. The other valve, working in the opposite direction, permits oil to come from the supply tank to the pump when the handle is pulled up. When the handle is pushed down, one valve closes while the other (the one permitting oil to enter the crank case) opens.

The supply tank may be located where most convenient, and is connected to the pump by copper tubing. The pump is placed under the front seat in a position where it can be operated easily.

Fenders

For fenders for Ford speed cars, we would suggest canvas guards, front and rear. They are easy to make and noiseless.

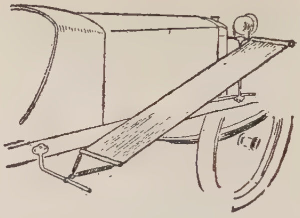

Fig. 37. **A canvas mudguard,** noiseless and easily made. The mudguard support also makes good lamp bracket.

Put a couple of coiled springs at the lower ends, and they will never sag. (*Newsabout Fords.*)

Lowering the Frame

The most important point in converting a Ford into a speedster is the lowering of the frame, because this car presents an awkward appearance with bucket seats and a big gasoline tank when high off the ground.

If semi-elliptic front springs are used, instead of the regular transverse spring, the semi-elliptic springs can be fastened under the axle by means of a U-shaped piece of flat steel (Fig. 38). Thus, the front of the car can be lowered several inches with but little change in the front axle itself. However, the frame will have to be changed, or special spring hangers must be fastened to the frame to form supports for the front ends of these semi-elliptic springs.

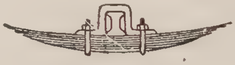

Fig. 38. One of the simple methods used to undersling Ford front springs.

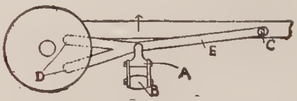

Fig. 39. **Underslung rear spring.** Forked rod (E) was anchored at the brake rods (D) and at the frame at (C). Spring (B) was shackled to the rod by (A).

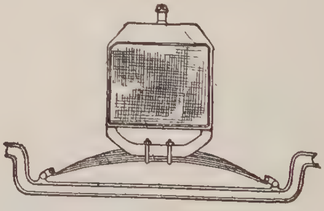

Fig. 40. This Ford front axle is a special forging with dropped ends.

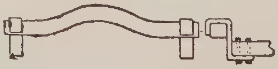

Fig. 41. Method of lowering rear spring 4 inches. The end of the panel was cut off and a gooseneck fitted as shown.

A special dropped front axle is shown in Fig. 40. It can be made to lower the front end of the car without making necessary inconvenient changes in the chassis frame.

The rear of the frame can be lowered by using the brake arm studs in the rear axle housing (Fig. 39) to fasten a forked steel bar from the axle to the frame. About two inches forward from the fork the spring shackles are bolted and the regular cross-spring is suspended from them. This gives about a 4-inch drop. (*Motor Age.*)

Another Method of Lowering the Frame

The work can be done by any good blacksmith, and will not cost more than $15. The principal changes in dropping the frame are in making the front and rear brackets which allow the frame to be hung 6″ lower, as shown in Fig. 42.

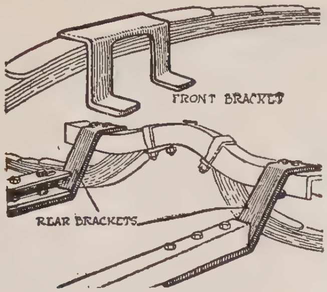

Fig. 42

The front bracket consists of a piece of iron, bent as shown, and made out of ½″ by 2″ stock. The method of attaching this is clearly indicated. The top is clamped over the spring, and the bottom ends are bolted to the cross-frame member.

The form of the rear bracket is also shown, and its attachment is even simpler than the front. The frame is sawed off, and the two brackets are bolted in place. Care should be taken in making the change not to alter the position of the axle relative to the frame backwards or forwards.

The attachment of the front bracket requires that the axle be pushed forward a certain amount—probably 3 inches. This must be compensated for by welding pieces in the radius rods running to the front axle.

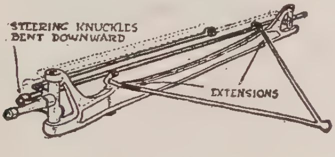

Fig. 43

The lower position of the crank case requires that the steering knuckles be bent downward, so that the tie rod will clear it. (*Newsabout Fords.*)

A Ford Racing Type Cam Shaft

A cam shaft designed to give more power and greater speed to a Ford is made by the Laurel Motor Corpn., Anderson, Ind., the installation instructions being as follows:

"The exhaust valve opens 55° before dead center and closes 10° past upper dead center. The intake opens 10° past top dead center and closes 55° past lower dead center. This is the same timing that was used on the Stutz 16-valve racing car.

"To remove the regular cam shaft, loosen the two set screws that hold the cam-shaft bushings in their place. Turn the motor over so that all the plunger pins can be inserted and so that they will not drop down into motor case. Remove the front cover plate and draw the cam shaft forward, and replace with a Laurel high-speed cam shaft. This is practically the same as changing any Ford cam shaft, excepting that you chisel a slight groove in the first and second bearing retainer, and 90° apart for clearance of the cam. The proper clearance between the valve stems and plungers should be about 10 one-thousandths of an inch. Set the cam-shaft gears to the Ford marks."

Ether, Picric Acid, and Gasoline

Q.: Can ether or picric acid be used for increasing power for racing?

Ans.: Yes, nitrous ether has been used, but is dangerous.

Nitrous ether is purchased in glass tubes and is put on ice at least 8 hours before the attempt to handle, as heat from the palm of the hand will explode it, and the shattered glass may put your eyes out. Mix one ounce to five gallons of gasoline, and you may have to add a little more gasoline or a little more ether to get the best results.

Ether bought in pound cans is suitable for easy starting in cold weather, if half ether and half gasoline is mixed and put in a small tank on the dash, using a small priming pump to squirt it in the intake pipe. This ether can be handled without danger, as long as it is kept away from a flame.

Picric acid: Put one pound of picric acid in a glass bottle and fill with gasoline or alcohol; keep in a cool place; stir twice a day for one week before using. The picric acid will not all dissolve, but pour out all the liquid, straining it through a fine sieve, and mix in the same proportion as you do ether. You can use both together by equally dividing them. There is one point to watch closely; do not get the mixture too rich. Picric acid is injurious to the engine, and will increase heat.

MOTOR BOAT AND MOTOR SLED

Ford Engine in a Boat

The length of boat suggested is 20 to 22 ft., by 5 ft. beam, and 1 ft. draft, the latter being for the hull only. The over-all draft, or water the boat draws, is determined by the size of the propeller. If there are obstructions in the water where the boat is to be used, it is better to fit some form of skeg or protection below the propeller.

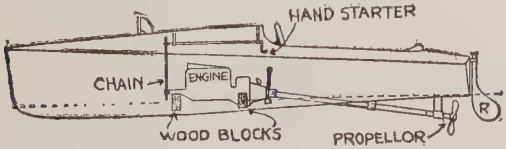

Fig. 44

In mounting the engine, fit strong oak cross-members in the engine compartment and fasten it in place with lag screws, using the same brackets fastened to the engine.

Leave the **transmission attached,** and mount the powerplant so that it will be level when the boat is in the water and under way. Boats rise out of the water when traveling fast, so you must make allowance for this. The engine will oil better when on a level. Proper adjustment can be made with shims under it.

The illustration (Fig. 44) shows a **cranking device,** by which the engine can be started from the seat. Arrange to drive a centrifugal or gear pump to force the cooling water around the jackets. Be careful not to get this pump too large, or the engine will be overcooled. Arrange to run some of the overflow water into the exhaust pipe, a foot or more from the engine, which will help to muffle the noise.

It is hard to give specific **propeller dimensions,** but if built somewhat after the design shown, one having a diameter of 15″, three blades, and a pitch of 22° would be about right. (*Motor Age.*)

A Motor Bob—Wheel Drive

Riding board 14″ wide x 1¼″ thick. Two 7″ strips may be used, but a single plank is best. Two 1″ x 3″ pieces strengthen it. Two **running boards** hung on steel brackets offer a foot rest for passengers. Sleds should be made of hardwood with steel runners.

The engine is of the motorcycle type, mounted in a frame of ⅜″ round stock (Fig. 47). The weight of the bob is not carried on the wheels; therefore two heavy coil springs force the wheel to the ground (Fig. 45), by pull on the frame.

Also note the **skid chain** on the motorcycle wheel, which is to give it traction. Steering is shown in Fig. 46.

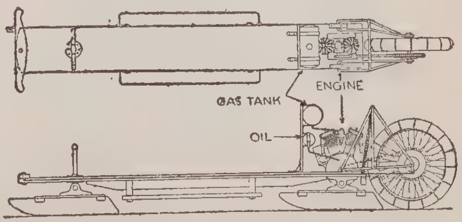

Fig. 45. Plan and elevation of the **wheel-driven** motor bobs. Note the trussed riding board and underslung foot rest. The brake is connected with the pivoted foot rest of the steersman

A Motor Bob—Propeller Drive

This is not recommended for narrow-gauge bobs. It has an advantage over the wheel in that the wheel has difficulty in obtaining traction in soft snow or on broken roads. If a propeller is used, it would be better to ask some aeroplane propeller manufacturer as to revolutions and size. (*Automobile.*)

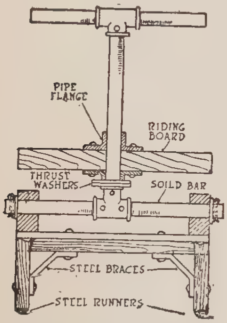

Fig. 46

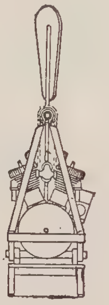

Fig. 47

Fig. 46. Detail of the front bob mounting, showing the steering mechanism.

Fig. 47. A simple method of mounting the propeller at the rear. The standards are made of 2-in. angle irons, rigidly braced.

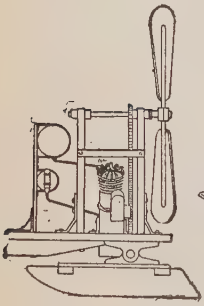

Fig. 48

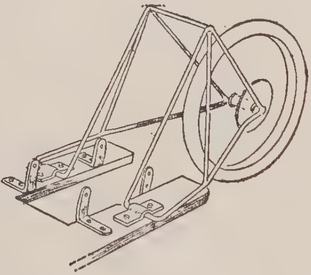

Fig. 49

Fig. 48. Side view of propeller.

Fig. 49. Detail of the motor mounting and the drive-wheel cradle.

Building a Motor Sled Using a Ford Engine

An idea of such a device is shown in Fig. 50. The narrower the job, the faster it will be, but it will require more efficient handling, particularly when making turns, where it will be necessary to slow down materially. The length will have to be worked out to suit the fittings. Because of the length required, there should be a truss under each side member, which can be made of a 3/16″ rod with about 3″ studs and a turn that goes to take up the slack. Besides having the front bob made to swivel to enable steering, there should be a step on each side upon which to brace the feet. The engine will set a little back of the middle, and this will about balance the weight of two passengers sitting ahead.

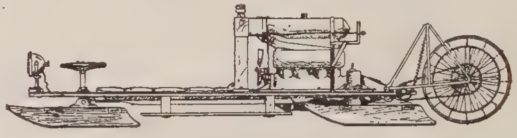

Fig. 50. A motor sled using a Ford engine.

To use a Ford engine, it will be necessary to fit a bevel gear to the end of the shaft, and a bevel gear on a cross-shaft, upon which is to be a driving sprocket, which can be the same as those used on motorcycles. Provide a truss bearing on the back of each bevel gear and, of course, the necessary oil holes in the bearing carrying the countershaft. The size of the shaft upon which the bevel gear should be, will depend upon the location of the drive wheel. It should be on the right side looking forward, as the flywheel of the engine should be set to the front, which will make the engine turn to the left when looking backward.

You can easily connect up the throttle, spark, and transmission levers to suit your needs in accordance with the position of the operator, who will sit in front. This can be arranged so that one can steer and one in the second seat can operate the levers; but this will be bad, in that one person could not manage the bob alone. The person in the second seat can operate the bob alone if an auxiliary steering arm is placed back and connected at right angles out to the side of the bob. We should recommend a mechanical starter as being a cheaper installation. The knob handle of the mechanical starter is shown at the rear of the gasoline tank. (*Motor Age.*)

MOTOR WHEEL AND AUTO-PED

The Smith Flyer (Fig. 51) is a light motor vehicle made from a four-wheeled buckboard with a Smith "**motor wheel**" attached to the rear.

This machine, though its entire weight is but 135 lbs.., is capable of running at 20 to 25 m.p.h., and runs from 50 to 60 miles on 1 gal. of gasoline.

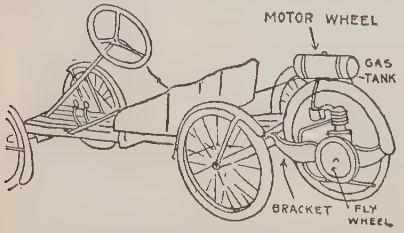

Fig. 51

The Auto-Ped, manufactured by the Auto-Ped Co. of America, Long Island City, N.Y., is shown in Fig. 52. To drive it, the operator is in a standing position. A 6-volt lighting generator is inclosed in the flywheel case.

USEFUL REPAIR HINTS AND SUGGESTIONS[1]

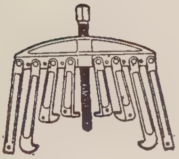

Fig. 1

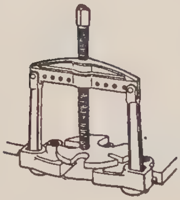

Fig. 2

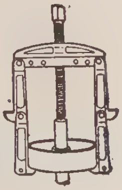

Fig. 3

Fig. 1. **Crane wheel pullers.** The complete outfit with various length attachments.

Fig. 2. A special attachment which makes an arbor press.

Fig. 3. Removing a flywheel.

All three of these are manufactured by the Crane Puller Co., Arlington, Mass.; also write to W. E. Prudden Hdw. Co., 864 8th Ave., New York, N.Y., for information on another type of wheel puller.

Pulling a wheel from a rusted axle is a bigger job than it appears. If the axle is greased before the wheel is put on, the probabilities are that it will come off readily; if not greased, it will, more than likely, be a task. A wheel puller can be bought of any auto supply house, or one can be made by a local blacksmith. Every repair shop needs a wheel puller.

A wheel puller can also be utilized for removing flywheels, transmissions, gears, collars, pulleys, couplings, marine propellers, etc.

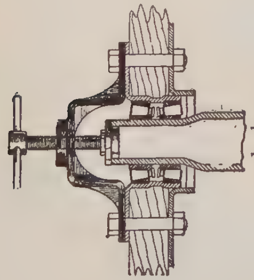

Fig. 4

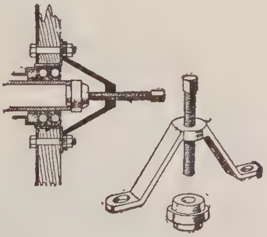

Fig. 5

Fig. 4. **Rear wheel puller.** This puller is used to remove the rear wheels of the Buick. The wheel flange and axle are removed and the puller bolted to the flange bolts. A steel button is then placed in the rear axle tube, and the pressure is applied by the central screw. By having several sizes of steel buttons, and making the flange bolt holes oval, this puller may be used on many cars.

Fig. 5. **A special puller is required for the removal of the Dodge rear wheel.** After the removal of the outside flange and the rear axle, the frame of the puller is bolted on to two of the flange bolts. The plunger on the end of the screw fits inside the rear axle housing, giving a leverage that permits the ready removal of the wheel. The frame is made of cast iron, reinforced by ribs; the screw is a ¾″ bolt.

Fig. 6. This **makeshift wheel puller** is made from two long bolts (B), with nuts, a short thick bolt (D), and three pieces of iron drilled as shown. These parts are applied to the wheel with the short pieces of iron behind the spokes of the wheel, and the bolt (D) communicating between the bar and the end of the axle shaft. By taking up evenly on the two nuts with the wrench (M) and occasionally striking the bar opposite the bolt (D) with a hammer, a very stubborn wheel can be easily removed.

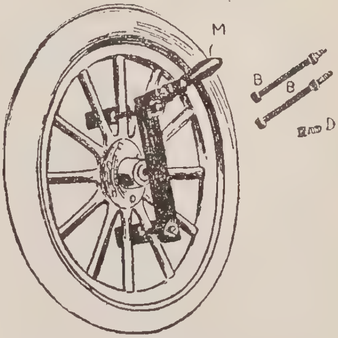

Fig. 6

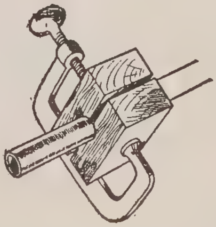

Fig. 7. **Steering-post puller.** Two wooden blocks clamped to the steering post by a heavy metal clamp offer a convenient brace for a jack, thus permitting the removal of the steering post. After applying a strain to the post by means of the jack, a few blows on the blocks with a heavy hammer so loosen the post that it may be drawn out without injury.

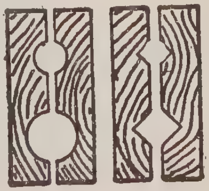

Fig. 8. **Vise clamps made of wood, ⅛″ sheet copper, and sometimes sheet lead.** These are useful and necessary where the material is to be clamped in a vise, which would mar its surface otherwise. When made of sheet copper or lead, use ⅛″ thick clamps cut to the size of the vise jaws, and bend over the top of the jaws to support them in place. When made of hardwood, bore holes through and then saw across, about ¼″ or more being cut away; or they can be cut to a V. These latter will take bars or pipes of various sizes without injury.

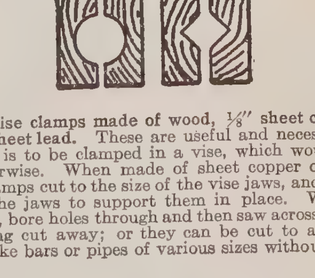

Fig. 9. **Vise clamps for working with tubing.** Note the spring tension which keeps clamps in vise when the jaws are opened.

---

[1] From *Motor World* and *Motor Age*. See page 1041 relative to a book which gives 1,500 time and labor-saving kinks, methods, and devices.

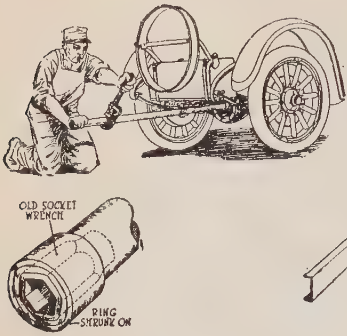

Fig. 10

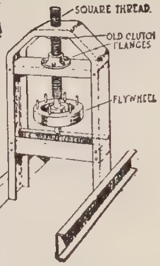

Fig. 11

Fig. 10. **Extension socket wrench.** By mounting a socket wrench head in the end of a 4 ft. length of 2" pipe, an extension wrench is made that facilitates the removal or replacement of the nut ~~on~~ the rear-axle drive pinion. A steel ring is first shrunk on the end of the pipe, to provide strength; the pipe is heated red, and the cold socket-wrench head is driven into the pipe. When cool, the head is firmly held in place. Because of the long handle, a pipe wrench may be used to get a leverage, and the workman may work from an uncramped position.

Fig. 11. **This home-made arbor press** is made of channel sections from an old frame. It comprises an inverted U-shaped member, supported in an upright position on the channel base as shown. The overall height is about 5½ ft. and the width 4 ft. The pressure screw is carried on two large nuts that are old clutch flanges tapped out, both the screw and the nuts having square threads. An old flywheel, keyed to the lower end of the pressure screw, serves as a hand wheel, and is provided with vertical pins so that a pinch bar may be used to increase the leverage.

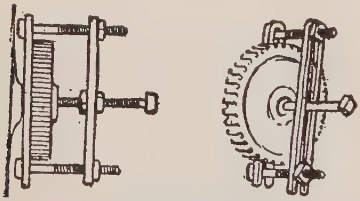

Fig. 12. **A gear puller** for removing tight gear wheels. The illustration explains its construction and action.

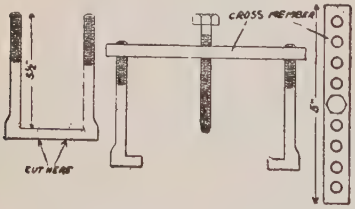

Fig. 13. **A home-made gear-wheel puller.** First get a piece of soft iron or steel. This piece must be 5" long and 1" square. Then find a long spring clip, the longer the better; cut the clip in two pieces at the bottom about ½" from the inside of the clip; then you have the arms completed.

To make the cross-member have a piece of iron or steel 1" square by 5" in length; drill a hole in the center and tap the threads for a ½" bolt. Next you can drill three or more smaller holes on each side of the large center hole, and tap these holes out to fit the threads on the spring clip; then you have an adjustment for three or more gears.

Fig. 14. **The brace rod from an old windshield may be made into an excellent wheel alignment tram.** After cutting the rod to a length about 2" less than the distance between the front wheels, a brass ferrule is soldered to one end. This ferrule is then drilled and tapped to carry a thumb screw in the manner shown. The adjustable part of the tram is a piece of ¼" drill rod, marked off into 1/16" divisions as shown, and placed within the tube.

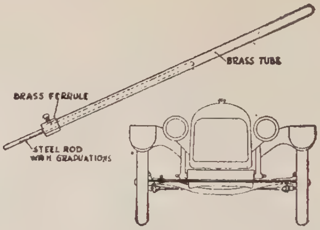

Fig. 14

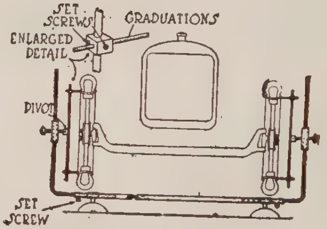

Fig. 15. **Wheel-aligning fixture.** The alignment of either the front or rear wheels may be tested by this fixture. The frame is made of wrought-iron pipe, and is adjustable by means of sliding joints. The feature of this fixture is that both sides of the wheel are tested at the same time; the camber and amount the wheel's toe-in can be readily determined. The front wheels should toe in from ¼" to ⅜".

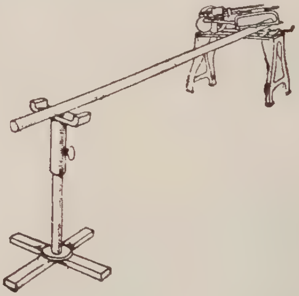

Fig. 16. **The saw stand** illustrated is useful in cutting off a long bar of stock in a power saw. Its construction is so simple that nothing further need be said.

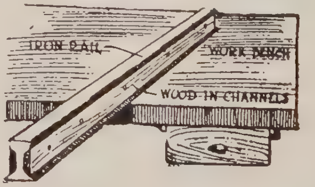

Fig. 17. **An iron rail is a useful device for any shop.**

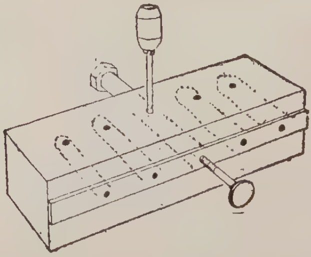

Fig. 18. **A jig for drilling cotter-pin holes in bolts and pins** may be made of a piece of square stock in which there are several transverse holes for receiving various sizes of pins. At right angles to each one of these is a hole through which the cotter-pin drill is inserted. The distance that the cotter hole is from the end of the pin is determined by the adjustment of a stop screw which is carried in a plate in the back.

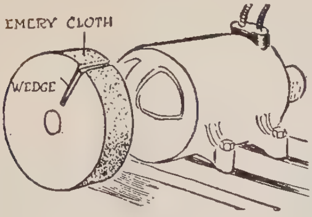

Fig. 19

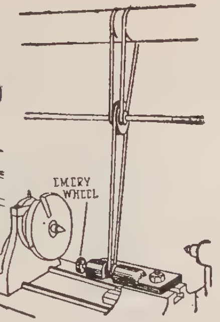

Fig. 20

Fig. 19. **A grinding wheel** for doing special work can be made by attaching a wooden wheel to the electric drill and wrapping a strip of emery paper around the periphery. The paper is fastened by cutting a notch in the wheel and holding the ends of the paper by driving a wedge into the notch.

Fig. 20. **A very small grinding wheel for mounting in a lathe** may be used for fine work. The wheel is approximately 1″ in diameter and runs several thousand revolutions per minute, this speed being obtained by a double belt reduction from the driving drum. The intermediate pulley really floats in the air, the shaft it slides on being merely to hold it in case one of the belts should break, thereby destroying its equilibrium.

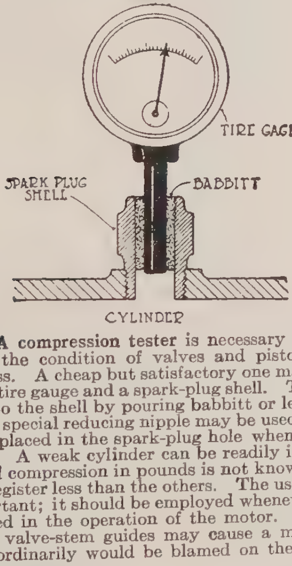

Fig. 21. **A compression tester** is necessary for accurately determining the condition of valves and pistons as regards their tightness. A cheap but satisfactory one may be made by combining a tire gauge and a spark-plug shell. The gauge may be fastened to the shell by pouring babbitt or lead in between the two, or a special reducing nipple may be used. The gauge, of course, is placed in the spark-plug hole when a cylinder is to be tested. A weak cylinder can be readily indicated, even if the normal compression in pounds is not known, by the fact that it will register less than the others. The use of this device is very important; it should be employed whenever any irregularity is noted in the operation of the motor. Leaky valves, pistons, and valve-stem guides may cause a miss or a jerky action that ordinarily would be blamed on the carburetor or ignition.

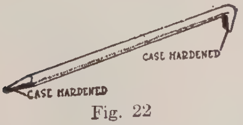

Fig. 22

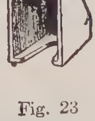

Fig. 23

Fig. 22. **A spanner wrench for facilitating the adjustment of the silent chain drive on the motor-generator of the Dodge car.** It consists of a piece of ½″ round stock about 9″ long, bent and formed in the manner shown. To adjust the chain, the chain-inspection plates are first removed from the motor gear cover. Then the set screw on the cylinder casting and the strap holding the motor to the hand-hole cover plate are loosened. By means of the spanner wrench the eccentric bushing is turned until the chain has the proper tension. When properly adjusted the chain should run without perceptible noise.

Fig. 23. **A puller for removing the generator gear on the Dodge car** is shown. The housing is made of cast iron, cut away at the base to engage the gear, and provided with a ¾″ set screw for obtaining a leverage on the generator shaft.

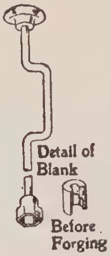

Fig. 24

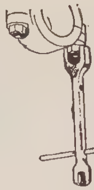

Fig. 25

Fig. 24. **Crank-case wrench.** The retaining nuts on the crank case may be quickly removed or replaced by the aid of this wrench. The handle is made of ½″ round stock bent in the form of a bit-stock, as shown. The upper end is fitted with a hand rest; the lower end with a socket for engaging the nut. A short piece of round stock, slightly larger in diameter than the nut eventually to be turned, is drilled, as illustrated in the smaller sketch. It is then heated and formed over the nut it is to fit, case-hardened, and secured to the handle by a pin.

Fig. 25. **Crank-shaft bearing wrench.** It is often difficult to get a socket wrench thin enough to fit between the nut and the bearing housing of the connecting-rod or crank-shaft bearing. Or if thin enough to do this, the wrench is too weak properly to tighten the nut. A solid S-wrench may be used, but is not as satisfactory as the socket for this purpose. A solid socket wrench, cut away in the manner illustrated, possesses the required strength and has all the advantages of the full-socket wrench. As the connecting-rod nuts are not the same size as the main bearing nuts, the wrench should be made double-ended and fitted with a removable handle.

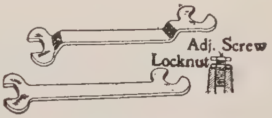

Fig. 26. **The valve tappets of the Maxwell may be readily adjusted by means of special wrenches provided for that purpose.** Two standard 626-X check-nut wrenches are purchased at any supply store, and bent, after heating, in the manner shown. After loosening the lock-nut the adjusting screw may be turned until a gage registers the proper clearance. This should be from .006″ to .009″.

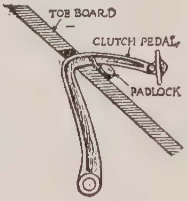

Fig. 27

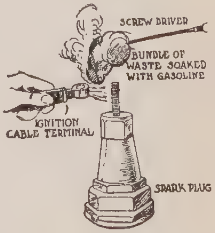

Fig. 28

Fig. 27. **One method of locking a car.** A hole is drilled in the clutch-pedal arm for the insertion of a padlock. It prevents the use of a clutch.

Fig. 28. **Substitute for a match.** A piece of waste or cloth dampened with gasoline is tied to a screwdriver. One of the ignition cables to a spark plug is removed and placed near enough to the electrode so that the spark jumps across. The cloth is introduced between the two, and the spark will ignite the gasoline.

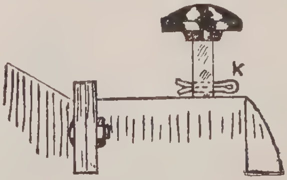

Fig. 29. **Silencing mechanical horns.** Car owners are often annoyed by small boys who persist in sounding the mechanical horn when the car is left unattended. A simple, but effective, method of discouraging this practice consists of drilling a small hole through the plunger rod and slipping a cotter pin through this hole when the car is left alone. The cotter pin may be easily removed when the owner of the car returns.

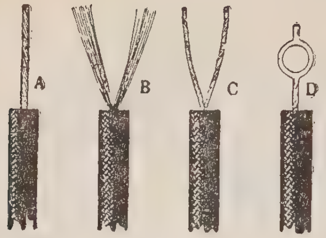

Fig. 30. Four steps in making a loop end: (A) insulation removed; (B) separating the strands; (C) twisting wires into two leads; and, (D) the looped end dipped in solder. (*Motor Age.*)

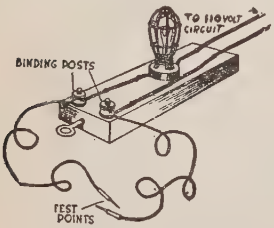

Fig. 31

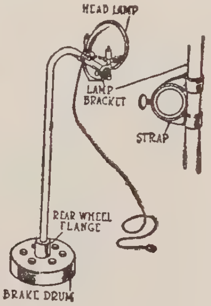

Fig. 32

Fig. 31. **This is a portable test lamp,** used in conjunction with a 110-volt lighting circuit, for testing lighting and ignition circuits on the car. It consists of a wooden base, on which is mounted a porcelain socket carrying a 16-candle-power lamp, connected to the lighting circuit as shown in the wiring diagram. The test points are connected to the binding post, and any metallic connection between the two causes the lamp to light. Hence if a wire is in proper condition, the lamp will light, when the test points are placed on each end of the wire. If there is an open circuit, it will not light. Similarly short circuits and grounds may be determined. By short-circuiting the two binding posts, the lamp may be used for inspection work.

Fig. 32. **This portable service lamp** was made both for night service in the shop, and for work on the road. A standard headlight, together with its bracket, is clamped to a pipe upright, bent as illustrated. This upright is fastened to a base that is an old rear-wheel flange bolted to a brake drum. Current is derived either from direct connection with the storage battery or by plugging into the dash lamp circuit. (*Motor World.*)

Fig. 33. **A shop light,** made of a can, protects the globe and is not easily turned over.

Fig. 34. **It is a very simple matter to build a device which will cause a bell to ring when the pressure in the air tank reaches the desired maximum or minimum,** thus reminding the man in charge that the compressor should be turned off or on. The indicating hand on the air gauge completes a circuit by touching a metal pin when it moves to either extreme, and thus makes the bell ring. These pins are mounted in a small fiber block, which is riveted to the face of the gauge. The two pins are thus completely insulated from the gauge and are connected to one terminal of the bell. A short piece of wire runs from the other terminal to the battery and the return wire is attached to the casing of the gauge, so that current flows through the casing and the hand to one or the other of these metal points.

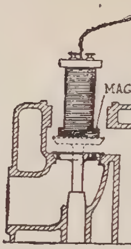

Fig. 35

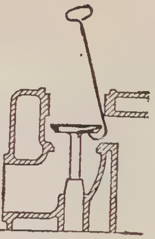

Fig. 36

Fig. 35. **A magnetic valve lifter.** Magnets have been used many times for picking up all sorts of iron and steel parts, but their use for pulling out valves is unusual. The magnet shown is approximately ¾″ x 3″, and is capable of exerting a pull of about 7 lbs., and will pull a valve out after the springs have been removed.

Fig. 36. **A simple tool which will be found of assistance for removing valves that stick badly, but may be raised slightly,** consists of a hook of Bessemer steel wire ⅛″ in diameter.

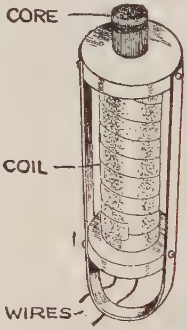

Fig. 37

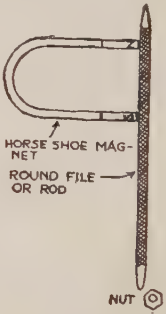

Fig. 38

Fig. 37. **Construction of the magnetic valve lifter.** An old make-and-break spark coil forms the basis of the device. The core is made of a bundle of coarse iron wires. The outside of the coil is covered with tape, and has a handle consisting of a strip of brass which extends down the sides of the coil to the end.

Fig. 38. **Another magnetic lifter,** which is useful for removing a nut which may have fallen into cylinder or other inaccessible place is shown. Simply touching the file with the magnet makes a magnet out of the file (a long rod may also be used instead).

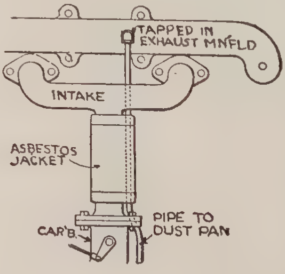

Fig. 39

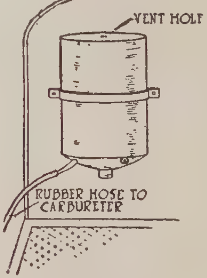

Fig. 40

Fig. 39. **Method of heating the carburetor mixture on old cars** that have a long inlet manifold. A ⅜″ or ½″ copper pipe is tapped to the exhaust manifold and run down along the intake manifold, being held away from the latter slightly by asbestos pads. Asbestos is then wrapped around the manifold and pipe, and the heat thus obtained will help to prevent the gases from condensing in the manifold at the point where it branches out to the cylinders.

Fig. 40. It is often desirable to determine the **exact consumption of a given car by determining how far it will run on a measured quantity of fuel.** A convenient means of doing this is to take an ordinary ½-gal. kerosene oil can and place in it a quart of gasoline. A rubber tube running to the carburetor is then attached to the spout, and the can is inverted and tied securely at some convenient place on the motor or dashboard.

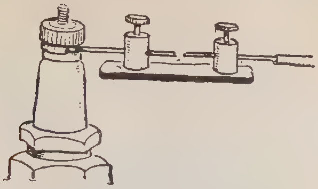

Fig. 41. **Ignition tester.** To find which cylinder is missing, a piece of fiber, ¾″ long, about ⅛″ thick, and ¾″ wide, is taken, and near the ends are inserted cable terminal posts. Through each post is passed a copper wire, the ends at the center being adjustable through lateral movement of the wires. One of the wires has a loop at the end for attachment to a plug. The ignition cable is attached to the other post. With one of these on each plug and the wires at a varying gap, it is possible, especially in a dim light or in darkness, to see the action of the plugs. See also page 237.

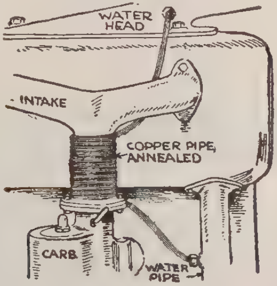

Fig. 42. **Method of heating a long inlet pipe.** Annealed soft copper pipe of small size is connected with the discharge pipe from the water pump, wrapped around manifold, and connected with the head.

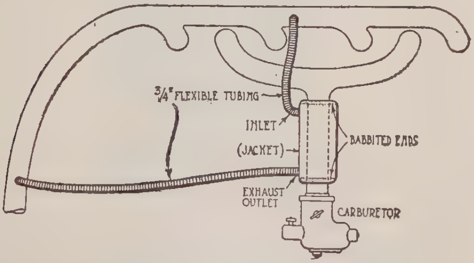

Fig. 43. **Heating the mixture on old carburetors:** Improving old-type carburetors which were designed for gasoline of higher vaporizing qualities and long inlet pipes.

Many of the old-model carburetors do not work well on the present low-grade gasoline. If a carburetor is too ancient, it is best to get a new model, but where it is in good condition, many of the older models can be improved by adding a hot-air jacket, as shown.

Use a pipe of some kind and slip over the intake manifold—about ¾ of its length. Weld it gas tight at each end (sheet iron can be made into a pipe), and pour a light layer of babbitt in each end to close up any holes or cracks.

A ⅜″, ½″, or ¾″ (the larger the better) flexible pipe is then attached to the top and bottom of the jacket to the exhaust pipe as shown, or the lower pipe can extend to the lower part of the engine.

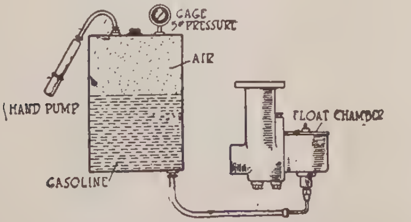

Fig. 44. **Float valve tester.** This illustration shows a device for determining whether the float valve of the carburetor leaks. It is designed particularly for pressure systems, although it may be used for the ordinary gravity system by simply removing the pressure. It consists of a tank partly filled with gasoline and provided with an air gauge and hand pump. The carburetor is attached, the pressure raised to the required amount, and then the carburetor is allowed to stand for several hours to determine whether any leakage takes place.

Float valves, which may not leak at all when tested under a small gravity head, will leak badly when put under a few pounds pressure.

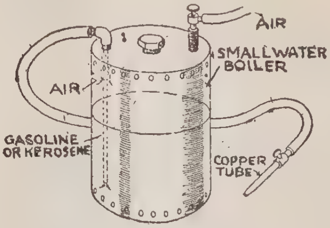

Fig. 45

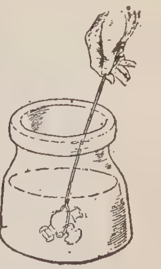

Fig. 46

Fig. 45. **This is a cleaning tank,** in which gasoline or kerosene is forced by air pressure in the form of a spray on to the part to be cleaned. The container is an old hot-water heater boiler. Air pressure is applied through a tire valve soldered to the tank, and the cleaning solution is drawn up through a small tube to the outlet pipe. A length of rubber hose, terminating in a copper tube, fitted with a valve, completes the outfit. Either gasoline or kerosene may be used as a cleaning solution, but the latter is preferable.

Fig. 46. **Cleaning brass parts.** Small brass parts, such as pet cocks, carburetor parts, etc., may be made to look like new by dipping them in the following bath: nitric acid, 75 parts; sulphuric acid, 100 parts; lampblack, 2 parts, and salt, 1 part. This solution should be mixed and kept in an earthenware or glass jar, and the parts should be thoroughly rinsed and dried after dipping. (See also Index.)

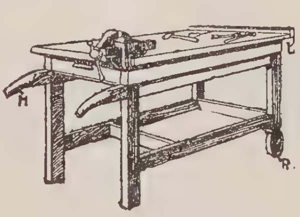

Fig. 47

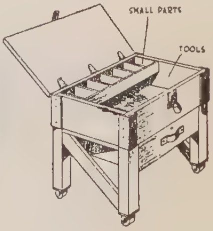

Fig. 48

Fig. 47. **A portable work bench.** An improvement would be to add shelves underneath for parts. Note the rollers (R) and handles (H).

Fig. 48. **This tool box** is made integral with its base, and is mounted on castors, so that it may be taken to the side of the car upon which the work is to be done. The tool box proper is shallow, and contains a space for the more common tools, in addition to several small compartments for miscellaneous parts. The more valuable, precise, and less frequently used tools are kept in a drawer beneath the box, which is locked unless in use. See also Fig. 52.

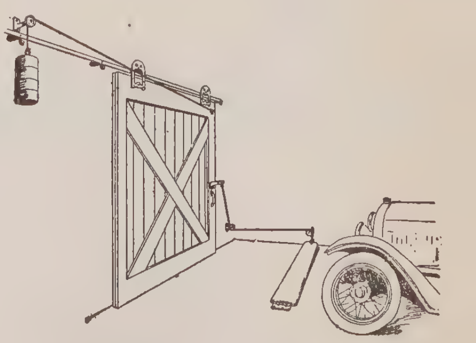

Fig. 49. **A self-opening repairshop door** is shown. The door is of the sliding type, hung on a horizontal track, but counter-balanced with weights swung over a pulley, so that it automatically opens when the catch is released. This catch is of the hook type, and connected with a hinged board placed across the roadway, the car itself releasing the catch and allowing the door to open. One of these hinged boards is placed both on the inside and the outside of the door, so that one entering or leaving has only to get out of the car once.

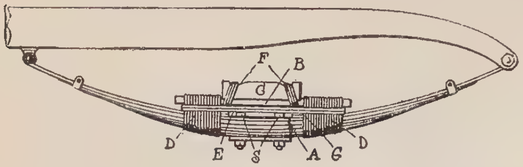

Fig. 50. **A temporary spring repair** was made upon a spring whose three lower leaves were broken on striking an apparently shallow hole in the road which was filled with water. After the break (**A**) occurred, the car was slowly driven to the next farmhouse, where some 2 x 4 blocks, a saw, and some baling wire were obtained. The short block (**E**) was cut off first, and two shallow grooves (**S**) were cut into one side of it so that it would clear the spring clips and rest flat on the central portion of the top spring leaf. The sides of these slots were cut with a saw and then finished up with a cold chisel carried in the tool kit of the car. The piece (**B**) then was cut off and nailed to the short piece (**E**), so that the sides were flush and its ends extended over the ends of the short block equally distant on either side. The top block (**C**) which was made just a trifle longer than the short bottom block, was cut off and slotted in the same manner as the under block, only the slots were not so wide and were farther apart, as designated by the letter (**F**). This block then was nailed to the long piece, centrally located with the slots up. The frame of the car was then jacked up so that the injured end of the spring was a little above its normal height, and the blocks were set in position as shown and securely bound into place with the wire (**D**). When this was done, a few strands were wound about the two top pieces, as at (**F**) to add to their security; then a few more strands were bound laterally around the whole, as at (G). This completed the temporary repair.

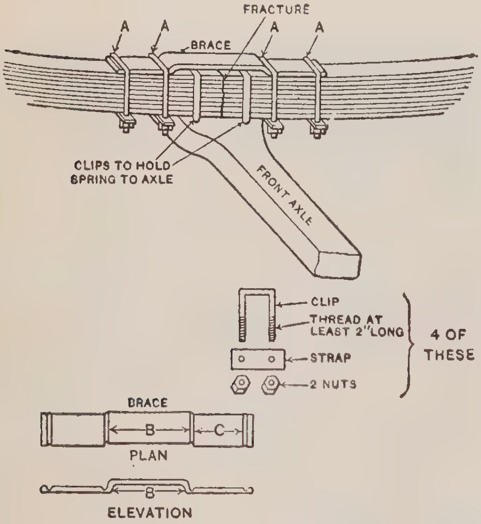

Fig. 51. **Another temporary repair on an automobile spring.** The width of the brace should be equal to the width of the spring and the part (**B**) long enough to lay over the clips holding the spring to the axle. The ends (**C**) should be about 3″ long. Such a brace will effectually repair either a front or rear spring.

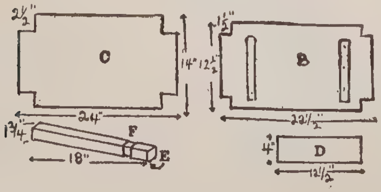

Fig. 52. **A portable tool stand.** Above illustration gives the dimensions and Fig. 52A shows stand completed. If you desire, the bins can be divided into smaller sections for cotter pins, washers, assorted bolts, nuts, etc.

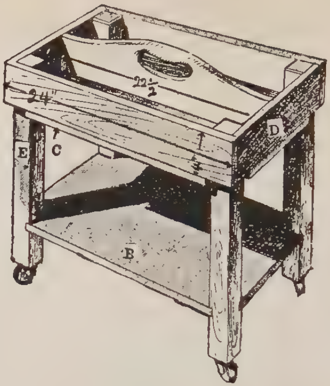

Fig. 52**A**. Portable tool stand completed.

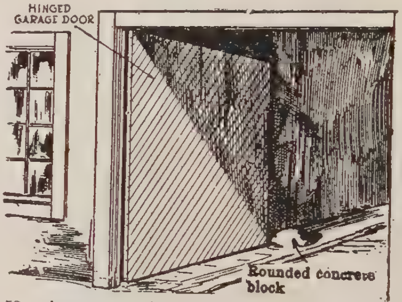

Fig. 53. **A concrete block** placed as shown will prevent driving and backing into the door.

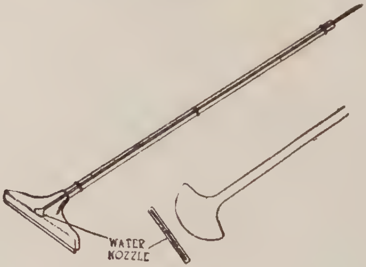

Fig. 54. **Window cleaner.** For removing dust from windows the ordinary rubber-edge window dryer combined with a nozzle which gives a flat spray the full length of the edge, may be used with a considerable saving of time. The nozzle is made from a piece of copper pipe, which is flattened and flared, as shown, and is then strapped to the handle. The water is turned on and the tool is rubbed up and down the window surface, thus removing all dust and dirt; then the water is shut off and the window is dried by scraping drops away.

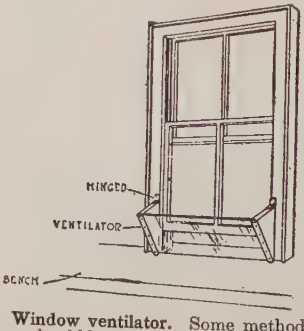

Fig. 55. **Window ventilator.** Some method of ventilating the repairshop should be provided, and a simple form of window ventilator is shown. It consists of a piece of an old windshield glass, held in an inclined position on the window sill by two triangular supports, and permits the window to be raised and the shop ventilated without causing a serious draught on the mechanic.

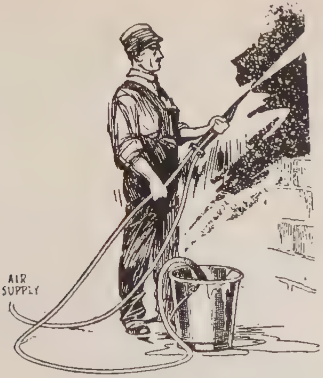

Fig. 56. **Rough surfaces, such as garage walls, may be painted or whitewashed** quickly and economically by the use of an air spray similar to that used for cleaning motors with kerosene. The paint or whitewash is placed in a bucket and the application of air pressure to the nozzle, whose construction is plainly shown, atomizes the liquid and sprays it against the walls. Valves are provided for regulating both air and liquid flow, and with a little experience it is easy to obtain an adjustment which will allow an even and economical application of paint. (*Popular Mechanics.*)

Fig. 57. **Automobile Repairshop Short Cuts.**[1] A book with over 1,500 time and labor-saving kinks, methods, and devices, from more than 1,000 of the best garages, service stations, and repairshops in the United States. Ideas that have been developed to save a good man's time, covering engine, clutch, gearset, running gear, and body repairs, managing and equipping the shop, etc. Collected and edited by *Motor World's* corps of experts. 256 pp., 9 x 12 in., 1,500 figs., cloth.

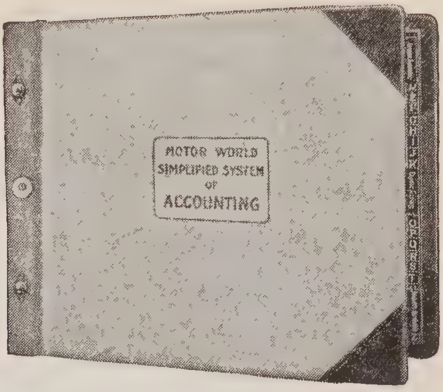

Fig. 58. **The "Motor World" Simplified System of Accounting.**[1] A simple method of keeping accurate records of what you pay out and take in, telling how much you made or lost on each department, and showing you how much you received, how much the stock and labor cost, how much your customers owe you, the amount of your overhead expenses, etc.

It is exclusively a garage and dealers' system and was prepared to meet every detail by an expert accountant who spent six months in both large and small garages and salesrooms applying it to the daily needs of the garageman and dealer. As a result the system is so simple that anyone can run it. 800 pp., 11½ x 15-in., leather index, heavy duck, leather corners.

Meaning of Some of the Words Used in Connection with the Auto

Cardan joint is the same as universal joint. **Pantasote** is an imitation leather used for upholstering and tops. The **bore of an engine cylinder** is the measurement across the circular space in which the piston moves; it is another term for the internal diameter of the cylinder. The **stroke** is the length of the path through which the piston moves in the cylinder, and is exactly equal to the diameter of the circle made by the crank pin. The purpose of an **accelerator** is to open the throttle by means of a pedal on the foot board independent of the hand throttle. It opens the throttle more quickly than the hand throttle, hence the term "accelerator."

Starter Out of Order and Crank Lost

To start engine if starting crank is lost, or starter fails to work: Jack the rear wheel, let clutch in, place gears in "high," and turn the wheel. Or let the clutch in and have someone push the car until the engine starts, and quickly throw out clutch when engine starts.

INSTRUCTION No. 83

GENERAL DATA: Horsepower; Miscellaneous Data; Specifications; Insurance; Laws

METHODS OF COMPUTING HORSEPOWER

The S. A. E. or N. A. C. C. Horsepower Formula

The horsepower of a gasoline engine is dependent upon the following things: the number of cylinders, the area of piston heads, the average number of pounds per square inch exerted upon the piston during the strokes (mean effective pressure), and the revolutions per minute of the engine.

S. A. E. means Society of Automotive Engineers. This formula was originally adopted by the A. L. A. M. (American Licensed Automobile Manufacturers), later by the S. A. E., and now by the N. A. C. C. (National Automobile Chamber of Commerce).

It has been worked out upon the assumption that the piston speed is 1,000 ft. per min., and that the mean effective pressure is 90 lbs. per sq. in. and a certain percentage of developed power is lost in friction. Inasmuch as the piston speeds of modern engines run up as high as 1,500 to 2,000 ft. per min., and the mean effective pressures per sq. in. go up to 110 to 120 lbs., it will be seen that this formula is not altogether accurate as to the actual horsepower, which would be considerably more. However, it is used for estimating, and serves its purpose.

Piston Speed

When this S. A. E. formula was first adopted most engines developed their horsepower at 1,000 feet of piston travel per minute. Therefore it was worked out under the assumption that the piston speed is 1,000 feet per minute.

The factor of piston speed takes in both the length of the stroke and speed of the crank shaft in revolutions per minute.

The shorter the crank, the quicker it can be turned; the longer the crank, the more piston travel per stroke. Therefore the crank can travel more slowly and still the piston will travel the required distance.

As an example: Suppose that the stroke of an engine is 4 inches: it would have to make 3 strokes to travel 12 inches, or 1 foot, because each stroke is 4 inches in length. Take, on the other hand, an engine with a stroke of 6 inches: it would have but 2 strokes to make for each 12 inches or 1 foot of travel. Therefore it is evident that the shorter the stroke, the faster the crank must move to cause the piston to travel 1,000 feet in the specified time.

The table below gives the piston travel in feet per minute, of engines with different strokes with various crank-shaft speeds.

RPM	Stroke in Inches 3	3¼	3½	3¾	4	4¼	4½	4¾	5	5¼	5½	5¾	6
200..	100	108	116	125	133	141	150	158	166	175	183	191	200
400......	200	217	233	250	267	283	300	317	333	350	367	383	400
600......	300	325	350	375	400	425	450	475	500	525	550	575	600
800......	400	434	466	500	534	566	600	634	666	700	734	766	800
1000......	500	542	584	625	676	708	750	792	834	875	917	958	1000
1200.....	600	650	700	750	800	850	900	950	1000	1050	1100	1150	1200
1400......	700	766	816	875	934	992	1100	1108	1165	1225	1282	1342	1400
1600......	800	868	932	1000	1068	1132	1200	1268	1332	1400	1468	1532	1600
1800......	900	975	1050	1125	1200	1275	1350	1425	1500	1575	1650	1725	1800
2000......	1000	1084	1168	1250	1352	1416	1500	1584	1668	1750	1852	1916	2000

Example: How many feet would a piston travel in an engine with a 3-inch stroke when the crank shaft was turning 200 revolutions per minute (r.p.m.)?

Ans.: The piston goes down 3 inches and up 3 inches to one revolution of the crank shaft. Therefore 3 inches down and 3 inches up would be 6 inches of travel of the piston to one revolution of the crank shaft. With 200 revolutions of the crank shaft, the piston would travel $200 \times 6 = 1{,}200$ inches. As there are 12 inches to a foot, then we should have $1{,}200 \div 12 = 100$ feet of piston travel per minute to 200 revolutions of the crank shaft.

This formula would be: $P = \frac{S \times 2 \times R}{12}$. P, is piston travel per minute which equals the stroke S, $\times 2$, $\times R$ (the revolutions per minute of the crank shaft) divided by 12.

How to Figure the S. A. E. Formula

This formula is used by all leading manufacturers and by the license offices in different cities. The formula is expressed as follows:

$$\text{Horsepower} = \frac{(\text{Diam. in inches})^2 \times \text{number of cylinders}}{2.5}$$

For example: What is the S. A. E. horsepower of a four-cylinder engine which has a 4-inch bore?

By referring to the table below, one 4-inch bore cylinder is 6.4 and 4 cylinders of 4-in. bore is 25.6 h.p.

This is arrived at as follows: $\text{h.p.} = \frac{D^2\ N}{2.5}$.

D^2 (diameter squared) $4 \times 4 = 16$.

N (number of cylinders) $16 \times 4 = 64$.

2.5 (constant) $64 \div 2.5 = 25.6$ h.p.

It will be noted that the stroke of the cylinder was not taken into consideration at all.

S.A.E. Horsepower Table

Inches	Millimeters	1 Cylinder	2 Cylinders	4 Cylinders	6 Cylinders	8 Cylinders	12 Cylinders
2½	64	2.5	5.0	10.00	15.00	20.00	30.00

POWER, WORK, HORSEPOWER, AND TORQUE; MEANING OF

Now that we know one method of computing horsepower, we will get down to fundamentals, so that we may have a clear understanding of this subject.

Power: In order to understand power, one must consider that its definition is the **rate (speed) of doing work.**

Work is a force acting through a distance. For example, if we lift 10 lbs. through 2 feet, we accomplish an amount of work equal to 10 lbs. × 2 ft., or 20 foot lbs.

The next factor is the rate (speed) of doing this work. For example, suppose we lift 10 lbs. through 2 feet in 10 minutes, our power is 10 lbs. × 2 ft.÷ 10 min., or **2 foot pounds per minute.**

Horsepower (h.p.) is, then, a unit of power, namely the accomplishment of 33,000 ft. lbs. of work in 1 minute, expressed as 1 horsepower (1 h.p.).

The horsepower unit is used in motor work as a standard rate of doing mechanical work, equal to 33,000 pounds (or weight) raised through a height of 1 foot in 1 minute; or any factors which multiplied together equal 33,000 ft. lbs. in the same time, is also equal to 1 horsepower. The horsepower has nothing to do whatever with the power developed by a horse—but in the days of Watt and early engineers (of the eighteenth century) the work in ft. lbs. capable of being done by an average draught horse in 1 minute was taken as the unit of power. The French horsepower equals 32,549 ft. lbs. of work in one minute, expressed as 1 horsepower, and is thus less than the English standard.

Torque is the product of force multiplied by the distance at which it is exerted from the center of rotation. For example, suppose we have a 1-foot pipe wrench and we apply a force of 40 lbs. on the end of that wrench, we shall then exert a torque of 40 lbs. × 1 foot, or 40 ft. lbs. of torque. On the other hand, if we had a 2-foot pipe wrench and exerted 40 lbs. on the end of it, we should exert a torque of 40 lbs. × 2 feet, or 80 foot lbs. of torque. This explains why it is easier to unscrew a pipe coupling with a 2-foot wrench than it is with a 1-foot wrench—the torque is greater.

When we say an engine develops 83 ft. lbs. torque, we mean that at a distance of 1 foot from the center of the crank shaft the engine would exert a force of 83 lbs., or at a distance of 83 feet from the center of the crank shaft the engine would exert a force of 1 lb. For instance, suppose we wished to stop an engine which exerted 83 ft. lbs. torque, by means of a pipe wrench. If a 1-foot wrench was used, by exerting a force of 83 lbs. on the end of the wrench, it would stop the engine. Or if an 83-foot wrench were used, a force of 1 lb. exerted at the end of the wrench, would stop the engine.

On the Ford engine the torque at 900 r.p.m. (see illustration of curve, Fig. 1), is 83 ft. lbs., and the h.p. is 14.2, whereas at 1,600 r.p.m., the torque is only 65 ft. lbs., and the h.p. is 20. Also note that the torque increases up to 900 r.p.m., and then falls off, and also note that the horsepower increases up to 1,600 r.p.m., and then falls off. To the layman it would appear that the greatest pull or force exerted would be at 1,600 r.p.m., but such is not the case. The greatest pull on this particular engine is at 900 r.p.m.

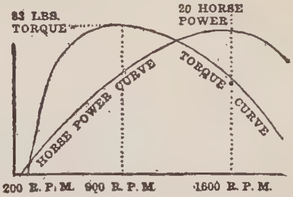

Fig. 1

The reason why greater horsepower can be developed with less torque is the factor of speed, which we have already seen is one of the items affecting power.

For example, the engine at 900 r.p.m. is like Tom, who can carry 150 lbs. of bricks (we will term the carrying capacity of Tom "torque"), **at a speed of 4 miles per hour.** Suppose the bricks had to be moved one mile. Tom could move 4 × 150=600 lbs. of brick in 1 hour.

The engine, while running at 1,600 r.p.m., is like Philip, who can carry only 125 lbs. of bricks, but can run at a speed of 6 miles per hour. Philip could then move the bricks a mile at the following rate of speed: 6 × 125=750 lbs. of brick in 1 hour. Thus, while Philip develops less torque, he develops greater power.

Therefore, at 900 r.p.m. the load carried (torque) is greater, but the speed is less, and the rate of doing the work is less. At 1,600 r.p.m. the load carried (torque) is less, but the speed and rate of doing the work (h.p.) are greater.

The reason why the engine develops less torque at 1,600 r.p.m. than at 900 r.p.m. is the fact that the cylinder receives a smaller charge of gas per stroke at 1,600 than at 900 r.p.m., because of the inertia and the friction of the gases passing through the manifold and valve. At the lower speed, the effect of inertia and friction is small, allowing a considerable quantity of gas to be introduced into the cylinder at each inlet stroke; on the other hand, at 1,600 r.p.m., the high velocity of the gas causes a considerable amount of friction, and the effect of inertia (tendency to move slower) is greater, which decreases the charge of gas entering the cylinder. This also accounts for the great decrease of torque and consequent falling off of power (h.p.) after 1,600 r.p.m. Therefore this engine exerts its greatest pull at 900 r.p.m., and the futility of racing an engine when attempting to pull out of a hole is apparent.

A given amount of power can be developed in cylinders of either large or small diameter. Thus there is the example of the stationary gas engine. To obtain, for example, 10 h.p. from this type of engine, a very large cylinder and comparatively slow speed would be employed, with a maximum speed of perhaps 300 to 600 r.p.m. A modern 10 h.p. automobile engine, on the other hand, has four very small cylinders, but a high speed, say 1,500 to 2,000 revolutions per minute. The individual power impulses are very much weaker than those of the large slow-speed engine, and consequently its parts can be made much lighter and smaller, as the shocks and stresses that have to be sustained are proportionately much less.

The Dodge engine, which has larger cylinders and valves, exerts its greatest pull (torque) at from 1,100 to 1,400 r.p.m., whereas its greatest speed and horsepower are at 2,200 r.p.m.

Power and Pressure and Other Terms

Brake horsepower (b.h.p.): Power delivered at the crank shaft.

Indicated horsepower (i.h.p.): Power delivered by the gas inside the cylinder to the piston.

If an engine develops 10 indicated horsepower, and it takes 3 horsepower to drive itself, the crank shaft would deliver 7 h.p., and the rating of the engine would be **7 brake** horsepower, or **10 indicated** horsepower.

To estimate the horsepower of an engine within a reasonable degree of accuracy, the following may be used.

Another H.P. Formula (not the S. A. E.)

The following formula takes into consideration the stroke as well as the bore, and also the speed.

H. P. Formula: $\frac{D^2 \times N \times L \times R}{C}$ = horsepower

This means, square the diameter or bore of the cylinder (**D^2**) and multiply the result by the number of cylinders (**N**); multiply this result by the length of stroke (**L**), and multiply this result by the revolutions (**R**) per minute of the crank shaft; then divide this total result by the "constant" (**C**) below.

The "constant" for a 4-cycle engine is 13,000.
The "constant" for a 2-cycle engine is 10,000.

Example: Suppose we have a 4-cylinder engine, 4-inch bore (diameter), and 5-inch stroke, and 1,000 revolutions per minute, what is the horsepower?

4 × 4 equals 16 (squaring the diameter **D^2**).
16 × 4 equals 64 (result multiplied by number cylinders **N**).
64 × 5 equals 320 (result multiplied by length of stroke **L**).
320 × 1,000 equals 320,000 (result multiplied by number of revolutions **R**).
320,000 divided by the "constant" 13,000, will give us 24.6 h.p. for a 4-cycle engine.
320,000 divided by 10,000 will give us 32 h.p. for a 2-cycle engine.

The "constant" is a figure arrived at by the founder of the formula. You will note there is a difference of 1 h.p. between the horsepower figured with this formula and the S.A.E. formula. There is usually a difference with all formulas.

To calculate the horsepower delivered by the crank shaft, the brake test must be made with a mechanical machine, such as a "prony brake test" (page 1045) or "dynamometer test" below; the result is the **b.h.p.**

Thermal efficiency of an engine: See dictionary, page 1078.

Mechanical efficiency of an engine: See dictionary, page 1077.

Compression pressure is the pressure of the gas after being drawn into the cylinder and compressed in the combustion chamber by the up compression stroke of the piston. This varies with the quantity of gas drawn into the cylinder, the speed of the piston, the size of the combustion chamber, and the condition of the valves, and rings, and the tightness of the parts. See also page 116.

The expansion pressure (often termed explosion pressure) would be the maximum or greatest pressure immediately following the combustion or burning of the gases. This pressure is many times greater than compression pressure. This expansion pressure (gas expands when ignited and heated) continues, but diminishes throughout the entire power stroke.

Mean effective pressure (**m.e.p.**): During the entire cycle of a gas engine, the cylinder is subjected to many variations of pressure. We have seen that during the power stroke, the pressure decreases as the piston proceeds along its stroke. All of this pressure causes the engine to deliver power. In the same way, during the compression stroke the pressure gradually increases as the piston travels upward. All of this pressure hinders the engine from delivering power, and should therefore be considered as a negative power. Now, if we average up all the pressures during a cycle and subtract those which hinder the engine from those which help it (the power stroke is the only stroke which helps), we shall arrive at the m.e.p., that is, the **average or mean pressure which is effective in producing power.**

M.E.P., meaning of: See dictionary.

Wind resistance increases in proportion to the "square" of the speed: thus at 20 miles per hour it is four times what it is at 10 miles, and at 30 miles per hour nine times, and so on.

METHODS OF MEASURING B. H. P.

There are several methods for measuring the b.h.p. of an engine, as, for instance, with a fan dynamometer, an electrical dynamometer, and by means of a prony brake test.

The Fan Dynamometer

This consists of a fan, driven by the engine. The power required to turn the fan increases with the speed, and at all times bears a definite relation to the speed. Hence, knowing the speed, it is possible to determine the horsepower being developed—see the r.p.m. (revolutions per minute) and h.p. table on the next page.

The speed is shown by means of a speedometer, driven from the fan shaft, but registering revolutions per minute instead of miles per hour.

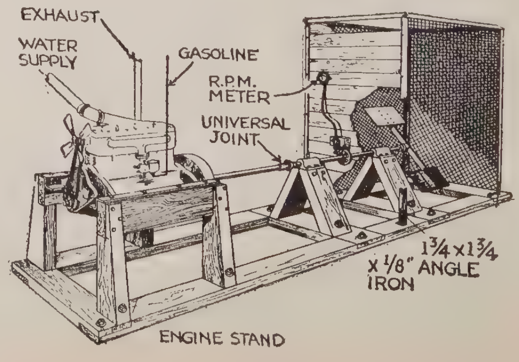

Fig. 2

The engine is bolted to a frame. The drive shaft is shown. The fan shaft is carried on two heavy pillow blocks bolted to wooden supports with ball or roller type bearings, if possible. The **fan arm** should be of solid bar nickel steel, 3″ x 3/8″ by 5/16″ long. The hub should also be of nickel steel.

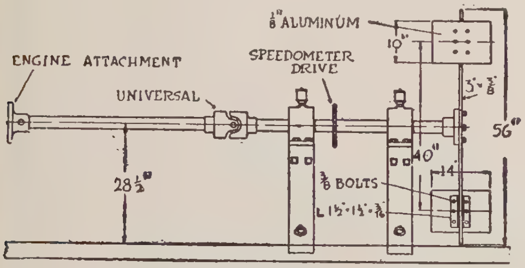

Fig. 3

Fan blades are of heavy sheet aluminum, placed 40″ apart on the centers, and bolted to the fan arm by means of angle-iron strips that are riveted back to back on the aluminum blades. To avoid accident the fan is enclosed in a cage of mesh wire netting.

Electrical Dynamometer

The method for testing the horsepower of a gasoline engine with an electrical dynamometer is as follows: The engine is belted or (preferably) coupled direct to a dynamo machine. Connected up with the dynamo are two specially accurate electrical measuring instruments, one a voltmeter and the other an amperemeter. The current which the dynamo produces when driven is used up, by either a group of lamps or a set of wire or liquid resistances. The amount of work the dynamo will do, such as lighting lamps, etc., depends on the power put into it from the engine.

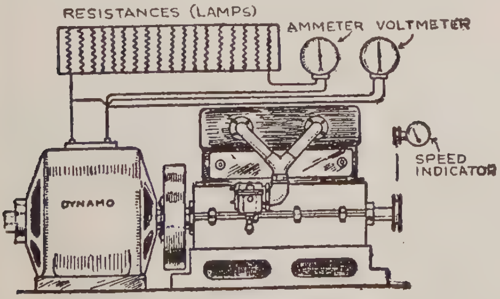

Fig. 4

It is easy to convert electrical power units into mechanical units. Thus: amperes multiplied by volts equals watts; there are 746 watts to a horsepower, so that by simply taking the readings of the voltmeter and ammeter, the amount of power the dynamo is giving out is at once calculated. The dynamo, of course, does not transform the whole of the power put into it into electricity, but it may transform somewhere near 90 per cent of it.

Certain mechanical and electrical losses occur in the dynamo, but these are calculated beforehand. Hence, knowing exactly how much of the power put into the dynamo is lost or wasted, and the maximum amount given out, the power actually produced by the engine will be the result.

Prony Brake Test

This is one method of testing the brake horsepower and torque of an engine.

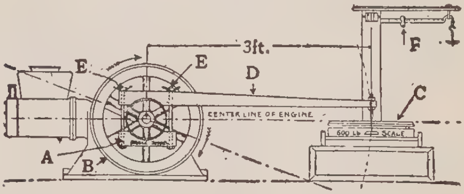

Fig. 5

One horsepower is defined as the power that will raise 550 lbs. 1 ft. high in 1 second, or, as the case may be, 33,000 lbs. 1 ft. high in 1 minute. The power that will do one will exactly do the other if the gearing is suitably arranged.

Torque is the product of force multiplied by distance at which it is exerted from the center of rotation. If arm (**D**) is 3 ft., and 30 lbs. pull is shown at (**F**) at 1,500 r.p.m., then the torque would be 30 lbs. × 3 = 90 **foot pounds torque.**

To find the h.p. at, say, 1,500 r.p.m., we start up the engine (having first rigged up to some convenient part a speed counter), open the throttle fully, tighten down the clamp by the screws (**E**) until the engine is slowed to the required speed, namely, 1,500 r.p.m. The number of pounds pull on arm (**D**) is now read off at (**F**).

Observe now the calculation. We first measure the distance from the central point of the flywheel to the point of the arm which rests on the scale. Assume this to be 3 ft., and the number of lbs. indicated on the scale to be 30, and we have all the necessary information.

This 3 ft. arm (**D**) is virtually the radius of an imaginary flywheel 6 ft. in diameter, which exerts at its rim., i.e., at the point resting on the scale, a pull of 30 lbs.

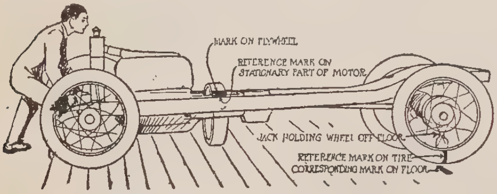
Now a flywheel having a diameter of 6 ft. has, roughly, a circumference of 19 ft., therefore during one revolution of the flywheel, the force of 30 lbs. will act through a distance of 19 ft., and if its speed is to be 1,500 r.p.m., we have here a rim speed of 28,500 ft. per minute, exerting a pull of 30 lbs., or in other words, 855,000 ft. lbs. per minute. But, as we have seen, 33,000 ft. lbs. per minute is 1 h.p.; therefore it requires but a simple division (855,000 ÷ 33,000) to find that the engine is developing nearly 26 h.p.

In actual practice, rather more elaboration is necessary to cope with secondary considerations. A suitable method of dealing with the friction on the flywheel, for instance, must be found, as well as a proper lining for the braking clamp, so that the drag on the flywheel is constant, free from jerks, etc.

Horsepower and revolutions. The gasoline engine, within certain limits, is dependent upon engine revolutions for power. If the revolutions are not maintained to a certain speed, especially on 1, 2, and 4-cylinder engines, the power is not sufficient to start a car or to climb hills. It is for this reason that transmission gears are necessary.

Relation of Speed of Engine to Road Wheels

If you do not know the ratio between the speed of the engine and the speed of the car, there is a way of arriving at this ratio approximately. Jack up both the rear wheels as shown in Fig. 6, and then, after throwing the car into low gear, crank the engine slowly by hand, counting the number of times the engine has to be completely turned over to one complete revolution of both rear wheels or two complete revolutions of one rear wheel.



MARK ON FLYWHEEL
REFERENCE MARK ON STATIONARY PART OF MOTOR
JACK HOLDING WHEEL OFF FLOOR
REFERENCE MARK ON TIRE
CORRESPONDING MARK ON FLOOR

Fig. 6

First make a reference mark on the flywheel, or take one of the timing marks as a reference, and after bringing this directly under the pointer, if there is one, or some other reference point on the flywheel housing, make a mark on the tire and another directly below this on the floor. **Now turn the engine slowly,** and when the rear wheel is again in line with its floor mark, count the number of times the flywheel has turned. If it has taken 20 revolutions of the engine, the ratio is 20 to 1, and so on.

Test the intermediate and high gear in the same manner. See page 8 for the meaning of "ratio" and page 9 for the ratio of different cars.

McCullough Formula for Finding the Speed of a Car

Engine speed per minute × diameter in inches of the rear wheel × .002975÷ratio.

The ratio of the drive, for example, is 4 to 1; which means that the engine crank shaft turns four times to one of the rear axle. Therefore the figure to be used to divide by would be four. The same holds good in all speeds, no matter if in first, second, third, or fourth speed.

Example: 1,000 (rev. of engine) × 30 (diameter in inches of wheel) × .002975, divided by 4 (4 to 1 ratio) equals 22.31, plus miles per hour.

PISTON DISPLACEMENT[1]

Piston displacement means the volume of gas displaced during one stroke of the piston. For example, when the piston is at top dead center, there is a certain volume in the combustion space above the piston, say, 10 cubic inches. When the piston is at the bottom of stroke, there is a greater volume above the piston, say, 63 cubic inches. The piston displacement in this case would be 53 cubic inches (63−10=53) for one cylinder, or 53×4=212 cu. in. displacement for a 4-cylinder engine.

To compensate for inferior quality of gasoline, some manufacturers have reduced the area of combustion chamber, so as to give a high compression. (See tables[1] of Piston Displacement on next page.)

How to find piston displacement: The formula would be designated thus: $D^2 \times .7854 \times S \times N =$ piston displacement. D^2 means diameter or bore squared or multiplied by itself, as 5×5. This result is then multiplied by the constant .7854 (the area of a cylinder 1 inch in diameter), this result by **S**, the stroke in inches, and this result by **N**, the number of cylinders.

Example: What is the piston displacement of four cylinders, 4-inch bore and 5½-inch stroke? Procedure: 4×4=16×.7854 =12.566×5½ (or 5.5)=69.115×4=276.5 cubic inches.

Example: What is the piston displacement of four cylinders 3⅛-inch bore and 4⅝-inch stroke? Procedure: 3⅛ × 3⅛ × .7854×4⅝×4=141.9 cubic-inch piston displacement.

GRADES

The general assumption is that a grade of 100 per cent would be vertical, or at a 90° angle, as in line (**D**) (Fig. 7); but this is incorrect.

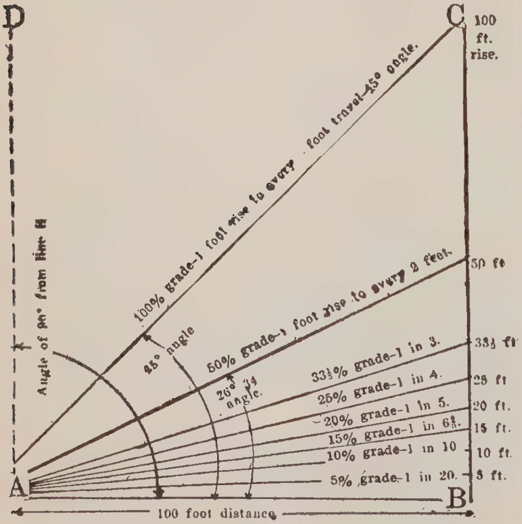


Fig. 7

A grade is expressed in terms of percentage, and means so many feet rise or fall in a given distance measured in a horizontal direction. This given distance may, for convenience, be 100, 500, 1,000 feet, etc.

A rise of 100 feet in the same distance measured horizontally is a 100 per cent grade; however, the included angle is 45°, and not 90°. Fig. 7 shows the grade percentage, which is based on a horizontal distance, line (**B**) of 100 feet.

Assume that line (**B**) is a straight line, 100 feet long and perfectly level. Therefore from (**A**) to (**B**) there would be no grade. If from (**A**) to (**B**) there was a rise of 1 foot in every 20 feet, when we reached line (**B**) we should be 5 feet higher than at (**A**). Therefore this would be a 5 per cent grade. It is not necessary, however, to travel the full distance. Just as long as there is a rise of 1 foot to every 20 feet, it is a 5 per cent grade at any point.

If the grade or steepness increased to 1 foot rise in 10 feet, then it would be a 10 per cent grade, and we should be 10 feet higher at line (**B**) than at (**A**). 1 in 6 2/3 is a 1 foot rise in 6 2/3 feet, and a 15 per cent grade, and so on up to 100 per cent grade, which would be a rise of 1 foot in 1 foot, as the slope from (**A**) to (**C**).

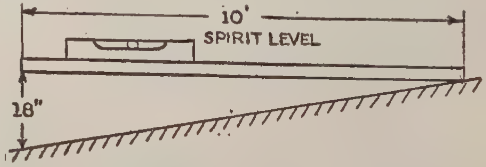

Fig. 8

To ascertain the percentage of a grade without the use of any special instruments: Secure a spirit level and a ten-foot stick (Fig. 8). Rest one end of the stick on the road surface and find its level position with a spirit level, by placing this on the stick and raising o lowering the stick until the bubble is in the center

---

[1] The tables of Piston Displacement on the next page are taken from the instruction book of the Stromberg Motor Devices Co. (carburetor manufacturers).

Then measure the perpendicular distance between the end of the stick and road surface, and multiply by 10, which will give the rise in feet in proportion to one hundred feet.

For example: Assume that the perpendicular distance measured 18 inches; this multiplied by 10 gives 180 inches, and reduced to feet gives 15 feet as the rise in 100 feet, or a 15 per cent grade.

The average of such measurements taken on grades will give fairly accurate results.

Per cent		Angle
100	1′ in 1′	45°
50	1′ in 2′	26° 34′
25	1′ in 4′	14° 2′
20	1′ in 5′	11° 19′
15	1′ in 6 2/3′	8° 32′
10	1′ in 10′	5° 43′
5	1′ in 20′	2° 52′

The affix to the figures in the center column, as 1′, means 1 foot; whereas in the right-hand column, as 34′, it means 34 minutes.

A 66 2/3 per cent grade is as steep as a car could possibly climb, as **gravity overcomes traction** at this angle.

NOTE:—S. A. E. Horse-power rating is based on *1000 feet per minute piston speed.*
To find equivalent horse-power in *1000 revolutions per minute,* multiply rating, for given bore, by factor "A" for given stroke.

MISCELLANEOUS TABLES, DATA, AND INFORMATION

Miscellaneous Computations

Atmospheric pressure equals 14.7 lbs. per square inch at sea level.

To find the circumference of a circle, multiply the diameter by 3.1416.

To find the diameter of a circle, multiply the circumference by .31831.

To find the area of a circle, multiply the square of the diameter by .7854.

To find the area of a triangle, multiply the base by one-half the perpendicular height.

To find the surface of a ball, multiply the square of the diameter by 3.1416.

To find the solidity of a sphere, multiply the cube of the diameter by .5236.

To find the cubic inches in a ball multiply the cube of the diameter by .5236.

Doubling the diameter of a pipe increases its capacity four times.

A cubic foot of water contains 7½ gallons, 1728 cubic in., and weighs 62½ lbs.

To convert gallons of water to pounds, multiply by 8.345

Decimal Equivalent of Fractional Parts of an Inch

In using this table it is not necessary to carry out all of the fraction. As a rule, three figures to the right of the decimal point is close enough for all practical purposes—which would be, of course, read in thousandths, as .015 (fifteen one-thousandths).

8ths

⅛=.125
¼=.250
⅜=.375
½=.500
⅝=.625

59/64=.921875
61/64=.953125
63/64=.984375

.015 is approximately 1/64″; .025 is 1/40″.

The one-thousandth part of an inch is explained elsewhere. See page 701.

Hundredths of an inch to sixty-fourths of an inch are explained elsewhere. See page 68.

Metric System[1]

The metric system, called the French standard, is used quite extensively abroad and is also referred to quite often in this book. Therefore a conversion of those figures most generally used is given. See tables below.

m is the designation of meter; **cm,** centimeter; **mm** or **m/m** millimeter.

1 millimeter is approximately 1/25″, and is exactly .03937″.

1 centimeter is approximately 13/32″, and is exactly .3937″.

1 meter is approximately 39¼″, and is exactly 39.37″, or 1.0936 yards.

1 kilometer is approximately ⅝ mile, and is exactly .6213 mile.

1 kilogram is approximately 2¼ lbs., and is exactly 2.21 lbs.

1 liter is approximately 2 1/9 pints, and is exactly 2.11 pints

10 mm. = 1 centimeter = 0.3937″
10 cm. = 1 decimeter = 3.937 ″
10 dm. = 1 meter = 39.37″
25.4 mm. = 1 English inch.

To convert inches to centimeters, multiply by 2.54

To convert meters to yards, multiply by 70 and divide by 64.

To convert kilometers to miles, multiply by 5 and divide by 8 (approx.).

To convert cubic inches to cubic centimeters, multiply by 16.39.

To convert cubic meters to cubic feet, multiply by 35.32.

To convert grams to ounces, multiply by 567 and divide by 20.

To convert liters to U.S. pints, multiply by 95 and divide by 45.

See page 595 (tires) for metric conversions.

---

How to Find Degrees with a Protractor

A degree is a unit employed in measuring angles, and is the ninetieth part of a right angle or one three-hundred and sixtieth part of a circle.

The degree explanation is given on page 60. See also pages 68 and 299, "Converting degrees into inches."

A protractor is used for dividing circles into any number of equal parts or degrees, and for determining angles.

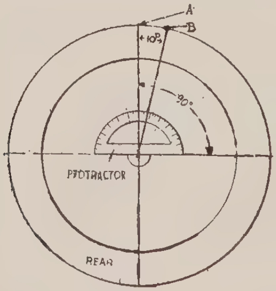

Fig. 10

For instance, to find the number of degrees in a circle with a protractor, say, of a flywheel of an engine: Place the protractor as shown. From the center line (A) to (B) is 10°; from (A) to the extreme right, the lower part of the protractor—if a line was drawn—you would have a right angle, or 90°. The number of degrees from the extreme left to the extreme right of the protractor would be 180°, or half a circle. The entire circle would be 360°. In other words, the circle is divided into 360 equal parts called degrees, and designated by the symbol °.

We can divide each degree into 60 parts, called **"minutes,"** and each minute can be divided into 60 parts called **"seconds."** One minute would be designated thus (1′), and one second thus (1″).

Signs or Symbols of Inches, Feet, Minutes, and Seconds

The sign for inches or seconds is (″), as 6″.

The sign for feet or minutes is (′), as 6′.

It will be observed that the same symbols are used for inches and seconds, and also for feet and minutes.

Freezing and Boiling Point and Specific Gravity of Water, Alcohol, Kerosene and Gasoline

Mercury freezes at 38.7° below zero, and **boils** or gives off gas at 357° above zero, Fahrenheit.

Constants	Water	Wood Alcohol	Ethyl Alcohol	Denatured Alcohol Formula #1	Kerosene	Gasoline
Freezing Point	+32°F 0°C	—144°F —98°C	—202°F —130°C	—200°F —129°C	Does not have a definite point Solidifies about —50°C	—202°F —130°C
Boiling Point	+212°F +100°C	153°F 67°C	173°F 78.4°C	171°F 77.4°C	387°F 197°C	173°F 78.5°C
Specific Gravity	1.000 at 0/4°C	.789 at 0°C	.8002 at 0°C	.8164 at 15°C	.815 at 15°C	728 at 15°C

1 lb. of gasoline of 58 specific gravity is approximately 8/10 of a pint. **A gallon of gasoline** (58 s.g.) weighs approximately 6.6 lbs. See page 1078, under "Thermal efficiency," for the number of B.T.U.'s to a pound of gasoline.

Capacity of Cylindrical Tanks

The formula for computing the capacity of a cylindrical tank is as follows:

$$C = \frac{D^2 \times L}{293.3}$$

C is the capacity in gallons.
D is the diameter of the tank in inches.
L is length in inches.

Example: What is the capacity of a tank 10″ in diameter and 12″ long?

C is the capacity of the tank, which we desire to know, and is equal to the diameter squared (**D**²) or multiplied by itself, as 10 × 10=100 × by (**L**), the length, or 12 inches =1,200. The line under **D**² × **L** means that the total of **D**² × **L**, which is 1,200, is divided by a constant 293.3=4.09 gallons.

The table gives the capacity of tanks in gallons for given sizes.

Length	12 in.	16 in.	20 in.	24 in.	28 in.	32 in.	36 in.
Diameter	Gal.	Gal.	Gal.	Gal.	Gal.	Gal.	Gal.
10 in.	4.09	5.45	6.81	8.17	9.53	10.89	12.25
15 in.	9.20	12.27	15.34	18.40	21.47	24.54	27.61
20 in.	16.36	21.80	27.24	32.68	38.12	43.56	49.00
25 in.	25.56	34.08	42.60	51.12	59.64	68.16	76.68
30 in.	36.81	49.05	61.29	73.53	85.77	98.01	110.25
35 in.	50.15	66.87	83.59	100.31	117.02	133.74	150.46

S.A.E. Recommended Sizes of Carburetor Flanges (Two-Bolt Type)

The following data give the **opening in carburetor** flange (A); thus one can **tell the size of a carburetor** by measuring this opening. See also page 109.

If a **carburetor flange** on the inlet manifold or on the carburetor is **to be repaired,** such as welding, etc., the **diameter and distance apart of bolt holes,** as well as of the threads are given.

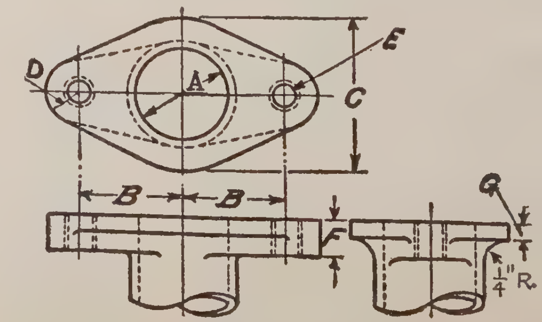

Fig. 11. S. A. E. Carburetor flange dimensions. See table, page 1051, giving the dimensions of A to G above on different sizes of carburetors.

Nom. Carburetor Size	A	B	C	D	E*		F†	G†
					Diam.	Threads per Inch		
½	13/16	29/32	1 7/16	9/32	1/4	20	5/16	3/32
⅝	13/16	29/32	1 7/16	9/32	1/4	20	5/16	3/32
¾	1 1/16	1 1/8	1 3/4	11/32	5/16	18	3/8	1/8
⅞	1 1/16	1 1/8	1 3/4	11/32	5/16	18	3/8	1/8
1	1 3/16	1 3/16	1 7/8	11/32	5/16	18	13/32	5/32
1¼	1 7/16	1 11/32	2 3/16	13/32	3/8	16	15/32	3/16
1½	1 11/16	1 15/32	2 1/2	13/32	3/8	16	15/32	3/16
1¾	1 15/16	1 21/32	2 13/16	15/32	7/16	14	9/16	7/32
2	2 3/16	1 25/32	3 1/8	15/32	7/16	14	9/16	7/32

* **U.S. standard thread.** All dimensions in inches.

† **Cast-iron carburetor flanges:** Flange dimensions (F) and (G) shall be increased ⅛″ for cast-iron carburetors.

Side-outlet carburetor flanges: The standard flange dimensions shall be used with the long diameter of the flange in a vertical plane when attaching carburetors of the side-outlet type.

Localities Where Cars Are Owned

The following is an analysis of present ownership of registered automotive vehicles, published by the National Automobile Chamber of Commerce, based on a survey made by J. M. Gunn, president of the U.S. Tire Co.

In towns of 1,000 and under 33 per cent
In towns of 1,000 to 5,000 20 per cent
In towns of 5,000 to 50,000 16 per cent
In cities of 500,000 or over 9 per cent

Location of Numbers and Weight of Cars (S.A.E. Standard)

The standard location for the engine number shall be on the crank case proper, at the front end, as near the middle as practicable crosswise, and on top, if possible. Consideration should be given to accessibility in the completely assembled car. If it is not possible to locate the number near the center at the front, that position should be approximated, preference being given to the right-hand side. The number should be deeply indented in the crank case in characters at least ¼″ high.

The standard location for the maker's identification number on car, chassis, or frame (whichever is used for identification) shall be on the outside flat of the right-hand frame member, as far forward as possible. Such number shall be heavily indented in the frame side-member in characters not less than ¼″ high. Where this location is inaccessible, it should be approximated.

The use of attached plates in lieu of numbers stamped as specified is discouraged, because of the ease with which a plate can be removed.

The standard weight of a car shall be the actual scale weight with complete catalog equipment, less fuel and water.

Example of location of serial numbers on a car (Reo): The location is shown on the illustration above (Fig. 12). The numbers vary on different cars. The part number of the spring and date of manufacture are to be found on short leaf.

VALVE TIMING, VALVE CLEARANCE AND VALVE DIMENSIONS, 1920 AND 1921 PASSENGER CAR ENGINES

The tables on pages 1052, 1053 give the valve setting in degrees and minutes for 1920 and 1921 cars. For example, the intake closes "46-40" on the Cadillac; meaning 46 degrees and 40 minutes.

The tables also give the valve clearance and the diameter and length of the valve, as taken from *Motor Age*.

Average Valve Setting

If the timing of an engine is not known, and you desire to set the valves, here is a plan to follow:

The pitch of the timing gears is generally coarse enough to allow of only one proper setting, and when

[*concluded on next page*

—*continued from page 1052*

the proper position is almost reached, the tooth of the cam-shaft gear, which should mesh between the two teeth on the crank-shaft gear, will be so close that less than the width of one tooth will be between that and the exact position.

The following is an average setting of 114 cars, as given by *Motor Age*. The intake opens 9.5° late and closes 37° late. The exhaust valve opens 50° before bottom, and closes 9° late. It is not necessary to pay any attention to more than one of these dimensions; for instance, set the exhaust closing with the cam shaft, since most engines are of the L-type, with all cams on one shaft.

After making this setting you can determine if the setting is wrong, as it will probably be out only one tooth on the cam-shaft gear, one way or the other.

NAME AND MODEL	VALVE TIMING Measured in Degrees and Minutes						Valve Diameter	Valve Stems

SPECIFICATIONS OF ELECTRICAL EQUIPMENT OF 1922 PASSENGER CARS

Pages 1064 and 1065 give the make of ignition system; gap to set contact-breaker points; position to set spark lever when timing ignition; spark-plug thread; make of generator; charging rate; make of starting motor; make of battery, and ampere-hour capacity.

Pages 1066 and 1067 give the voltage of the electric system; wiring; fuse capacity; lamp bulb candle power; diameter of headlight lens. (From *Motor Age.*)

Registration of Cars, Trucks, and Motorcycles in the U. S., up to February, 1922. (from Table compiled by Automotive Industries, New York.)

Passenger cars, 7,628,949; *Commercial cars*, 958,259; *Motorcycles*, 181,194; *Total Registrations*, 10,449,785; *Total Fees*, $98,499,925.66.

The state with the greatest number of registrations is New York, with 754,085; Ohio is next with 742,713; Pennsylvania is next, with 689,589; California is next, with 674,830; Illinois is next, with 670,452. The state with the least number is Nevada, 10,819. *Ohio has the greatest number of passenger cars*, 647,774; California next, 638,922. *New York has the greatest number of trucks*, 172,170; Illinois next, 79,906; Pennsylvania next, 57,048. *New York has the greatest number of motorcycles*, 25,024; Ohio next, 21,938; Pennsylvania next, 21,111.

SPECIFICATIONS OF THE ROLLS-ROYCE CAR[1]

Engine: 6-cylinder; cast in two blocks of 3 cylinders each.

Bore: 4½″.

Stroke: 4¾″.

Carburetor: Special Rolls-Royce design and make.

Engine H.P.: 48.6 (N.A.C.C. Rating); Max. 80.

Max. torque at 1,300 revs.

Engine r.p.m.: 200-2,750.

Total length of frame: 178¾″.

Total width of frame: 30″ front; 36″ rear.

Wheelbase: 143½″.

Wheel track: 56″.

Size of tires: 33″ x 5″.

Ground clearance: 12¼″.

Gear ratio—rear axle: 3.25 to 1.

Gear box: 4 speeds ahead and 1 reverse.

Gear-box ratio: 3.25-1; top, 1-3.25; third, 1-4.83; second, 1-7.23; first, 1-11.06.

Type of steering: Worm and nut.

Turning radius: 23.8′ left—25′ right.

Chassis speed: 4 to 80 miles per hour on direct gear.

Chassis weight: 3,200 pounds.

Lubricating system: Pressure.

Fuel feed: Pressure.

Gas consumption: 11 to 13 miles per gallon (U.S.)

Oil consumption: 1 gallon per 1,000 miles.

Capacity of gas tank: 21 gallons.

Capacity of crank case: 6 quarts.

12-volt starting and lighting system.

Ignition system: Two systems: magneto and battery; may be used separately or together.

Water system: Centrifugal pump; recording thermometer on dash board.

Rear axle: Full floating type; Gleason spiral bevel.

Clutch: Cone type, cotton fabric lined.

Brakes: Both internal expanding on rear wheels.

Ferodo lined foot brake: 17″ diameter.

Hand brake: 12″ diameter.

Springs: Front, semi-elliptic; solid eye top plate; rear, cantilever.

SPECIFICATIONS FOR DUESENBERG STRAIGHT EIGHT AUTOMOBILE[2]

Engine: Eight cylinders in a row; bore 2⅞″; stroke 5″; displacement 260 cu. in.; developing from 90 to 100 h.p.; speed 3 to 90 m.p.h.

Cylinder block: Gray iron; the upper half of the crank case and cylinder block are cast in block.

Cylinder head: Removable, with overhead cam shaft, rocker-arms, valves and springs enclosed by a detachable cover; the vertical drive shaft and gears are so arranged that the timing of the valves cannot be changed when the head is removed.

Cam shaft: One-piece hollow drilled for pressure oil feed to the five bearings; it is driven by a vertical drive shaft and spiral bevel gears.

Rocker-arms: Forged alloy steel; locked adjustment for the valve clearance at the end of the rocker-arm; bearings are oiled under pressure through a hollow drilled rocker-shaft.

Valves: Two per cylinder, each actuated by a rocker-arm and two springs, one inside the other; springs secured by taper keys.

Combustion chamber: Bored out in a spherical shape and polished to prevent collection of carbon.

Vertical drive shaft: In two pieces so arranged that the head can be removed and replaced without the possibility of changing the valve timing.

Oil pump: Driven direct from the crank shaft; a special Duesenberg feature consisting entirely of a system of gears capable of delivering a pressure of 250 lbs. per sq. in.

Water pump: An impeller of the centrifugal type.

Crank shaft: One piece having three main bearings; front 2⅜″ x 2¼″; center 2⅜″ x 2½″; rear 2⅜″ x 3″; the connecting rod bearings are 2″ x 1⅞″; the crank shaft is drilled, and oil is forced to all bearings under pressure.

Connecting rods: Length 9¾″; machined all over; hollow tubular type; piston pin held in place by a lock screw; lower end is arranged with fins which provide lightness, strength, and a large cooling area.

Pistons: Flat-top 3⅛″ rings are used; diameter 2⅞″; length 3⅛″.

Oil pan: Aluminum, removable while engine is in frame; lower half is used as a reservoir for oil; oil is drawn through a strainer from the sump in the bottom of the oil pan by the oil pump and forced to all bearings under pressure.

Breather: Covered by a hinged cap which also acts as a convenient oil-filler pipe and has the oil gauge mounted on the front of it.

Flywheel: Steel forging machined all over with gear teeth cut in periphery for the starting motor.

Carburetor: 1½″ mounted on right side of engine; gas passes from the intake manifold through the head of the motor to the left-hand side, where it is distributed to the cylinders through an aluminum ramshorn intake; a part of the exhaust manifold is cast integral with the intake manifold, and through this the exhaust passes, creating a hot spot.

Electrical equipment: Delco is used throughout; the distributor is mounted on the generator; this locates the distributor centrally making possible a very neat distribution of wires to the spark plugs.

Spark plugs: Metric threads, one per cylinder, set in the head at an angle to prevent fouling; amply cooled and very accessible.

Engine mounting: Three-point suspension; the rear of the engine is suspended by side arms on a bell housing bolted directly to the frame; the front is supported by a patented trunnion, which makes an extremely strong, light, and flexible mounting.

Accessibility: Adjustment on the engine, carburetor, electrical equipment, and spark plugs are extremely easy to make because of the simplicity of engine construction.

Clutch: Single dry plate of a special Duesenberg design with an adjustable pedal.

Transmission: Three speeds forward and one reverse, with ground gears of a special Duesenberg design; gear ratio reverse 4.016 to 1; first speed, 3.167 to 1; second speed, 1.654 to 1; high direct drive 1 to 1.

Universal joints: The drive to the real axle is through a double flexible joint and a tubular drive shaft, which is enclosed in a torque tube.

Drive gears: Spiral bevel; ratio of 4.6 to 1.

Rear axle: One-piece reinforced molybdenum steel of a new design extremely light and strong; ball bearings are used throughout.

Differential: Consists of a forged steel case enclosing a spider arm, four bevel gears and two side gears splined for the axle shaft.

Axle shaft: Molybdenum steel hollow; shaft and hub are one piece.

Rear axle mounting: The front end of the torque tube is hinged to the center cross-member by a yoke; both ends of the springs suspend the frame by shackles; two radius rods run from the axle to the front end of the torque tube to provide strength.

Front axle: Tubular; axle ends and steering knuckles are of molybdenum steel of a new design from 25 to 40 per cent lighter than the majority of axles now in use and from 25 to 40 per cent stronger.

Wheel base: 134″.

Springs: Semi-elliptic; front 2¼″ wide by 40″ long; rear 2½″ wide by 59″ long.

Frame: Chrome nickel steel 6 7/16″ in depth of section by 2⅛″ cross-section; it is strongly braced by five rigid cross-members.

Hydraulic brakes: 16″ forged drums are fitted to all four wheels, ground to give a perfect braking surface; circumferential fins are machined on the outer edge to provide strength, lightness, and radiating surface; the four brakes are operated by hydraulic pressure; a master-cylinder is attached to the foot brake and the liquid is forced through the lines running to the four wheels by a piston in the cylinder; a small cylinder in each one of the four brakes has a piston which is forced upward by the liquid entering the cylinder; the piston then operates a toggle arm which in turn expands the two brake shoes in each brake.

Hand brake: Operates manually a contracting brake on a drum at the forward end of the propeller shaft.

Wheels: Rudge Whitworth wire wheels are used.

Spare wheels: One spare wheel is carried on a 3-point mounting on the rear of the car and locked in place by a patented Duesenberg device.

Tires: 33″ x 5″ cord tires are used all around.

Weight: The weight of the car is 3,200 lbs.

Clearance: Clearance, lowest point 10″.

---

[1] Manufactured by Rolls-Royce Co. of America, Springfield, Mass.

[2] Duesenberg Auto & Motor Co., Indianapolis, Ind.

Bumper: The bumpers are a part of the car and are of a special design.

Shock absorbers: Are standard equipment.

Chassis lubrication: Alemite.

Gas tank: Capacity 20 gallons; located at the rear.

Vacuum system: A special Stewart vacuum tank is located on the cast-aluminum dash.

Body: Aluminum; steel fenders; running boards.

Instrument board: Instruments are grouped and enclosed under plate glass, making them dust proof; they are illuminated by indirect lighting.

Dimming head lights: A specially designed dimming arrangement is located in a convenient position on the steering wheel.

Manufactured by Duesenberg Automobile & Motors Co., Inc. Indianapolis, Ind.

SPECIFICATIONS OF THE PIERCE ARROW "MODEL 32"

The Pierce-Arrow: model "32" car numbers run from 321,001 to 329,999. This model is manufactured in conjunction with the 38 and 48 h.p. right-hand drive models, the latter being produced in limited quantities.

Engine: 6 cylinders, T-head which is removable with cylinders in-block, instead of in three pairs, as in the 1918, 1919 and 1920 models. **There are two cam shafts,** one on each side of the engine. One cam shaft (right-hand side) operates the exhaust valves, and on the left side, the inlet valves. **There are two inlet and two exhaust valves to each cylinder,** called "dual valves." The outside diameter of the inlet and exhaust-valve head is 1⅝″. The diameter of the throat, where the bevel of the valve begins, is 1½″, and the lift of the valves is 11/32″. This dual-valve engine was first incorporated in "Series Five" in June, 1918. The **valve clearance** on the exhaust valve is .005″, and the inlet .003″, adjusted when the engine is hot.

Cylinder dimensions are 4″ bore by 5½″ stroke. The speed of the engine is 200 to 3,000 r.p.m., the latter speed corresponding to 75 miles per hour. See page 54 for illustration of Pierce-Arrow engine.

Ignition: Delco closed-circuit system, with automatic spark advance. There are two spark plugs to each cylinder, this being called "double ignition," comprising two complete systems, either of which can be used alone if desired. The two plugs in each cylinder insure positive ignition and complete combustion.

Spark plugs: ⅞″ A.L.A.M., with 1/32″ gap; timer contacts should open .030″; **firing order,** 1, 5, 3, 6, 2, 4.

Starting motor: A Delco starting motor in a separate unit, with a mechanically shifted pinion which meshes with the gear on the flywheel, is on the right side of the engine.

The generator is a third-brush regulated, shunt-wound Delco generator, mounted as a separate unit on the right side of the engine. **Storage battery:** Willard, 6-volt. See Index under "Wiring diagram Pierce-Arrow electric system."

The carburetor is the Pierce-Arrow, similar to that used in the 1919 model. A few of the first cars of this model were equipped with a special Stromberg carburetor.

Gasoline feed is by air pressure. One pipe from the fuel tank in the rear is connected to a power and hand air pump, and is called the air-pressure pipe; the other is the fuel pipe to the carburetor. The **air pressure** of the gasoline gauge varies from 3½ lbs. to 4 lbs. per square inch.

The oiling system is a full-force system. The oil is not only forced to the cam-shaft and crank-shaft bearings, but is also forced to the piston pin. **Oil pressure** varies from 0 to 75 lbs. per square inch. A pressure of from 2 lbs. to 3 lbs. should show when the engine is throttled down to its lowest speed, and from 14 lbs. to 20 lbs. when the engine is running at 40 m.p.h. on level roads. Readings are taken when the engine is warm.

Transmission: Three forward and one reverse speed. Some of the earlier models had four speeds. The **final drive** is by means of spiral bevel gears. **Rear axle,** semi-floating. **Tires,** straight side 33″ x 5″. **Gasoline capacity,** 26 gallons. **Wheel base,** 136″. **Tread,** 56″. **Clutch,** multiple disk, dry plate. **Gear shift** is the standard S A.E.

The rear-axle ratio of the six and seven-passenger car, model "32," is 4.29 to 1; on the four-passenger car, 4.00 to 1; on the model "RBT," 3.75 to 1.

Transmission ratio in first speed, 3.45 to 1.
Transmission ratio in second speed, 1.73 to 1.
Transmission ratio in third speed, direct.
Transmission ratio in reverse speed, 4.26 to 1.
Total gear reduction in third, 4.29 or 4.00 or 3.75.
Total gear reduction in reverse, 18.27 or 17.04 or 16.01.

Earlier models of the Pierce-Arrow: Three models were formerly made; the model using a **38** h.p., 6-cylinder engine with bore of 4″ and a stroke of 5½″, speed 200 to 2,200 r.p.m.; the model using a **48** h.p., 6-cylinder engine, bore 4½″, stroke 5½″, speed 250 to 2,000 r.p.m.; the model using a **66** h.p., 6-cylinder engine, bore 5″, stroke 7″, speed 150 to 1,800 r.p.m.

Ignition used was the Bosch type "ZR 6," model 4, high-tension magneto, and a second system consisting of a battery and coil which was a part of the Westinghouse **generator.**

The starting motor was a Westinghouse, with an automatic electromagnetic pinion shift.

The double-unit Delco ignition was used on the "48," model "511," in 1919. (Pierce Arrow Co., Buffalo, N.Y.)

SPECIFICATIONS OF THE "STAR" CAR[1]

This car is a Durant creation, manufactured by the Star Motors Inc., 511 Fifth Ave., New York, N.Y.

Engine: 4 cylinders; L-head; made by Continental Motors Corpn.; cylinders cast integral with upper crank case; detachable cylinder head; lower crank case detachable, made of sheet metal; **bore** 3⅛″; **stroke** 4¼″; develops maximum of 35 h.p. at 2,500 r.p.m.; 152.1 cu. in. piston displacement; cam shaft and generator shaft driven by chain at front end of engine; chain has triangular layout; **engine has 4-point suspension.**

Lubrication: Oil under pressure is forced through hollow cam shaft, and thence, still under pressure, to the main bearings; connecting-rod bearings and pistons are lubricated by splash system.

Manifolds: Inlet and exhaust manifolds are cast in one common wall, thus producing "hot spots" for incoming charge.

Fuel system: Fuel tank of cylindrical shape mounted on rear of frame; Stewart-Warner vacuum feed to carburetor; Tillotson carburetor.

Clutch: Single-plate disk (see Fig. 14).

Transmission: Selective type, 3 speeds.

Universal joints: Spicer.

Axles: Front axle I-beam; rear axle of Timken make, semi-floating, spiral bevel gear, 4⅞ to 1 ratio; differential can be removed through cover plate in rear-axle housing.

Cooling: Water-circulating pump driven by extension of generator shaft; belt-driven fan.

Steering: Cross type; steering gear of worm-and-wheel type; steering wheel of usual type, but carries horn button only.

Spark and throttle levers: Mounted on dash, of bell-crank type (see Fig. 14), foot accelerator inter-connected.

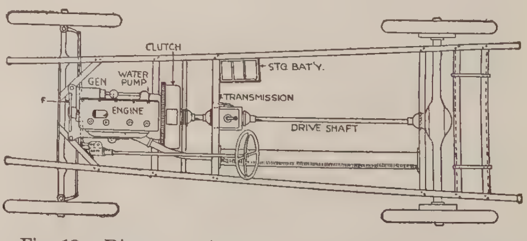

Fig. 13. Diagrammatic view of Star chassis, showing approximate layout of various units and general type of construction employed. Note that a device termed a "tubular backbone," extending from the transmission cross-member to the rear cross-member, is used which prevents racking or squeaking of the body. The muffler is enclosed therein.

Springs: Front springs semi-elliptic, 1¾″ wide by 34″ long; rear are semi-elliptic, 6-leaf, 1¾″ wide by 48″ long.

Brakes: Internal hand brake and external foot brake acting on rear wheel drums.

Bearings: Wheels and differential mounted on Timken bearings.

---

FRONT VIEW OF INSTRUMENT BOARD NOTE SPARK AND THROTTLE LEVERS "L"
L L
TOP VIEW OF INSTRUMENT BOARD. NOTE LEVERS "L"

Fig. 14

Ignition: Auto-Lite make; high-tension coil mounted on top of generator; distributor mounted on vertical shaft behind generator.

Electrical system: Auto-Lite generator; cut-out mounted on side of generator ; U.S.L. battery; this equipment furnished on all cars.

Tires: 30″ x 3½″ all around; demountable rims furnished on chassis, runabout, or phaeton at extra cost.

Wheel base: 102 inches.

The prices of the Star car, f.o.b. Detroit, are as follows:

Chassis	$285.00
Phaeton	348.00
Phaeton with starter and demountable rims	443.00
Runabout	319.00
Runabout with starter and demountable rims	414.00
Coupé with starter and demountable rims	580.00
Sedan with starter and demountable rims	645.00

STANDARD ADJUSTMENTS OF THE PACKARD TWIN SIX "3-25" AND "3-35"

Ignition interrupter points should be set .015″ to .020″ when fully separated.

Ignition timing: The spark setting in the fully advanced position should be 2⅝″ (measured on the circumference of the flywheel) before upper dead center.

Should it become necessary **to check this,** proceed as follows: Remove the motor-starter switch cover over the flywheel. Set the spark lever on the steering wheel in the fully advanced position. Open all priming cups with the exception of the one in No. 1 cylinder in the right block. Crank the engine by hand until compression begins in this cylinder; then open this priming cup and continue to crank the engine slowly to the point where the right interrupter points just begin to separate. In this position, the letters "S.R." on the flywheel should be just opposite the center line of the engine, as indicated on the crank case.

In order to test the synchronism of the left hand block, proceed as above, excepting that the priming cup in No. 1 cylinder in the left block should be closed. Under these conditions, the letters "S.L." should be just opposite the center line of the engine as above.

Spark-plug points should be separated .032″.

The auxiliary air valve should have a 5/32″ drop when the control on the instrument board is set for the best idling position.

To check, proceed as follows: Set the auxiliary air-valve control for the best idling position. In this position groove No. 4 is flush with the end of the instrument board bracket.

Measure the height of the top of the air-valve stem from some fixed point on the engine. Depress the air valve until it strikes the inside spring. Measure the height of the top of the stem as before. The difference in these two measurements is the air-valve drop.

Make sure that the air-adjusting connecting rod clevis is so adjusted that the air shutter completely closes when the control on the instrument board is pulled out.

Clutch brake: Adjustments for wear can be made by loosening the nut on the stud which projects through the slot in the clutch cover, and by sliding the whole assembly toward the rear.

Before tightening the nut, be sure that the brake facing does not make contact with the clutch-brake disk when the clutch is engaged.

The amount of clearance should be governed by the speed of shift desired.

The standard setting allows ⅛″ to 3/32″ compression of spring with the clutch completely disengaged.

To adjust the foot (external) brakes properly make the clearance between the band and the drum 1/32″, and equal all around. In making this adjustment proceed as follows:

Adjust the nut on the rear support until the clearance between the drum and the brake band is 1/32″ at this point. Adjust the two nuts on the shank of the clevis just below the eye bolt at the front of the brake until the distance between the lower half of the brake band and the drum is 1/32″. Adjust the T-handle, which operates the adjusting screw, until there is a clearance of 1/32″ between the upper half of the brake band and drum.

The hand (internal) brakes should be evenly adjusted, so that when applied there is the same resistance on each rear wheel. The following adjustments are to be made:

Make all adjustments for wear on the side-pull rods connected to the cam-shaft levers.

By removing the rear wheel the hand-brake band can be set concentric with the brake drum by means of the adjusting set screw at the rear. The band should just clear the drum at this point.

The hand lever should be in the sixth notch from the front when brakes are applied.

Adjust the accelerator pedal to have a clearance of 3/16″ between the pedal and the top of the floor board when the throttle is wide open.

The oil pressure should be 20 lbs. to 25 lbs. at 1,000 r.p.m., corresponding to a speed of approximately twenty-five miles per hour; with the engine hot. A lower pressure when the supply is up to level indicates that the oil being used has low viscosity, or that the relief valve opens too far.

To adjust the relief-valve opening, change the tension of the relief-valve spring located in the pump housing.

Compression in the cylinders should show 75 lbs. plus or minus 3 lbs. pressure with the engine cold and at cranking speed, with all cylinder petcocks closed and the throttle wide open.

Gasoline pressure: The gauge on the instrument board should show 1½ lbs. to 2½ lbs. pressure.

The pressure may be increased by removing the plug at the top of the pressure-pump cylinder and unscrewing the smaller plug at its base. To decrease pressure, screw in the plug.

Valve clearance: Inlet and exhaust valves should have .004″ clearance between the valve stem and the roller-holder set screw when the engine is cold. Be sure that the valve is fully seated when measuring clearance.

The vibration damper on the front end of the crank shaft should be adjusted to slip under a pull of approximately 140 lbs.

Clutch pedal: When the clutch is in the fully engaged position, the pedal should depress 1¼″ under light spring pressure before resistance of the heavy clutch spring is encountered.

If the pedal is brought against the floor board before the clutch is entirely engaged, full action of the clutch spring is not obtained, and the clutch will slip.

The rod connecting the clutch pedal with the clutch release lever on the left of the clutch housing gives the necessary means for obtaining the correct adjustment for the clutch pedal. Lengthening the rod by means of the thumbscrew will increase the amount of travel under light pressure before disengaging the clutch.

No other change from the original adjustment will be required, as the clutch surfaces are automatic in their compensation for wear.

Front wheels should "toe-in" ⅜″.

Refer to the Index for the different parts of the Packard car.

INSURANCE

Fire insurance is very essential in the operation of an automobile, on account of the exposure it is subjected to, both on the street and in the garage, and most owners carry fire and theft policies.

Liability insurance is also a very important asset, and owners should be very careful about their selection of a company to carry their risk. The company should necessarily be one with large assets, and of sufficient financial strength to protect the policy holder through years of action in the courts, because in some cases, especially where serious injury is involved, regardless of the cause or blame for the accident, years have elapsed before settlement is agreed upon, or final judgment is rendered.

Kinds of Insurance

There are five classes of automobile insurance, as follows:

1. Fire and theft.
2. Liability.
3. Property damage.
4. Collision.
5. Loss of use.

Fire and theft can be combined in one policy, or fire insurance can be written separate, excluding theft; but the theft feature cannot be written unless accompanied by the fire insurance. Collision can also be included in the fire policy, or in the fire and theft policy, but it, like the theft insurance, cannot be written separately. Liability and property damage is usually written in a separate policy although several companies are writing a joint "all risks" policy covering fire, theft, liability, property damage, and collision. This can be done by re-insurance between the liability and the fire companies.

1. **The standard automobile fire and theft policy** covers the body, machinery, and equipment of the car. Extra bodies, robes, automobile coats, hats, caps, gloves, leggings, boots, goggles, and chauffeur's livery are not included unless provided for under a separate endorsement, for which additional premium is charged in accordance with the amount of coverage desired. Automobile fire insurance is written in two forms: one covers fire and theft, and is known as a "valued policy," on account of the company being liable for the amount stated in the policy at the time of a loss; the other provides that the company may deduct a reasonable amount from the loss for depreciation, however caused. A credit in the rate is given for the latter form of coverage, which is known as the "non-valued form." A credit of 15 per cent is granted from the fire rate where an approved chemical fire extinguisher is attached to the automobile.

Theft insurance, as stated above, can only be written in connection with a fire policy, and the same conditions regarding "valued" and "non-valued" clauses apply. On all cars listing under $2,000 the companies require the attachment of an approved locking device for which a credit of 15 per cent is granted from the theft rate. Where no lock is provided, an additional charge of $15 is made.

2. **Liability insurance** provides protection against accidents to the public resulting in injury or death. The usual limits of liability are $5,000 for an accident resulting in an injury to one person, and $10,000 for an accident resulting in injury to more than one person. The purpose of this insurance is to pay judgments, costs of court, attorney fees, witness fees, investigation and settlement costs, and other expense necessary to the protection of the automobilist, not exceeding, however, the limits above stated. These limits may be increased where necessary, by payment of an additional premium.

3. **Property damage insurance** covers damage to the property of others, not exceeding $1,000.

4. **Collision insurance** covers loss or damage to your car caused by a collision with another object. There are three classes of collision insurance: one, known as the $50 deductable form, provides that the company will deduct $50 from each claim; another known as the $100 deductable form, provides that the company will deduct $100 from each claim, and still another, known as the full-coverage form, which provides that the company will pay all claims in any amount. The insurable value on collision insurance is based upon the same principle as fire insurance, a fixed percentage of the list price of the car being granted in accordance with the age, use, physical condition, etc.

5. **Loss of use:** This form of coverage has just recently been included, and applies in connection with the property damage insurance, providing reimbursement to the owner on account of sums he may be called upon to pay to others through the loss of the vehicle which has been damaged, i.e., cost of rental of another vehicle pending repairs to the one damaged, not exceeding $1,000.

Rates

Insurance rates vary in different parts of the country. Therefore it is advisable to see your local insurance agent.

LAWS

The automobile laws of the different states are so varied that it would require far too much space to give them in detail in this book.

If those who are interested will write to the Touring Board of the American Automobile Association (A.A.A.), 1108 16th Street, N.W., Washington, D.C., and enclose twenty-five cents in stamps, mentioning *Dyke's Automobile Encyclopedia* in connection, a complete **Digest of the Motor Car Laws of the United States and Cars entering Canada** will be mailed. This will be found as comprehensive as its title indicates, and it will be extremely serviceable, as well.

It is well, also, to write to the Secretary of State of your own state, and he will inform you where to obtain the laws of that state on the subject.

Automobile Licenses of Different States: the Cost and How to Secure a License

There are, in most states, two kinds of licenses issued for automobiles: One is issued to the owner of the car, covering a tax or fee on a car, as well as entitling the owner to drive the car. The other kind is a license issued only to a **professional chauffeur.**

Some states do not require chauffeur's license. Other states require the chauffeur to obtain a license, which is usually done by writing to the Secretary of State at the capital city for a form to fill out. When this is filled in, and the amount of the license is remitted, he is then furnished with a badge and receipt. Other states require an examination.

The necessary information, even though you do not purchase a license, can be obtained by writing to the Secretary of State of your state. Inasmuch as the laws are sometimes amended or changed, it would be well for the reader to write for the information, which will be supplied to him gratis, or send for the complete Digest of the laws of all states mentioned on page 1072.

The age of driver of an automobile in most states must not be less than 18 years. This varies, however, in different states, and is to be ascertained definitely from the complete **Digest of Motor Car Laws** issued by the A. A. A. Touring Board.

Note. We advise all who are interested in automobiles to join the A.A.A. See page 655.

QUESTIONS AND ANSWERS AS TO SOME OF THE "FIRSTS"

First Auto Show

Q.: In what year was the first automobile show held in Chicago and also in New York?

Ans.: The first show held in New York was in November, 1900, at Madison Square Garden, under the auspices of the Automobile Club of America. A feature of the show was a board hill built on the roof of the garden, to prove that the new vehicle would not only propel itself, but would climb a grade. The novelty of the idea appealed to the public. The first automobile show in Chicago was at the Coliseum in March, 1901. Eighteen vehicles were displayed. The gate receipts were $3,200. Mr. Sam Miles was the manager.

First Four-Cycle Gasoline Engine

Q.: Who invented the first gasoline engine?

Ans.: Nicolaus August Otto, Deutz, Germany, on August 14, 1877, was granted patents covering the four-cycle engine and the principle of compressing the mixture before exploding it. This is the principle still used on automobile engines at present. The conception of compression and four-cycle operation was not, however, original with Otto. He combined these ideas into a practical engine. They were twelve years in the making, and three countries participated in their evolution. The conception started in 1862, when a Frenchman, Alphonse Beau de Rochas, obtained a patent and wrote a pamphlet on the four-cycle engine. Six years later Boulton, an Englishman, secured a patent covering the use of compression in an engine. However, Boulton failed to work out the necessary means for compression in a practical way.

First Power-Propelled Vehicle

Q.: When was the first power-propelled vehicle invented?

Ans.: Experiments date back to 1770, when Joseph Cugnot, a French engineer, built the first automobile. He constructed a steam automobile that hauled 2½ tons at 3 miles per hour, and this vehicle is still preserved in France. In 1802, the first practical steam automobile was built by Richard Trevitluck of England, using a crank shaft for the first time, and driving by gears from the engine to the road wheels. In 1821, Julius Griffiths of England built the first comfortable steam vehicle, the first vehicle to have a coach design of body, with seats carried on springs, as they are today. In 1831 Summers & Ogle of England built a three-wheel tubular boiler and two-cylinder engine which attained a speed of thirty-two miles per hour. The first motor vehicle to carry passengers regularly for hire was built by Walter Hancock of England in 1834. The motive power was steam.

First Pneumatic Tires

Q.: (1) Who invented the pneumatic tire? (2) In what year did American manufacturers of automobiles begin to use the double-tube tire? (3) What were the prices of tires from 1900 to 1915?

Ans.: (1) At present the honor of inventing pneumatic tires is disputed between two claimants: R. W. Thompson, a Scotchman, and John Dunlap, an Irishman. The former devised an automobile rubber tire in 1839, but it never came into use, as it was a very crude affair, and seemed of no practical service. Thompson's tire was a single-tube appliance, and was invented in 1845. The solid rubber-cushion tire and the single-tube air tire were used considerably in 1899 and 1900. The double-tube pneumatic tire did not come into general use on automobiles until 1902. (2) Single-tube pneumatic tires were generally used up to 1903. Double-tube tires were in use in 1902, and were extensively adopted in 1903. (3) For a 30″ x 3½″ single-tube tire the price in 1900 was $28; in 1901, $25; in 1903 the double-tube tire casing and tube cost $41; in 1913, $21.95; in 1915, $14.30.

First American Auto Road Race

Q.: Where and when was the first American Automobile Road Race run in America?

Ans.: *Motor Age*, April 19, 1900, says: "America's first auto road race was run over a fifty-mile course on the famous Merrick road on Long Island yesterday morning. A. L. Riker, with a five horse-power electric racing wagon, won by a quarter of an hour; time, 2:03:30. S. T. Davis, Jr., in a steam Locomobile, four and a half horsepower, was second; time, 2:18:27. Alexander Fisher, in a gasoline runabout built by the Automobile Company of America, was third; time, 2:30:01." The article further states that the racers wore auto caps, goggles, and mouth protectors. Riker wore no auto togs at all, but got there just the same. This speed is averaged now almost daily on the streets.

First Auto Race

Q.: Where was the first automobile race held in America? How many cars started? How many finished?

Ans.: Chicago made the earliest attempt at an automobile race, November 25, 1895. Six cars started over a course of fifty-four miles, from Jackson Park to Evanston and back again, for a prize of $500 offered by the Chicago *Times-Herald*. Four of the cars were propelled by gasoline and two by electricity. Two cars finished. Charles E. Duryea won in ten hours and twenty-three minutes. The course was covered under highly unfavorable conditions, the roads being heavy with mud and snowy slush.

First Rubber Tire

Q.: When was rubber first discovered, and who made the first rubber tires?

Ans.: The first mention of rubber was in 1525, when the Spaniards in Mexico saw the natives playing with balls of a remarkable elasticity. In 1770 it was suggested as an eraser for pencil marks. In 1823 Macintosh of Manchester, England, found that rubber would dissolve in benzine, and began making waterproof fabrics. In 1832 the Roxbury Rubber Company was formed in Massachusetts to engage in this work, and Charles Goodyear was one of its employees. Goodyear discovered vulcanization in 1835. In 1842 he began producing rubber shoes. The first use of rubber tires was when Dietz in 1835 patented a rubber cushion applied to an iron ring or tire. R. W. Thompson, an Englishman, on December 10, 1845, patented the first pneumatic tire.

Auto Club of America

Q.: In what year was the Automobile Club of America organized, and how many cars were produced that year?

Ans.: On Wednesday, January 7, 1899, a public meeting was held at the Waldorf-Astoria Hotel New York, and as a result the National Automobile Club of America was chartered on the following August 6. Six hundred machines were produced in 1899.

Jump-Spark Coil Invented

Q.: When was the jump-spark coil invented and first used?

Ans.: In February, 1852, Emperor Napoleon of France offered 50,000 francs to the man who could produce the most important electric invention during the next five years, which period was later extended five years. This award was finally given to H. D. Ruhmkorff, a Paris instrument maker, for inventing the jump-spark coil, often referred to as the Ruhmkorff coil or high-tension coil. This coil, however, was first actually developed by Prof. Charles G. Page of Washington, D.C., following the researches of Faraday, Joseph Henry, and W. Sturgeon, about 1831, and really should be more properly termed Page's coil.

Knight Engine: Its History

Q.: Has the Knight engine been tried out fully, or is it still an experiment? What foreign manufacturers use it?

Ans.: The Knight sleeve-valve type of engine was invented in Chicago in 1903. The engine was under experiment until 1905, at which time it was given severe tests in Elyria, Ohio. In 1906 Charles V. Knight submitted his engine to the largest motor car company of England, the Daimler Company. After tests, the Daimler Company adopted it. Other leading European automobile manufacturers who adopted this type of engine are the Panhard Company, France; Mercedes Company, Germany; and the Minerva Company, Belgium.

INSTRUCTION No. 84

DICTIONARY: Meaning of Motoring Terms

Note. If the Dictionary does not give the meaning, or if a description is desired, see Index for the subject.

See page 529 for "Storage Battery Words and Terms." See page 1079 for English-French Dictionary.

By referring to the Index, the definition of many other words can be found.

A

Abrasion: The act of wearing or rubbing away; a chafe.

Accumulators: A set of secondary cells—also called storage batteries containing positive and negative plates, and filled with electrolyte.

Advance Spark Lever: See Index.

Air: Composed of approximately one-fifth oxygen and four-fifths nitrogen, with some carbonic gas.

Air gap: A term having almost the same meaning as "clearance." Often applied to the space between the field poles of a generator, motor, or magneto and its armature.

A.L.A.M.: Means Associated Licensed Automobile Manufacturers. Now known as S.A.E. (Society of Automotive Engineers).

Alternating current: A current changing its direction of flow, or "alternating" backwards and forwards.

Aluminum: This metal, the chief characteristic of which is its lightness, is not generally used in its pure state, but is alloyed with a small proportion of zinc; sometimes, for special requirements, a small quantity of copper and manganese are added.

Ammeter: An instrument that indicates amperes or rate of current flow.

Ampere: See page 529.

Ampere-hour capacity of a battery: A term used to express the amount of current that can be gotten out of a battery of a given size. An actual 50 ampere-hour accumulator should be capable of giving 1 ampere for 50 hours, or 2 amperes for 25 hours; but the ratio becomes disproportionate as a higher rate of current is taken from the cell. See also page 560.

Annealing: Softening of metal. By placing it in a fire and getting it red hot, and then permitting it to cool without water, it softens.

Annular ball bearing: See page 19.

Anode: The positive (+) pole of a current; opposed to cathode.

Anti-clockwise rotation: Same as counter-clockwise.

Asbestos: This material is of mineral origin (large quantities come from Canada). In its natural state it is fibrous and somewhat brittle. As it resists great heat, it finds considerable application in motor work for engine jointing in the form of packing washers (of copper sheet and asbestos). Asbestos cord is used for covering exhaust pipes where these pass through woodwork, etc. Worked up into a fabric with brass wire, it is largely used for brake-band linings and clutch covering, as it cannot be burned out by excessive friction.

Atmospheric pressure: The earth is surrounded by a large, thick envelope of gases which is known as the atmosphere, and is commonly spoken of as the air. Contrary to general belief, the air does possess weight. In fact, if we went to the sea-shore and took a column of air one inch square and as high as the atmospheric envelope exists, this column would weigh about 14.7 lbs.; consequently the atmospheric pressure at sea-level is 14.7 lbs. per square inch. The higher the altitude above sea-level, the less will be the atmospheric pressure.

Atom: The smallest divisible part of a chemical element.

Aviatrix: Feminine for Aviator. A woman who operates a flying machine.

B

Backlash: The play between the teeth of two gears which are engaged (in mesh); see also Index under "Backlash."

Back-pressure: Term applied to restricted exhaust discharge. Unless the muffler is of sufficient size, there will be back pressure, and the exhaust will not be discharged as rapidly as it should.

Ballast resistor: See page 430.

Benzol: A promising motor fuel. It is a by-product of coke. It contains the same elements as gasoline, but the chemical formula is slightly different. In England it is used to great extent for fuel, also for explosives, dyes, and chemicals. All gas plants in England are being equipped to produce benzol. It is stated that experiments with the material are being made in the United States.

Bezel: The groove in which the glass cover of the speedometer or clock is fitted.

Bore and stroke: See Index.

B.H.P. (Brake horsepower): Measurement of horsepower of an engine of actual net work of the engine or horsepower delivered at the crank shaft. See page 1044.

British thermal unit (B.T.U.): The amount of heat required to raise the temperature of 1 lb. of water 1° F. (at its maximum density, which is at 39.1° F.). This expression is much referred to in the study of the value of various fuels for engines: thus gasoline ranges about 19,000 to 20,000 B.T.U. per lb. A pound of gasoline of 58 s.g. is approximately eight-tenths of a pint. 1 B.T.U. is equivalent to 778 foot lbs. of work. See also "Thermal efficiency."

B.T.U.: See "British Thermal Unit."

By-pass: A means by which a flowing substance can take a course other than its usual one; an extra passage.

C

Calorific value: This term is used with reference to various fuels, such as gasoline, benzol, paraffin, etc., and represents the effective heating power per pound in terms of British Thermal Units. 1 lb. of gasoline contains about 19,000 B.T.U.'s.

Calorimeter: An instrument to determine the heat content of a substance, that is, how much heat it will give off when burned. Used to determine the number of B.T.U.'s per pound of gasoline.

Calory: The unit of heat (metric system) to express the amount of heat required to raise 1 gram of water from 0° to 1° Centigrade.

Cam shaft: The shaft running through the engine which has the cams placed upon it at certain fixed positions.

Camber: To curve or bend. As applied to the automobile, it refers to the camber of the front wheels at the ground. See page 906.

Carbon: One of the well-known non-metallic elements. It is an excellent conductor of electricity. As applied to the automobile, it refers to the carbon deposit which accumulates in the combustion chamber of an engine. In a hard state it works well as a contact medium in conjunction with copper or brass; it is, therefore, largely used for the brushes of the magneto, and also for the brushes of car-lighting dynamos. Carbon, in its natural form of graphite, is used as a lubricant for gearing. It is generally mixed with grease, and is supplied ready prepared by lubricant manufacturers.

Carbonize: The deposit of carbon upon the points of the spark plugs and the various internal portions of the engine cylinder and exhaust passages.

Caster: As applied to the automobile the word refers to the "caster" or "cant" or inclination from the vertical, as given to the front axle. See page 907.

Cathode: The negative pole (−) of a current; opposed to anode.

Cell: An electrical cell is a vessel complete with its contents, and a number of these form a battery, or a set of storage batteries. Each cell must contain positive and negative plates, and some form of electrolyte.

Celluloid: A compound of camphor and gun-cotton. Its transparency and flexibility are its chief characteristics. Non-inflammable celluloid is now made for windshields.

Center of gravity: The point at which a body balances. For example if you lift an engine out of a car with a hoist, you always try to attach the chain so that the engine will stay level when hoisting. In other words, you try to place the chain at the center of gravity of the engine. If a car has a high center of gravity, it has a tendency to turn over when making a turn at high speed. Such a car would be called "top heavy." In order to prevent turning over, racing cars are built with a low center of gravity. For example, the center of gravity of a wheel is the center of the wheel hub, because that is where it balances. If a body is placed below that center it will have less tendency to be "top heavy" than if placed above the center of the wheel, because the center of gravity of the automobile would be nearer the ground.

Centigrade: A scale of temperatures usually used in foreign countries and in scientific work. See page 1048.

Chamfer: A small channel or groove cut in metal or wood; the corner beveled off.

Change gears: The transmission or system of changing the gears in the gear box.

Chassis: Pronounced "chas-sy." Derivation, French; a frame in wood or metal; the framework of a wagon; later the term was applied to the framework of a locomotive; then to the longitudinal and transverse frame members of a motor car. By extension it also designates the whole of the mechanical portion of a motor car. More correctly, however, the word chassis should only apply to the metal framework receiving the engine gearset and controlling mechanism.

Chauffeur: Pronounced "Sho-fur." Derivation, French, chauffeur, a person or a thing that heats. A chauffeur is a man in charge of a furnace or boiler fire. The first use of the word chauffeur was during the revolution of 1789, when bands of brigands heated (*chauffé*) the feet of their victims in order to make them reveal the place where their money was hidden. The "chauffeurs" were stamped out during the Consular period. The word chauffeur was first applied to motor-car drivers under the popular supposition that they had to tend a fire. On the French railroads the chauffeur is the fireman; the engine driver is the mechanician.

Chauffeuse: A woman chauffeur.

Check-valve: A valve which permits the passage of a fluid or gas in one direction only.

Chemical compound: When two or more chemical elements are united they form a chemical compound. This can be a solid, a liquid, or a gas.

Chemical element: Matter which cannot be divided into simpler chemical forms. It can be a solid, a liquid, or a gas.

Circuit: The path of the electrical current; the conducting material, or wires.

Circuit-breaker: See "Contact breaker"; "Interrupter."

Circulating pump: Pump used to circulate the cooling water. Operated by the engine.

Clearance: As applied to the automobile, this refers to the permissible space or air-gap between the valve stem and tappet; also to the air-gap space between ignition contact points when separated; also to the air-gap of spark-plug points and other parts. It also refers to the lowest point of an automobile which is above the ground. It also refers to the space or oil film allowed between a bearing surface and the shaft.

Clockwise rotation: Rotation to the right, or in the direction of the hands of a clock. See Index under "Magnetos, clockwise rotation from drive end."

Clutch: A device for connecting and disconnecting the engine from the transmission—usually placed in or on the inner face of the flywheel rim.

Clutch pedal: The foot pedal which connects and disconnects the clutch.

Coefficient: A known constant quantity. That which co-operates with a variable or unknown quantity.

Coil and battery system of ignition: In a battery the electricity is obtained by chemical means instead of mechanical means, as when a dynamo is used. The coil has nothing to do with the generation of the electric current, its function being "to gear up," intensify, or increase the pressure or transform the low-voltage primary current into a high-voltage secondary current, to enable a spark to be produced across the air gap of the plug points.

Combustion space: The space between the end of the piston (when on upper dead center) and the head of the cylinder. That portion over the valve is also included.

Compensating air valve: Also termed auxiliary air valve; a valve which counteracts the tendency of an over-rich mixture as the speed increases.

Compensating gear: See "Differential."

Compound: A mixture of several ingredients.

Compression: A term implying that the explosive charge of gas and air drawn into the cylinder on the suction stroke is subjected to a strong squeezing effect on the next stroke. The charge is pressed into a space about one-fifth the volume or space of that occupied by it on the suction stroke, equaling 55 lbs. to 90 lbs. pressure per square inch. See also page 116.

Compression tap or cock: A small tap placed at the upper end of the cylinder, which can be opened to relieve the compression, to make cranking easier.

Concentric: The opposite of eccentric. Applied to carburetor floats and piston rings.

Condensation: The process of turning a vapor into a liquid. As an example: The carburetor takes in raw gasoline and air, thus forming a gaseous "mixture" known as a vapor and thereby performing the process of vaporization. If this mixture (vapor) now comes into contact with a cold inlet manifold, it will be turned into small drops of raw gasoline; this latter process is called "condensation." Another example: Small drops of water often collect on the outside of a glass of ice water, due to the condensation of the moisture (vapor) in the air, or due to the warm air vapor striking the cold glass. If steam comes in contact with a cold surface, it will condense into water, just as the vapor in the air did in the example above: the reverse of evaporation.

Condenser: An important part in a spark-coil or high-tension magneto. See Index.

Conductor: A material along which electricity will readily flow, such as copper, platinum, steel, and, in fact, all metals. Silver is the best conductor, but copper is only very slightly inferior. Carbon is a non-metallic element, but an excellent conductor much used in magneto construction for the brushes. The wires or cables of the ignition circuit are sometimes referred to as conductors or "leads."

Connecting rod: That member which connects the piston to the crank shaft of an engine. It has an oscillating movement.

Constant: A value which remains the same under all conditions, that is, the value is constant. The word is often used in connection with another value which is variable. See also page 1044.

Contact-breaker: The interrupter on a magneto. Also applied to the interrupter arrangement on the "make-and-break" igniter. See "Interrupter."

Contact-screw: The small screw, having a platinum point, against which the trembler vibrates.

Contact sector: One of the sectors in a timer or distributor.

Continuous or direct current: This implies that the current flows in one direction. The direct opposite of alternating current.

Contraction: The opposite of expansion, usually the result of cooling.

Counter-clockwise rotation: A direction opposite to clockwise rotation.

Crank shaft: The main shaft in an engine which rotates as a result of the force exerted on its cranks which are connected to the pistons.

Current: The flow of electricity.

Cut-out (electric): See Index.

Cut-out (muffler): A valve opening into the exhaust pipe at a point between it and the muffler, which, when opened, permits the exhaust gases to escape through it directly into the atmosphere instead of being forced through the muffler.

Cylinder en-bloc: The cylinders cast together in one piece.

Cylinder priming cock: Same as the compression relief cock. Usually placed in the head of the cylinder for injecting gasoline.

D

Dead rear axle: A rear axle that does not turn. Type usually used on double chain-driven cars, and internal gear-drive trucks.

Demountable rim: A form of rim that can be taken off the wheel without deflating the tire.

Density: Compactness; mass of matter per unit of volume See also page 530.

Depolarize: To deprive of polarity.

Differential gear: See page 17.

Direct current: Electric current where the current flows continuously in one direction. Unlike "alternating" current.—the opposite.

Distributor or Distributer: A special form of rotary switch, which directs the high-tension current to the various spark plugs.

Dry battery: Called dry cells or primary cells. A series of primary cells which do not contain liquid electrolyte.

Dynamo: A generator of electricity. The dynamo is usually used on a motor car to light the electric lights and to recharge storage batteries and in some instances furnishes current for the ignition.

E

Earth connection, or "ground": An inaccurate term when applied to the electric circuits of a motor car. The car is insulated from the road by the tires, hence the "earth" is not used at all. What is meant is that the framework of the car is used as a return conductor, so as to dispense with some of the wires.

Eccentric: Two circles (one inside the other) are said to be eccentric when their centers are not at the same point.

E.H.P.: Electric horsepower (746 watts).

Electric ignition: Any form of ignition by which the mixture in the combustion chamber is ignited by means of an electric spark.

Electrode: The insulated part placed in the igniter of a low-tension system of "make-and-break" ignition. The center rod of a spark plug.

Electrolyte: A liquid that undergoes chemical decomposition when an electrical current is passed through it. The solution used in a storage battery. Is generally made by mixing sulphuric acd and distilled water in proportion of two parts of acid aid five parts of water. These parts are measured out by volume. An earthen vessel must be used and the solution stirred while mixing. Never pour the water into the acid. See "Specific gravity."

Electro-magnet: If an insulated wire is wound around an iron core and current is passed through the wire, this is an electro-magnet. Sometimes the wire is wound on a spool made of non-magnetic material, and is so arranged that the core can be inserted or withdrawn as desired. This form is known as a solenoid magnet.

Element: The simplest divisible conception; for example, a pencil may be considered as made up of several elements, namely, the wooden case, the lead or graphite core, the rubber eraser, etc.; as applied to the storage battery, see page 527, and Index.

E.M.F.: Electromotive force. The voltage. The pressure. Tension. See pages 175 and 180.

En-bloc: Cast in one piece, as four or six-engine cylinders. A French term. The English expression is "in-block."

Energy: The capacity for doing work. Passing a current of electricity through a storage battery causes energy to be stored up in a chemical form. Then this energy is taken off in an electric form. Winding a watch causes energy to be stored up in a mechanical form in the spring.

E.P.M.: Explosions per minute of a gasoline engine.

Exciter brush: Could refer to the third brush of a third-brush regulated generator, as the current for exciting the field windings passes through this brush.

Exhaust box: See "Muffler" and "Silencer."

Expansion: When anything becomes larger in size, it is said to expand. This term is usually used in connection with the effect of heat. For example, if a valve stem is heated up, it will become longer; if an engine cylinder is heated, the bore will become greater; if a piston is heated, it will become larger in diameter.

F

Fahrenheit: A scale of temperatures usually used in English-speaking countries. See page 1048.

Fiber: A slender, thread-like substance, or filament; raw material which can be separated into threads for making up textile fabrics, such as brake lining, clutch lining, etc. Also used for insulated bases for electrical purposes.

Field: The seat of magnetic flow, between the pole pieces of a generator or motor.

Field coil: The coil of insulated wire which surrounds the field poles.

Fierce clutch: See Index.

Flash point: See page 165.

Fliverboob: A reckless driver; the term is used in the same manner that the term "jaywalker" describes the careless pedestrian.

Flux, magnetic: Lines of magnetic force that pass or flow through a magnetic field.

Flywheel: A heavy wheel rotating without contact with anything save its axle, by the momentum of which an even running of the engine is obtained.

Foot pound: This is a unit of work or energy. The lifting of one pound one foot. The same unit is also applied to torque. See page 1043.

G

Galvanometer: An instrument for measuring the presence, extent, and direction of an electric current.

Garage; plural, garages: Derivation, French. The word has been taken bodily, pronunciation and spelling from the French language, in which it is a variation of the word *gare*, a station or terminal for either railway trains or boats. Garage, as a noun, means, in both French and English, a place in which motor cars are kept, and is sometimes applied to shops wherein motor cars are repaired. The verb, "to garage," means the act of putting a car in the garage building. Pronounced with the final *g* soft, the final *a* open and the accent upon the last syllable.

Gas: A substance which readily changes both shape and volume according to physical conditions imposed upon it, as, for instance, pressure and temperature which determine the volume. If the gas is a compound, it can be divided into molecules. If the gas is an element, it can be divided into atoms. A gas which is a compound may be divided into two or more gases, which are elements. Each one of these gases can then be divided into atoms.

Gasoline or gasolene: English, gas; Latin *oleum* (oil). A light grade of petroleum.

Gear box: See "Transmission."

Gear ratio: The number of revolutions of the engine made for one revolution of the road wheels—this depending on which "speed" or gear is in use. Thus the high-speed gear ratio may be 4 to 1, i.e., four revolutions of the engine to one of the road wheels. See Index.

Gear set: The transmission.

Governor: A device to regulate the speed.

Gram: A metric unit of weight. One pound equals 454 grams. A gram is, therefore, the 1/454th part of a pound.

Gravity: The attraction between the earth and various matter; the force which causes bodies to fall, water to run down hill, etc. The term is usually applied to the gasoline fuel-feed method, where the gasoline is fed to the carburetor by gravity or from a higher level to a lower level; also often applied to the specific gravity of a storage battery. See also page 529.

Ground: Connection of electric wiring to the frame of the car or metal part of the engine. The term was originally derived from the fact that with telegraph and telephone systems one wire was used, which was insulated from the ground. For the other, or return wire, to complete the circuit, the ground was used. A piece of wire was attached to an iron pipe and driven deep into the ground at each end of the circuit. This same principle is used in automobiles. One wire is insulated from the frame or metal part of the car. The frame is used as the return wire.

Gudgeon pin: The wrist pin, also referred to as the piston pin, the latter being the correct term.

H

Half-speed shaft: The small shaft, revolved at one-half the speed of the crank shaft by means of any suitable gearing—the cam shaft.

Heat units: The unit of heat. See "British Thermal Unit."

Helical: Shaped as a helix.

Helix: A line shaped like a screw thread or a coil of wire (page 181), or a coil tube.

High gear: Combination of gears ordinarily used in running. The highest ratio of gearing—on some cars 2½ to 1, others 3 to 4½ to 1.

High tension and low tension: See Index.

Hydraulic: Pertaining to fluids in motion. For example, hydraulic analogy is often mentioned in this book, and refers to water.

Hydraulic analogy: A method of explaining something by means of stating how water would act under like conditions. Often used in this book to show how a current of electricity acts in a manner similar to a current of water.

Hydro-carbon engine: A gasoline, kerosene, or gas engine.

I

Idling: Refers to the engine when running slow, and the car is standing still.

Igniter: Has various meanings. On "make-and-break" ignition, the part that makes the spark. On high tension it sometimes means the spark plug, and others call the "commutator" or "timer" the igniter. The correct meaning should be the part that ignites the gas.

Ignition cam: The small cam on the half-speed shaft which either causes a make-and-break of the current, or is notched to receive the nose of the trembler in timers of the mechanical vibrator type.

In-block: English form of the French expression "en-bloc."

"Indicated" horsepower or I.H.P.: The power delivered to the piston inside of the cylinder; it can be measured by taking an indicator diagram which shows the pressure of the explosion in pounds per square inch. From this the mean effective pressure during the stroke can be calculated.

Induced current: The momentary current set up in a circuit, by the proximity of wires conveying the primary current, but not connected with those wires.

Induction: An influence exerted by an electrically charged body, or by a magnetic field, or by neighboring bodies, without apparent communication or connection.

Induction coil: A step-up transformer. An apparatus through which the primary current is made to pass close to the secondary wires, thus setting up the induced, or high-tension current.

Inductor: See Index under "Magnetos, inductor types."

Inertia: A property which tends to keep still bodies at rest. The same property also tends to keep moving bodies in uniform motion. For example, an automobile is standing still on a level road. It will require considerable effort to move it, because the inertia tries to keep it at rest. Another example: an automobile is traveling at the rate of 60 m.p.h. It will require considerable effort to stop it, because the inertia tries to keep it in uniform motion.

Inlet-valve cage: A housing used over an inlet valve.

Inspiration: Means the same as "suction" or "intake," as, suction stroke, intake stroke, or inspiration stroke.

Insulated: When one conductor is separated from another conductor by an insulator they are insulated from each other. In the single-wire system, the conductors connected to the negative (−) terminal of the battery are insulated from the car frame when the positive (+) terminal of the battery is connected to the frame.

Insulation: The protection of wires, or leads by some suitable material which is a non-conductor of electricity.

Insulator: A material through which electricity cannot flow, for instance, porcelain, mica, india-rubber, fiber, vulcanite, glass, celluloid, paraffine-wax, silk, shellac, steatite, slate, etc.

"Int": When found stamped on a coil or terminal, means interrupter connection.

Integral: The whole made up of parts.

Intensify: To increase, to render more intense—to intensify the voltage (pressure) means to increase the voltage.

Intensity coil: See "Induction coil."

Intermediate gear: Combination of gears intermediate in power and speed, between the low gear and the high gear, usually "second gear."

Intermittent: Applied to a cam on the engine, meaning that the motion is not steady but at intervals.

Internal combustion engine: See Index.

Interrupter: A device used on ignition systems for interrupting the flow of current in the primary winding of a coil or magneto. Also termed "contact-breaker" and "circuit-breaker" (which see, under respective headings).

J

Jaywalker: A careless pedestrian. One who does not observe regulations.

Jump spark: A spark which jumps from one terminal of the secondary coil to the other. See "Induction coil."

Jump-spark coil: Another name for induction coil, spark coil, or high-tension coil.

Jump-spark plug: See Index.

K

Kilometer: 1,000 meters, or ⅝ of a mile.

Kilowatt: 1,000 watts, or 1 1/3 horsepower

L

Laminate: Built up of thin plates of metal, as shims or a "laminated core" in armatures.

Lapping: A term applied to the operation of grinding in or fitting rings, pistons, etc.

Limousine; plural limousines: Derivation, French. A motor car body with a permanent top projecting over the driver and having a protecting front. The name was originally applied to a cloak worn by the inhabitants of Limousine, an old province of central France. It was later extended to the covering of a carriage, and then to one type of enclosed motor-car body. At present, the term often is applied to a complete car having a limousine body. (See page 5.)

Liners: Metal plates, usually very thin, placed between two halves of a bearing so that by taking out a liner the bearings can be tightened.

Lines-of-force: Imaginary lines, in the direction of which it is assumed that the lines of magnetic attraction and repulsion pass or act. See also pages 179, 180, 250, 338.

Liquid: Any substance which remains constant in volume, but readily assumes the shape of the vessel in which it is contained.

Live: The parts connected to the negative (−) or insulated battery terminal are referred to as "live" when the (+) terminal is connected to the frame of the car.

Live axle: See page 6.

Lost motion: Suppose that, for the purpose of towing, we attached a tow rope between a disabled automobile and a trouble car. Owing to the slack in the rope, the trouble car when started would move a certain distance before it started to pull the disabled car. This distance would be "lost motion." In general, when one mechanical device is connected to a second mechanical device (as, for example, two gears where the teeth are meshed), and the first moves a certain distance before it imparts motion to the second, this distance is known as "lost motion." There is also lost motion between a shaft and a worn bearing, more often termed "clearance" (see Index.).

Low speed: The ratio of gearing in a transmission for running the rear axle at the lowest speed.

M

Magnetic circuit: The complete circuit, or course through which magnetic lines-of-force pass from N pole around the circuit returning to the same N pole. See page 179.

Magnetic field: The field surrounding a magnet through which the magnetism flows from N pole to S pole.

Magneto: A device operated mechanically and driven direct from the engine, and which generates electric current but "alternating" instead of "direct." There are two forms: the low tension and the high tension.

"Make-and-break" ignition: Low-tension system. No spark plug used.

Manganese bronze: Composed of copper, zinc, and manganese. It makes very strong and tough castings. Forged front axles of this alloy are used on some American cars.

Mechanical efficiency: The ratio between the indicated h.p. and the h.p. available for useful work at the engine shaft.

Mechanical equivalent of heat: This is represented by the number 778, which is the number of foot pounds of work equivalent to one British thermal unit of heat.

Mechanical valve: Applied to either the exhaust or inlet valves when operated by a cam or mechanical means. The exhaust valve is always mechanically operated, whereas the intake is sometimes opened automatically by the suction of the piston.

Mechanician: A racing driver's helper.

M.E.P.: See page 1044.

Mesh: Usually applied to the meshing of the teeth of two gears; for instance, the teeth of the large half-time gear, in Fig. 82, page 52, (G2), meshes with drive gear (G1) on the crank shaft.

Misfiring: Term applied to missing of one of the spark plugs.

Molecule: The smallest divisible part of a chemical compound. Iron or steel is said to be made up of molecules. They may be considered as little magnets. See Index.

Mono-block cylinders: Another name for in-block, or all in one casting.

Motor: The engine or motive power. Technically it refers to an electric motor, and should never be used when referring to the engine.

M.P.H.: Miles per hour.

Muffler: A device used to muffle or silence the noise of the exhaust gases passing from the exhaust valve of an engine. See page 48.

N

Negative pole—minus sign: The point to which the current returns after passing through the circuit. Designated thus: (−)

Nickel: Used in the form of an alloy with steel, viz., nickel-steel. For exhaust valves a high percentage (20 to 25 per cent) nickel steel is the most suitable material, as it effectively resists the intense heat and oxidizing action of the exhaust gases. Nickel is now the standard material for spark-plug electrodes.

North pole: The pole of a magnet from whence the lines-of-force start.

O

O: A small (°) placed alongside of a figure expresses degrees. See Index for meaning of degrees.

Ohm: A unit of electrical measurement of resistance. The resistance that an electric current meets in flowing through a conductor is measured in ohms.

Open circuit: If a conductor is broken, or if it becomes loose from its connection, the electrical circuit is open and no current can pass.

Oscillate: To swing back and forth like a pendulum. A connecting rod has an oscillating movement. The word also refers to the action of a condenser of an ignition system where the electric current oscillates when the condenser is in action. See page 191.

Oscillating discharge of condenser. See page 191.

Otto, or four-stroke "cycle." is an expression often used in connection with gasoline engines. It means that the power is developed during a complete cycle or four strokes, the principle first adopted in the Otto gas engine. The complete cycle comprises four distinct operations, one occurring at each half-revolution or every stroke of the piston: thus (1) suction stroke, (2) compression stroke, (3) impulse or firing stroke, and (4) exhaust stroke.

P

Parabolic: Pertaining to, or formed like a parabola. One of the conic sections. See also page 436.

Periphery: That part of a wheel or disk farthest from its center. The circumference.

Permanent magnet: A magnet made of hard steel that possesses magnetic power and tends to retain it.

Pet cock (also called relief cock and compression cock): A small valve usually placed in the head of a cylinder or on the carburetor.

Petrol: Gasoline.

Phosphor-bronze: An alloy mainly consisting of copper and small proportions of tin, lead, and phosphorus, the proportion of the latter being very small. It is a very tough hard-wearing alloy. Largely used for engine bearings.

Pinions: Gears that have the teeth cut right in the hub.

Platinum: This very expensive metal (price ranging from $30 to $40 per oz., according to the market) is used for the contacts of the magneto. It is practically infusible (it has a very high melting point) and non-corrodible, and thus effectively resists the burning and oxidizing action of the electric spark. It is also used for the "leading in" wires of the electric bulbs used for car lighting, as its ratio of expansion (due to heat) is the same as glass. Sparking-plug electrodes are, in a few instances, also made of it. Tungsten is now extensively used instead.

Polarity: Refers to the North or South pole of a magnet; the positive or negative terminal of an electric circuit.

Poppet valve: The word poppet probably is a corruption of the name puppet applied to this type in England, on account of its resemblance to the popping up and down of the puppets in the old-time Punch and Judy shows.

Porcelain: The insulating material of the spark plug.

Port: Openings in the cylinder for exhaust, inlet, water, or valves.

Positive pole: Usually indicated with a plus sign (+), means the positive terminal, or wire from which the current starts in an accumulator or dynamo. The carbon terminal of a primary or dry battery is positive.

Potential: Refers to ability to exert electrical energy. Usually expressed in terms of volts.

Potential difference: Difference of electrical pressure which causes an electric current to flow. See also page 175.

Potential drop: Loss of electrical pressure. See also page 175.

Precision: Accuracy.

Pre-ignition: Ignition occurring earlier than intended.

Primary battery: A series of either wet or dry cells depending upon chemicals for the generation of electricity, without charging from a dynamo or other battery.

Primary wires: The wires, or leads, conducting the primary or low-tension current to the place, or places, where it is required for use.

Propeller shaft: The drive shaft from the transmission to the rear axle.

Q

Quadrant: Usually applied to the quarter-circle on which the spark lever and throttle lever is attached on the steering wheel.

R

Reciprocating: A back-and-forth movement applied to the action of the pistons in the engine.

Rectifier: An electrical device for changing alternating into direct current.

Relay: An electrical device usually termed a "cut-out." See "Cut-out, electric" in Index.

Resistor. See pages 547, 554, 564.

Retard: A decrease in the speed. Usually applied to "retarding the spark," meaning to set the timer back so that the ignition will be later or slower.

Rotary: Revolving motion; opposite of reciprocating motion.

Rotary valve: See page 52.

R.P.M.: Revolutions per minute.

Rubber: For tire construction rubber supplies come from various parts of the world. Among the finest grades is the well-known "Para" or Brazil rubber. South America rubber generally is considered very good, but excellent supplies now come from Borneo, India, Ceylon, Federated Malay States, and, in fact, many other tropical lands. Pure rubber lacks certain important physical characteristics indispensable for tires, such as stability under change of temperature. Pure rubber becomes soft under the influence of heat, and hard and brittle when subjected to cold. The process of vulcanization renders the rubber proof against heat and cold, and also renders it tough and resilient, so as to possess "life" and vibration-absorbing properties.

S

Scored: Marred by ridges or grooves. Usually referred to in connection with cylinders.

Seats: That part of the chamber upon which the valve rests. Applied to the valve in the engine.

Secondary battery: A storage battery.

Secondary coil: The winding in which the high-tension current is generated, which is quite distinct from the primary current.

Seize: As applied to the automobile, this refers to the piston, as when it is said that the "piston seizes" or sticks to the wall of a cylinder when unduly heated as a result of expansion. It also applies to the bearings when they "seize." Generally caused by lack of lubrication or too tight a fit of the piston.

Shim: Thin sheets of paper or metal which are used as spacers to regulate the distance between two objects, such as two halves of a bearing. See pages 36, 783.

Short-circuiting: Providing a shorter path; placing a wire or other conductor from positive to negative side.

Shunt: To turn aside or branch off. See also Index.

Silencer: See "Muffler."

Sleeve valve: See page 88.

Solid: A substance which does not readily change either shape or volume.

Solenoid: An electromagnetic helix. See page 181.

South pole: The pole of a magnet where the lines-of-force flow into it.

Spark: The spark which passes between the points of the spark plug.

Spark coil: A coil through which electric current is passed and intensified.

Spark control lever: The lever on the steering column (usually the short one) attached to the timer.

Spark gap: A safety device on a magneto to prevent the armature windings being strained or short-circuited owing to a faulty spark plug or wiring circuit; also applies to the gap between the points of the spark plug.

Spark plug: A device consisting of two electrodes separated by an air-gap and used to obtain a spark from high-tension electricity, thus igniting a charge of gas. See pages 188, 233.

Specific gravity: The relative weight of a substance as compared to water at 4°C. Thus if a cubic foot of a substance weighs twice as much as a cubic foot of water, the specific gravity of that substance is 2. See page 530.

Spelter: Zinc; used for brazing, etc.

Starting crank: A crank for starting the engine.

Starting plug: A small brass plug which fits into an opening on the dashboard and closes the circuit. When removed, the circuit is broken.

Streamline body: See Index.

Stroke: Usually referred to as the stroke of an engine, meaning the length of the up-and-down motion of a piston.

Stroke of engine: See page 48.

Studs: Bolts, with threads cut on both ends, screwed into engine cylinders to fasten them to the base; also used to fasten down cylinder heads.

Substance: Refers to any type of matter, such as solids, liquids, or gases.

Suction: Assume two tanks A and B. In tank A, we have any kind of gas such as air, gasoline, vapor, etc., at a pressure of 20 lbs. per square inch, while in tank B, we have a gas at a pressure of 10 lbs. per square inch. If we now connect the two tanks with a pipe, it is obvious that gas will flow from A to B, that is, from the high pressure to the low pressure. In this case, since B has a lower pressure than A, we should consider that B exerts a suction on A. In ordinary usage, we consider that suction exists when the pressure is lower than atmospheric pressure. Thus if we had gas in tank B which was at a pressure less than 14.7 lbs. per square inch, and opened a valve in this tank, air would rush into the tank and we should consider the tank as exerting a suction on the air. (See "Vacuum.")

Symbols: See Index.

Synchronization: The act of synchronizing.

Synchronize: To cause to happen at the same time. To time two or more sparks to occur exactly at the same instant, or at a similar period in a given cycle of operation. To set the distributor brush on contact with a spark-plug terminal at the same time that the contact-breaker is made to open —timing the ignition, for example; termed "synchronization."

Synchronous: Happening at the same time. For example, on an ignition system, where a distributor and contact-breaker are used, the contact points of the timer are made to open or close at the same time that the distributor brush makes contact with a spark-plug terminal. See page 195.

T

Tappet: A push rod connected between the cam and valve; also termed a plunger.

Thermal efficiency: The ratio of work actually done, when expressed in heat units, to the total heat supplied in the fuel that enters the combustion chamber is always less than 100 per cent. For example: Suppose we introduce a pound of gasoline (approximately .8 pint) into a cylinder. This amount of gasoline contains about 19,000 B.T.U.'s (see "B.T.U."). Now suppose we received from the crank shaft, during the consumption of this pound of gasoline an amount of work equal to 4,424,600 foot pounds of work. One B.T.U. is a unit or quantity of heat, therefore energy, and by experiment has been found to be equal to 778 foot pounds. The 4,424,600 foot pounds of work we received from the crank shaft could be expressed as

$$\frac{4{,}424{,}600}{778} \text{ or } 5700 \text{ B.T.U.}$$

The thermal efficiency of the engine would then be 5,700 B.T.U. ÷ 19,000 B.T.U., or 30 per cent thermal efficiency.

Third brush: Refers to an auxiliary brush used for the purpose of exciting the field-windings. It is so placed on the commutator in relation to the main brushes that it serves to regulate or govern the current output of the generator.

Throw: Usually referred to as the crank, or the part where the big end of the connecting rod attaches to the crank shaft.

Timer: Refers to the ignition commutator. Also often referred to as the "ignition interrupter" or "contact-breaker."

Timing gears: The gears connected with the crank shaft of the engine and the cam shaft, which, when timed or meshed correctly, cause the valves to open and close at the correct time.

Toe-in: Refers to the "toe-in" of the front wheels, at the front, opposite the hubs. See page 906.

Tonneau (plural Tonneaux): Derivation, French word meaning a barrel; a wooden vessel formed of staves and hoops and made to contain a tonneau (1,000 kilogrammes) of oil. Later, a horse-drawn carriage, known in England as a governess car, having a rear entrance. A similar type of body was first applied to a motor car by M. Huillier, of Paris, and by reason of its resemblance to a barrel and to the horse-drawn tonneau already existing, was known as a tonneau.

Torque: The word torque is a definite one and means the same whether referring to automobiles or to any other piece of mechanism, and means the twisting or wrenching effect produced by the engine or motor. See also page 1043.

Touche: The small plug used in the switch to complete the electrical circuit when required. (French.)

Transformer: Another name for a high-tension coil. An electrical device for transforming the current from a low tension to a high tension. An induction or secondary or high-tension, double-wound, coil.

Transmission: A system of gearing for reducing the ratio of the driving member (engine crank shaft) to that of the driven member (rear axle) of an automobile.

Trembler: The small vibrating spring used for making and breaking the primary circuit of a coil.

Tube ignition: A small tube, usually of platinum —having its outer end closed—is screwed into the combustion chamber. This tube is so placed that the flame of a blow-lamp, generally supplied from a separate and small tank of gasoline acts upon it and causes it to become incandescent. An old method of ignition now out of date.

Tuning an engine: Extreme care and special adjustment—as tuning up a car for a race, etc.

Two-to-one gear: The gearing, usually consisting of two-gear wheels, one having exactly double as many teeth as the other; also called "timing gears" and "half-time gears."

V

Vacuum: Exists where there is absolutely no pressure. A perfect vacuum has never been made. In connection with the automobile, this word is used to define a pressure less than atmospheric pressure, that is, a suction. The vacuum in a cylinder means the suction; a vacuum tank is a suction tank. (See "Suction.") For example, when the piston of an engine starts down on suction stroke, a vacuum is created within the cylinder because the pressure in the cylinder becomes less than atmospheric pressure; therefore the atmospheric pressure behind the gas in the carburetor pushes it into the cylinder. Thus it will be noticed that the piston does not draw the gas into the cylinder, but serves to decrease the pressure in the cylinder so that the atmosphere can force the gas into the lower pressure of the cylinder.

Valve lifter: An additional lever by means of which the exhaust valve may be raised and kept out of action, thereby reducing the compression and preventing the creation of a vacuum within the cylinder, so causing the inlet valve to remain closed. Used extensively on aero and stationary gasoline engines. This term also applies to a "valve spring lifter."

Vaporizer: An early form of carburetor valve. The vaporizer is also a means of heating the fuel.

Venturi: Applies to the mixing chamber of a carburetor; Venturi shaped. See page 98.

Viscosity: The adhesive or glutinous characteristic of oils used for lubrication.

W

Water: Composed of two parts hydrogen and one part oxygen. Its greatest density and the point at which it occupies least space is at 39° F.

Watt: The unit of electrical power obtained by multiplying volts by amperes.

Wet-cell: A battery using a liquid solution.

White metal or anti-friction metal: An easily fusible alloy of lead, antimony, and tin used for "lining" re-metalling bearings.

Wind resistance: Increases in proportion to the "square" of the speed: thus at 20 miles per hour it is four times what it is at 10 miles, and at 30 miles per hour nine times, and so on.

Worm gear: A device for transmitting power, consisting of a screw as the driving member, which engages with a toothed wheel as the driven member. See pages 7, 17 "Worm gear"; see page 956, "Worm-gear ratio."

INSTRUCTION No. 85

THE MODEL "T" FORD: Principle of Construction; Operation; Care and Repair; Useful and Instructive Hints and Suggestions

FORD PRODUCTS

These consist of the following:

1. Touring car.
2. Runabout.
3. Coupé.
4. Sedan.
5. Chassis.
6. Truck (see page 912 "Ford truck").
7. Tractor (see page 990 "Fordson tractor").

Ford touring car: Five-passenger. May be purchased either with or without Ford electric starting and lighting system, and with or without demountable rims. Demountable rim equipment includes 30″ x 3½″ non-skid tires all around, extra rim and tire carrier. Price, without electric starting and lighting system, $348.00; extra for the same with demountable rims, $95.00.

Ford runabout: Two-passenger. May be purchased either with or without Ford electric starting and lighting system, and with or without demountable rims. Demountable rim equipment includes 30″ x 3½″ non-skid tires all around, extra rim and tire carrier. Price without electric starting and lighting system, $319.00; extra for the same with demountable rims, $95.00.

Ford coupé: Two-passenger. Standard equipment includes Ford electric starting and lighting system, demountable rims, non-skid tires all around, extra rim and tire carrier. Interior finished in grey whipcord. Permanent top with sliding plate-glass windows. Price $580.00.

Ford sedan: Five-passenger. Standard equipment includes Ford electric starting and lighting system, demountable rims, non-skid tires all around, extra rim and tire carrier. Interior finished in grey whipcord. Permanent top with sliding plate-glass windows. Price $645.00.

The Ford chassis: Chassis equipment includes hood for motor, front fenders, running boards with running-board shields, headlights, tail light, horn, and set of tools. Ford dealers are able to supply the type of light delivery body required for your business. Chassis may be purchased equipped with or without Ford electric starting and lighting system and with or without demountable rims. Price without electric starting and lighting system, $285.00; extra for the same with demountable rims, $95.00.

GENERAL DATA AND INFORMATION ON THE FORD

Engine Numbers

Cars are recorded by engine numbers, rather than by car numbers, and the numbers of the engine and of the car are not the same.

Year 1912	88,900 to 171,300
1913	171,300 to 370,400
1914	370,400 to 611,000
1915	611,000 to 1,029,200
1916	1,029,200 to 1,614,600
1917	1,614,600 to 2,449,100
1918	2,449,100 to 2,831,400
1919 (to Sept. 30)	3,429,400

These numbers are stamped on the left-hand side of the cylinder block, above the inlet hose connection.

Engine

Bore, 3¾″; **stroke,** 4″; **piston displacement,** 189 cu. in.; **piston rings** (3), 3¾″ x ¼″; **valves:** diameter, 1½″; **valve clearance** 1/32″; **firing order,** 1, 2, 4, 3; **timing gears:**

cam gear	42 teeth
cam gear, diameter	5 1/3 in.
crank-shaft gear	21 teeth
crank-shaft gear, diameter	2 2/3 in.

Ford Torque and H.P. Table

R. P M.	Speed in miles per hour		Pounds Torque	Horsepower
	Car	Truck		
300	7 5	4	35	2
400	10	5 25	57	4 5
500	12 5	6 55	69	6 5
600	15	7 9	73	8 5
700	17 5	9 2	78	10 40
800	20	10 50	81	12 33
900	22 5	11 85	83	14.20
1000	25	13 15	82	15 60
1100	27 5	14 50	81	16.66
1200	30	15 80	79	18 20
1300	32 5	17 10	77	19
1400	35	18 45	73	19.66
1500	37 5	19 75	70	20
1600	40	21 05	65	20
1700	42 5	22 40	60	19 40
1800	45	23 75	53	18 20
1900			47	17

The words "Pounds Torque" above should be "Foot Pounds Torque."

The **torque and horse-power figures given above were obtained with a wide-open throttle.** They represent only the maximum power that can be developed at the given speeds. As the throttle is seldom wide open when driving the car, the speed is rarely indicative of the horsepower the engine is developing. Notice that the torque (pounds pull) begins to drop off at 900 r.p.m. The engine exerts its greatest pull at this speed (900 **r.p.m.**). See also page 1043, "Torque, meaning of."

Cooling System

Thermo-syphon principle: Radiator capacity including jackets, 12 quarts, formerly 11 quarts; not including jackets, 8 quarts, formerly 7 quarts.

Radiator hose: Inlet, 1¾″, 3-ply, 2¼″ long; outlet 2″ internal diameter, 4-ply, 3¼″ long.

Hose bands are 2⅛″ and 2½″ inside diameter.

Gear Ratio

Rear axle ratio: The drive pinion gear has 11 teeth; the driven differential ring gear has 40 teeth; therefore 40÷11= 3 7/11 (or 3.63). Thus on **high gear or direct drive,** the engine crank shaft turns over 3 7/11 (or 3.63) times to 1 of the rear wheels.

On **low gear** the total gear reduction is 9.99 to 1.

On **reverse gear** the total gear reduction is 14.5.

See also pages 8 and 9; "Gear ratio, how to compute."

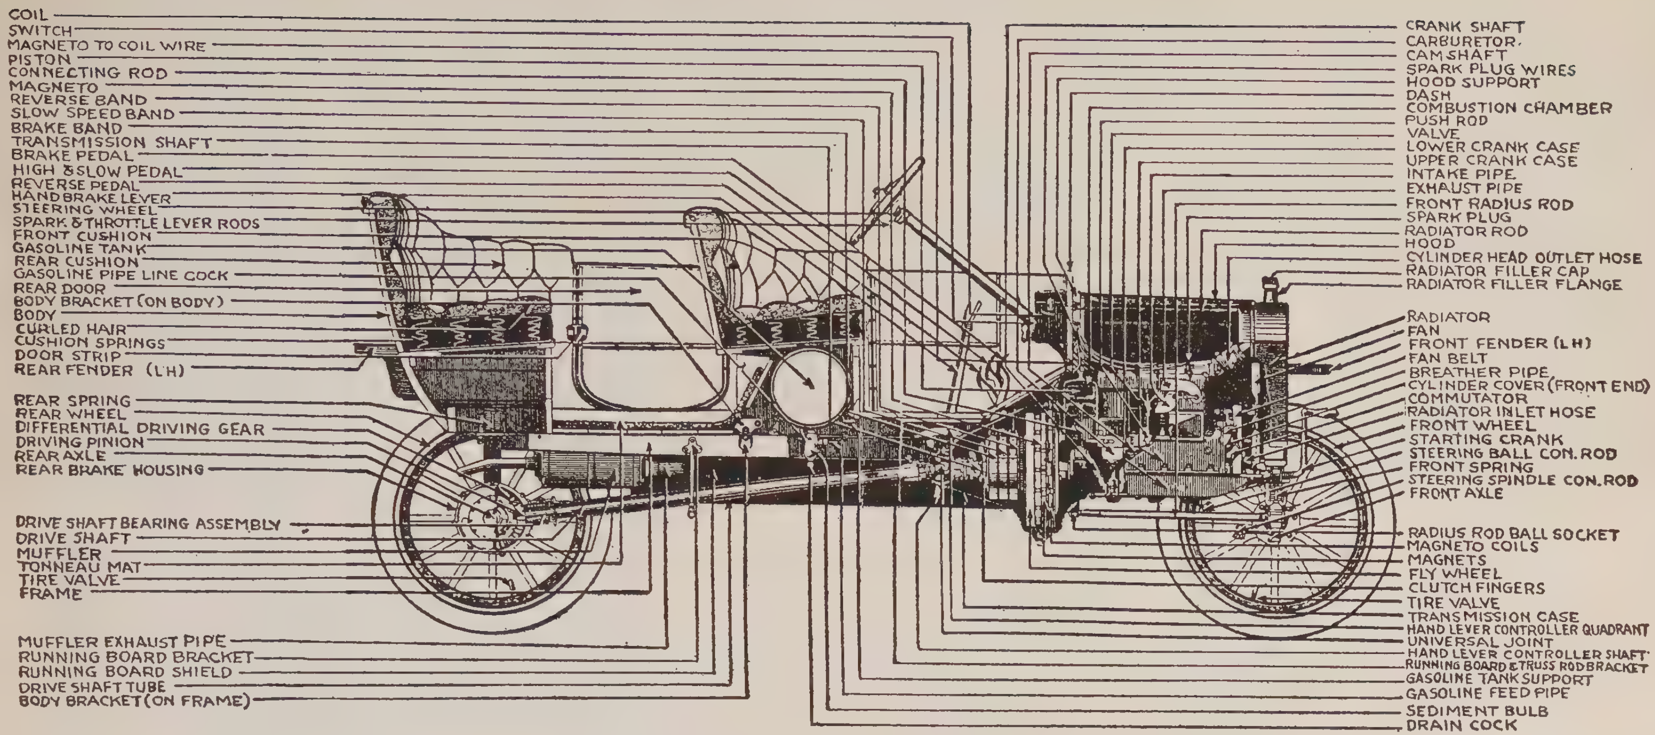
To find the speed in miles per hour:

Eng. Speed per min.	Mi. per Hr. Reverse	Mi. per Hr. 1st Speed	Mi. per Hr. High Speed
500	3.892+	5.589−	12.295+
600	4.761+	6.706−	14.754+
1,000	7.784+	11.178−	24.590+
1,500	11.676+	16.767−	36.885+

Engine speed per mile: The crank shaft of a Ford car makes 2,446 revolutions in one mile on high speed, and when running at a rate of 22 m.p.h. it turns over 897 times every minute.

Overall Dimensions

Model	Height	Width	Length
Touring	7′	5′ 7½″	11′ 2½″
Runabout	6′ 9″	5′ 7½″	11′ 2½″
Sedan	6′ 9″	5′ 7½″	11′ 2½″
Coupe	6′ 9″	5′ 7½″	11′ 2½″
Chassis	....	5′ 7½″	10′ 8″
Truck Chassis	....	5′ 7½″	12′ 9″



Parts of the Ford Car (Model "T")[1]

Engine: Four-cylinder. Cylinders cast en bloc. L-head, detachable type, with valves on the right side. Bore, 3¾″; stroke, 4″; horsepower, 20.

Transmission: Special Ford planetary type. Multiple steel disk clutch operating in oil.

Ignition: Magneto; special Ford design, built in and made a part of the engine. Magneto is built into the flywheel.

Starter: Ford starting and lighting system, optional on touring car, runabout, or chassis. Included as **standard** equipment on coupé and sedan.

Cooling: Thermo-syphon water system, with a fan behind the radiator.

Wheel base: 100 inches.

Wheel equipment: Demountable rims, including 30″ x 3½″ non-skid tires all around; extra rim and tire carrier are **standard** equipment on coupé and sedan, and optional equipment on touring car, runabout, or chassis.

Track or tread: 56 inches.

Road clearance: 9 inches.

---

[1] By courtesy of *Fordowner and Dealer*.

Shipping Weights

Touring A	1,500 lbs.	Engine and trans	380 lbs.
Touring B	1,580 lbs.	Runabout body	300 lbs.
Runabout A	1,390 lbs.	Touring body	415 lbs.
Runabout B	1,480 lbs.	Coupe body	450 lbs.
Sedan B	1,875 lbs.	Sedan body	600 lbs.
Coupe B	1,685 lbs.		
Chassis A	1,060 lbs.		
Chassis B	1,080 lbs.		

A = without starter equipment; B = with starter equipment; add 18 lbs. if equipped with demountable rims; if equipped with 5 demountable rims, add 29 lbs.

Space for Housing a Ford

The smallest garage measurement for housing a Ford, and which will allow 2′ 2¼″ on the sides and 2′ 4¾″ play at each end, would be 10′ wide, 16′ long, and 8′ high.

Gasoline Tank Gauge and Measurements

A good idea for a simple gasoline gauge for Ford gasoline tanks is to get an 18″ flat rule, marked in inches and fractions thereof. Coat it with plumbago by applying the domestic stove-polish brush. If you insert this rule vertically into the tank, right down to the bottom—the car being level—the gasoline will leave a mark on it. The quantity can be gauged by marks on the rule.

Gallons	Square Tank	Round Tank	Oval Tank
1	3/4″	1 17/32″	1 7/16″
2	1 1/2″	2 9/16″	2 3/16″
3	2 1/4″	3 1/2 ″	2 15/16″
4	3″	4 11/32″	3 5/8 ″
5	3 3/4″	5 1/8 ″	4 5/16″
6	4 1/2″	5 29/32″	5″
7	5 1/4″	6 3/4″	5 11/16″
8	6″	7 11/16″	6 7/16″
9	6 3/4″	8 23/32″	7 3/16″

Note. While the **round tank** dimensions vary considerably for each gallon, it will be noted that in the **square tank** each three-quarters of an inch represents a gallon. The **oval tank** may be roughly estimated by one and one-half inches for the first gallon and three-quarters of an inch for each additional gallon up to nine.

Magneto Speed and Voltage

The Ford magneto varies in voltage, amperes, and cycles with the speed of the engine. The table below gives the variation compared to the speed in the engine and the speed of the car and truck:

R.P.M.	Miles Per Hr.		Volts	Amperes	Cycles
	Car	Truck			
200	5	2.63	5	6.1	26.4
400	10	5.26	9.8	7.9	52.8
600	15	7.89	14.4	8.5	80.0
800	20	10.52	18.8	8.8	106.4
1,000	25	13.15	22.8	8.9	146.4
1,200	30	15.8	26.2	9.	160.0

Brakes

Brakes on the hub of the rear wheels have cast-iron shoes, size 7⅞″ x 15/16″ x ⅛″. Brakes are controlled by a side-hand lever. **The brake on the transmission** is controlled by the foot.

The size of the brake, low speed and reverse drum lining on the transmission can be 5/32″ or 11/64″ thick, 1⅛″ or 1 3/16″ wide, and 23 5/16″ or 23⅜″ long.

Prices of Ford Cars from 1909 to 1922

Year	Touring	Run-about	Chassis	Sedan	Coupelet	Towncar	Truck
1909	$850	$825	$.	$ . .	$ 950	$1,000	$ . . .
1910	950	900	. . .	. .	1.050	1,200	. . .
1911	780	680	. . .	. . .	1.050	1,200	. . .
1912	690	590	. . .	. . .	. . . . .	900	. . .
1913	600	525	. . .	. . .	. . .	740	. . .
1914	490	440	. . .	975	750	690	. . .
1915	440	390	360	740	590	640	. . .
1916	360	345	325	640	505	595	. . .
1917	360	345	325	645	505	. . .	600
1918	525	500	475	775	650	. . .	550
1919	525	500	475	775	650	. . .	550
1920	575	550	525	975	850	. . .	600
1920	575	550	525	975	850	. . .	640
1920	440	395	360	795	745	. . .	545
1921 (Jan.)	415	370	345	660	595	. . .	445
1921 (Sept.)	355	325	295	660	595	. . .	445
1922	348	319	285	645	580	. . .	430

Note. The prices for 1921 and 1922 are without the electric starting and lighting system or demountable rims on the touring car, roadster, and chassis; extra for these, $95. Price of coupelet and sedan includes the electric starter and lighting system and demountable rims. The price of the truck is without electric starting and lighting system; extra for these, $70.00. The terms coupelet and coupé refer to the same style of car.

OPERATING AND LUBRICATING A FORD CAR

Before attempting to start the engine, see that the hand-brake lever is pulled back. This hand lever disengages the clutch and applies the brakes at the rear hubs, so that the car will not travel forward when the engine is being cranked.

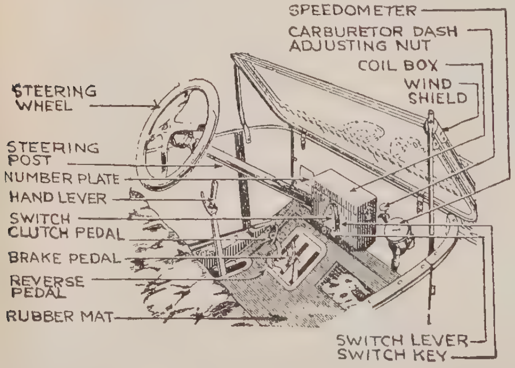


Fig. 1. Control members and parts as viewed from the seat.

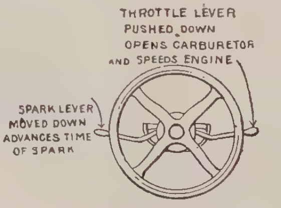
Be sure to retard the spark lever, that is, move the lever on the left-hand side of the steering column **upward**, or toward the front of the car, as far as it will go. (When speaking of the right or left-hand side of the car, it is always considered that one is sitting in the driver's seat and facing forward.)



THROTTLE LEVER PUSHED DOWN OPENS CARBURETOR AND SPEEDS ENGINE
SPARK LEVER MOVED DOWN ADVANCES TIME OF SPARK

Fig 2

The throttle lever, on the other side of the steering column, should be pulled downward about five or six notches from the extreme forward, or closed position.

Now close the switch on the coil box, that is, move the switch key all the way over to the "mag." mark on the cover of the switch. If the switch key is moved over to the battery side, the engine cannot be started. The cars are not fitted with batteries, and this connection is left on the switch only in case (at some future time) you should wish to equip your car with batteries for starting.

Priming: With present-day grades of gasoline, it is usually necessary to prime the engine while it is being cranked. Priming shuts off some of the air, so a richer mixture of gasoline vapor is drawn into the carburetor.

This priming is done by pulling forward a small ring on the end of a wire that projects out through the radiator at the front. This priming ring must be held out, at the same time that the engine is cranked.

Cranking the engine: Grasp the starting handle firmly with the right hand, and push the starting crank in as far as it will go, feeling for the ratchets which the starting crank should engage. Hold the priming ring out with the left hand, and pull the starting crank up quickly.

The crank should be kept pushed in, while the handle is being pulled up. This requires a certain knack that is soon acquired by practice. If not pushed in, the crank will slip out of the notches, and the sudden release may throw the driver off his balance.

The crank should be pulled up sharply. Slow pulls are of no value, for, unless the engine is turned over quickly, the magneto will not give enough current to make a good spark.

Starting the Car

Speed up the engine a little by opening or moving the throttle lever toward you, a couple of notches. Also, advance the spark to a normal running position, about five to seven notches, from the front of the quadrant.

Place one foot on the foot brake, which is the pedal farthest to the right, so that you will always be prepared to stop; accidents may thus be prevented. Place the other foot on the clutch pedal, which is the farthest one to the left. Hold it in about mid-position, that is, do not push this pedal all the way down, or let it come back all the way.

Now grasp the hand-brake lever handle with the left hand, having the palm of the hand turned toward the outside of the car and the thumb turned downward, so that the thumb can be used for disengaging the latch. This may seem awkward at first, but it is the way this lever is intended to be operated. Now, pull back on the handle, then press the latch with the thumb. It is easy to release the latch, if one pulls back on the lever first. **Now hold the steering wheel with both hands,** and push the clutch pedal forward slowly, until the car begins to move. At the same time that the clutch pedal is pushed forward, push the side hand lever forward as far as it will go, so that the clutch pedal may return to "high" when the car is under way.

Gradually push the clutch pedal harder until you feel that there is no slipping in the low-speedgear and then speed up the engine so that the car is traveling at from 8 to 10 miles an hour.

Let the clutch pedal come all the way back quickly, and your car will be in high gear. Practice will teach you how to make the change from low to high gear smoothly and easily, without jerk to the passengers or strain on the mechanism.

Reversing the Car

Pull the hand-brake lever back just far enough to draw the clutch pedal forward and disengage the clutch, but do not pull the brake lever back far enough to engage the rear hub brakes.

Place one foot on the brake pedal, for use if necessary, and press gently on the middle, or reverse pedal. Do not attempt to drive backward rapidly at first, for the steering is very likely to be confusing, and it is not easy to drive backward in a straight line. After the driver has become more experienced, he can reverse by holding out the clutch with the clutch pedal, and using low speed forward as a brake.

Stopping the Car

Partially close the throttle; release the high speed by pressing the clutch pedal forward into neutral; apply the foot brake slowly but firmly until the car comes to a dead stop.

Do not remove the foot from the clutch pedal without first pulling the hand lever back to neutral position, or the engine will stall.

To stop the engine, open the throttle a trifle to speed up the engine and then throw off the switch. The engine will then stop with the cylinders full of explosive gas, which will naturally make the next start easier.

Spark Control

The left-hand lever under the steering wheel is the spark lever. Good operators drive with the spark lever advanced just as far as the engine will permit. But if the spark is advanced too far, a dull knock will be heard in the engine, owing to the fact that the explosion occurs before the piston has completed its compression stroke. The best results are obtained when the spark occurs just at the time that the piston reaches its highest point of travel—the gas being then at its highest point of compression. The spark should be retarded only when the engine slows down on a heavy road or a steep grade; but care should be exercised not to retard the spark too far, for when the spark is "late," instead of getting a powerful explosion, a slow burning of the gas, with excessive heat, will result. Learn to operate the spark as the occasion demands. The greatest economy in gasoline consumption is obtained by driving with the **spark advanced sufficiently to obtain the maximum speed.**

How Speed of Car is Controlled

The different speeds required to meet road conditions are obtained by opening or closing the throttle. Practically all the running speeds needed for ordinary travel are obtained on high gear, and it is seldom necessary to use the low gear except to give the car momentum in starting. The speed of the car may be temporarily slackened in driving through crowded traffic, turning corners, etc., by "slipping the clutch," i.e., pressing the clutch pedal forward into neutral.

Oiling Engine and Transmission

Oiling is most important, and is taken care of by pouring oil through the breather pipe on the front end of the engine base on the right side. This pipe is covered by a metal cap, which can be easily pulled off, when oil is to be poured into the crank case. The lubrication of the engine is explained on page 159. See page 1137 for one method of cleaning the oil pipe.

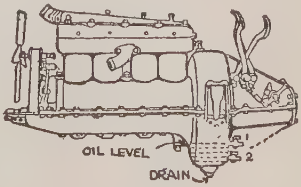


Fig. 3. Oil level.

When the engine is new: Pour in oil until it runs freely out of the upper petcock in the engine base (1) (Fig. 3). Be sure to close this petcock, for if it is left open, the action of the flywheel will splash all of the oil out through this petcock and the bearings will be ruined for lack of oil.

After the engine has been limbered up. The best results will be obtained by carrying the oil level about midway between the two petcocks—but under no circumstances should the oil level be allowed to get below the lower petcock.

Testing the oil level: Open the upper petcock. If oil does not drip out, open the lower petcock. If oil drips out, then there is enough oil for a short distance, but it is better to put more oil in if the car is to be driven a considerable distance. It is necessary at intervals to clean out these petcocks, as they become clogged with dirt or sediment.

Oiling Other Parts

This includes the filling of the different oil cups on the front axle system, the rear axle system, and the oiling of parts of the control system, which move but little. Oiling of these parts will tend to eliminate squeaks and prevent wear.

Oiling of the Commutator

Oil is injected through the small cup on the top of the commutator shell. Engine oil is rather heavy for the oiling of the commutator, and is likely to so insulate the roller from the contact points that starting may be difficult. This is especially true in winter, when the cold will so congeal a heavy oil that it will be almost impossible to obtain a good spark. "Three-in-one" oil is thin enough to be used in the commutator.

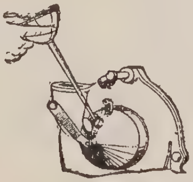

Fig. 4

Kind of Engine Oil to Use

A light, high grade of gas-engine cylinder oil is recommended. This light oil will reach into the closely fitted bearings of the engine more quickly, and so less heat and friction will be developed. The oil should have sufficient body to prevent the heat and pressure in the cylinders from squeezing out the oil from between the cylinder walls and the pistons. It is expensive to use a cheap oil. Good oils save repairs to the engine, increase the mileage per gallon of gasoline, and do not form carbon nearly as rapidly as do inferior oils. In cold weather an oil that does not congeal easily at low temperatures must be used. Otherwise the clutch will drag, owing to the oil acting as an adhesive.

Among the oils that are recommended for the Ford engine are Gargoyle Mobiloil "E," and White Star Extra Quality Oil, which is used at the Ford factory.

Graphite should never be used in either the engine or the transmission, as it is apt to short-circuit the magneto and thus cause expensive repairs.

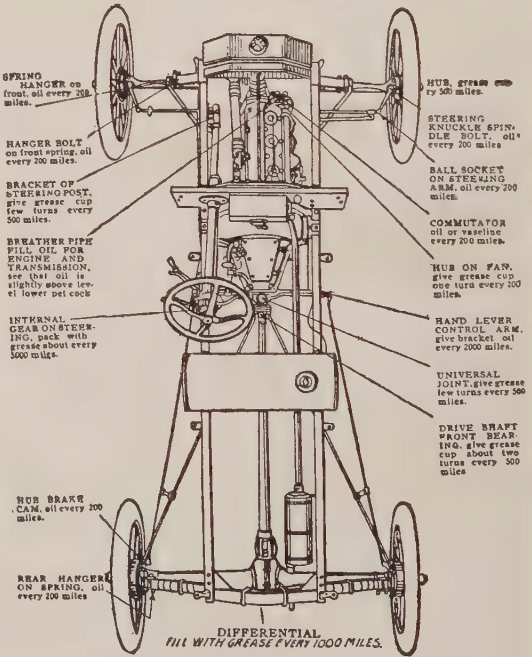
Draining Oil out of Engine

The new car should have the oil drained out at the end of the first 500 miles. This also applies to an overhauled engine, when the bearings have been refitted. The oil is drained out by removing the plug at the bottom of the crank case, and by cranking the engine. The front wheels should be about six inches higher than the rear wheels, so that the oil will drain to the rear of the crank case. Use at least a gallon of fresh oil, when refilling the crank case, and be sure to replace the plug in the bottom of the crank case tightly. If this plug drops out, the engine bearings are almost sure to be ruined for lack of oil. After the first 500 miles the oil should be drained from the crank case every 1,000 miles.

Lubrication of Chassis

The plan view of the chassis (Fig. 5) should be studied carefully, so that one will know how often the parts should receive attention and lubrication.

The oil cups can be supplied with the same kind of oil used in the engine, although a slightly heavier oil will not run away so rapidly and is better adapted to this use.



SPRING HANGER on front, oil every 200 miles.
HANGER BOLT on front spring, oil every 200 miles.
BRACKET OF STEERING POST, give grease cup few turns every 500 miles.
BREATHER PIPE FILL OIL FOR ENGINE AND TRANSMISSION, see that oil is slightly above level lower pet cock
INTERNAL GEAR ON STEERING, pack with grease about every 5000 miles.
HUB BRAKE CAM, oil every 200 miles.
REAR HANGER ON SPRING, oil every 200 miles
HUB, grease every 500 miles.
STEERING KNUCKLE SPINDLE BOLT, oil every 200 miles
BALL SOCKET ON STEERING ARM, oil every 200 miles
COMMUTATOR oil or vaseline every 200 miles.
HUB ON FAN, give grease cup one turn every 200 miles.
HAND LEVER CONTROL ARM, give bracket oil every 2000 miles.
UNIVERSAL JOINT, give grease few turns every 500 miles.
DRIVE SHAFT FRONT BEARING, give grease cup about two turns every 500 miles
DIFFERENTIAL
FILL WITH GREASE EVERY 1000 MILES.

Fig. 5. Lubrication chart for Ford car.

Greasing a Ford Car

This includes the filling of the grease cups, the universal joints, and the rear axle housing with grease. Cup grease, or grease containing graphite, can be used in the grease cups. **The rear axle housing** should not be filled too full. About 1½ pounds of grease is enough for the rear axle gears. If thrust washers are not worn, ½ lb. more can be added. A larger amount of grease will run out of the ends of the axles and spread over the wheels and tires.

The rear-axle housing should not be more than one-third full. The oil plug should be removed about every 1,000 miles and more grease added if necessary. If a fluid grease is used, the level should be approximately 1½" below the oil hole.

If grease or oil works out the rear hub-brake drums it is due to one of three causes: (1) too much lubricant in rear-axle housing; (2) thrust washers worn; (3) oil from engine working down drive shaft to rear-axle housing.

The universal joint should be packed with fresh grease. Fill the "dope" cups (grease cups) on the universal joint and drive-shaft front end bearing with grease and screw them down, refill, and repeat the operation several times until sufficient grease is forced **in** and the old grease is forced **out.**

The advantage of packing the universal joint with heavy grease is that it forms a packing which prevents oil from the engine crank case working down the drive-shaft housing and thinning the lubricant in the rear axle housing, thus working out the rear hub brake drums. See also page 1098.

Fan lubrication: The lubrication chart (Fig. 5) specifies grease every 200 miles. This applies to the old-style fan equipped with grease cup. The later-style fan should be lubricated by occasionally unscrewing the oil plug and filling the hub with heavy fluid oil.

CONSTRUCTION IN GENERAL

The Ford chassis is divided into units, such as: the **front axle** system; the **rear axle** system; the **engine** and **transmission** unit; and the **dashboard,** which includes the **steering column.**

It is well to remember these units when making repairs to cars, for it often is necessary to remove the entire unit from the car when a certain part is to be repaired.

For example, when repairing an axle shaft, it is necessary to remove the entire rear axle system, in order that the shaft may be removed.

The carburetor is a Holley or a Kingston instrument, having a hot-air fitting which clamps over the exhaust manifold, giving a complete supply of heated air for cold-weather evaporation. There is a dash carburetor adjustment controlling the needle valve.

Lubrication is by gravity, with the oil carried to the front end of the engine and the timing gears by means of the flywheel, through the oil tube, after which it returns by gravity to the flywheel casing in the crank shaft.

The clutch is a multiple disk in oil, delivering the drive to a two-speed planetary gearset in unit with the engine. From here the final drive is by means of a propeller shaft.

The propulsion stresses are taken through the radius rods, which are fastened by means of pivot connections at the outer ends of the rear axle and through the tube which surrounds the propeller shaft. The driving torque is taken through the torsion tube which surrounds the propeller shaft.

The springs are different from the usual construction on other cars (see illustration, Fig. 7).

The tire equipment is pneumatic, 30" x 3" in the front and 30" x 3½" in the rear when clincher wheels are used. When demountable rims are used, both front and rear tires are 30" x 3½".

The wheels are of the wood artillery type, with oval spokes. The foot brakes are on the transmission, and the hand brake is on the rear wheels.

The transmission drive-shaft brake is an external contracting type, and the hand brake is an internal type expanding on the rear wheel drums.

The steering gear is mounted on the left, and the control system is the standard Ford layout with three pedals and the brake lever.

Fig. 7. Top view of Ford chassis. The crank shaft operates on three bearings and the cam shaft is driven by spur gears.

STEERING-GEAR SYSTEM

The Ford steering device is the "planetary gear" type. See also pages 11 and 1087.

The **steering reduction gears** are placed at the top of the steering column, instead of at the bottom (Figs. 8 and 9).

These gears increase the power and the sensitiveness of the control over the front wheels of the car. If these gears were not used, a slight turn of the steering wheel would send the car into the ditch, while road obstructions, or bumps, would wrest the steering wheel out of the driver's control.

The lower part of steering column merely has an arm (A) (Fig. 10) which is connected to rod (B) extending to the steering knuckle arm (SA) (Fig. 11).

The steering wheel has a short shaft, on which a drive pinion is mounted. This pinion is held in place by the cover and nut of the steering gear case.

The steering rod proper, on the end, is fitted with a flange (triangle shape under the gears), on which three studs project, which carry the three small gears. These gears mesh with the drive pinion and also with an internal gear cut on the inside of the steering-wheel case (see also Fig. 18).

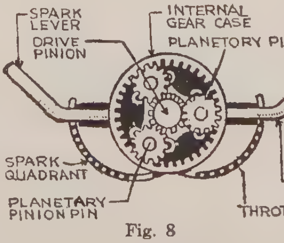

Fig. 8

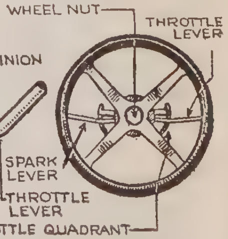

Fig. 9

To obtain access to the gears: Remove the small screw which holds the gear-case cover. Then unscrew the gear-case cover, and the steering wheel and the cover can be removed together as a unit. It is not necessary to remove the lower part of the steering wheel from its shaft to obtain access to the steering gears.

There are two small **retaining keys** in the top of the steering column. Keep these keys snug, for if they come loose, considerable play will result.

Removing the Steering Wheel

Unscrew the nut on the top of the post, and drive the wheel off the shaft, using a block of wood and a hammer. Do not batter the threads of the shaft, or it will be difficult to replace the nut. See Fig. 18.

Tightening the Steering Gear

A loose steering gear will make steering difficult and cause wear of tires. To tighten, see that the nut which holds arm (A) at the lower end of steering rod (R) (Fig. 10) is tight.

Ball and Socket Joints

There is a ball on the end of arm (A) which fits into a socket (C) (Fig. 13). If this is not kept oiled, play will develop.

There is also a ball on the end of the thrust rod (B), which connects the steering arm (SA) (Fig. 11).

If the ball and socket becomes worn from lack of oil, it can be ground by rubbing over emery cloth, or filing, as shown in Fig. 16.

Spring ball sockets which take up wear automatically are now supplied by specialty manufacturers.

Bushings in Front-Axle Spindles

There are bushings in the spindle arms (S) (Fig. 11). The "spindle arm bolt" works in the bushings. The bushings wear first, and, if worn should be replaced.

Removing bushings: Split expanding bushing removers are best for this purpose, or else the bushing can be threaded and fitted with a bolt and driven out. The bushings are short, and one is at each end of the spindle body.

New bushings should be pressed in with an arbor press or vise, or be carefully hammered in with a lead mallet, or with wood between hammer and bushing.

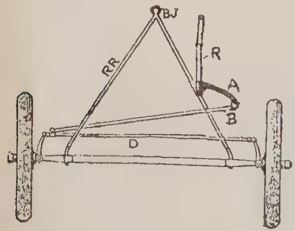

Fig. 10

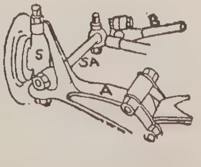

Fig. 11

Fig. 10. Arm (A) of the steering device is the only part connected to the steering, or drag rod (B), by means of a ball and socket joint (Fig. 13). The movement of the steering rod (R) moves (A), then (B), then the steering knuckles, thus causing the front wheels to move.

Both ends of rod (B) are fitted with ball and socket joints, as shown in Figs. 11 and 15.

After fitting, the bushings should be reamed out. Special reamers are made for this purpose. See "Ford tools" (farther on), and Index under "Reamers."

The bushings must fit snug, so that the bolts will turn and not the bushings.

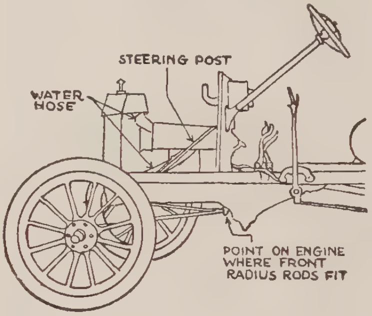

Fig. 12

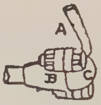

Fig. 13

Fig. 12. Note the ball joint (BJ) (Fig. 10) which fits into a socket on the engine base to support the front radius rods.

Fig. 13 is the part connecting (A) and (B) (Fig. 10).

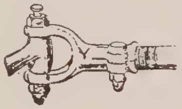

Fig. 14

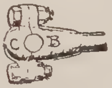

Fig. 15

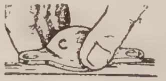

Fig. 16

Fig. 14. Yoke which connects each end of the tie rod (D) to the steering knuckle arms.

Fig. 15. The part shown at (B) (Fig. 11).

Fig. 16. Method of taking up wear on socket (C) which places the sockets closer together over the joint. The method is to emery the halves of the parts down, as shown.

Front Wheels

Removing the front wheels: Use the special hub-cap wrench to remove the hub-cap. Pull out the cotter pin; then take off the castle lock nut and lock washer. Unscrew the adjustable bearing cone. Then pull the front wheel off.

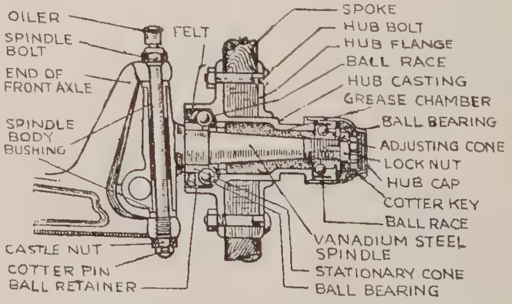

Fig. 17. Names of parts of **front wheel spindle assembly.** Note that the bushings do not extend entirely through the spindle body, but only at each end. Ball bearings shown above.

The cones and castle nuts must be replaced on the spindles from which they were removed. There are left-hand threads on the right spindle and right-hand threads on the other spindle. (Note. Turn the top of the nut toward the rear of the car to tighten. This holds good for all wheel nuts.)

If the cones or cups are worn, they should be replaced with new parts. While slightly longer service can be obtained by turning the cones half-

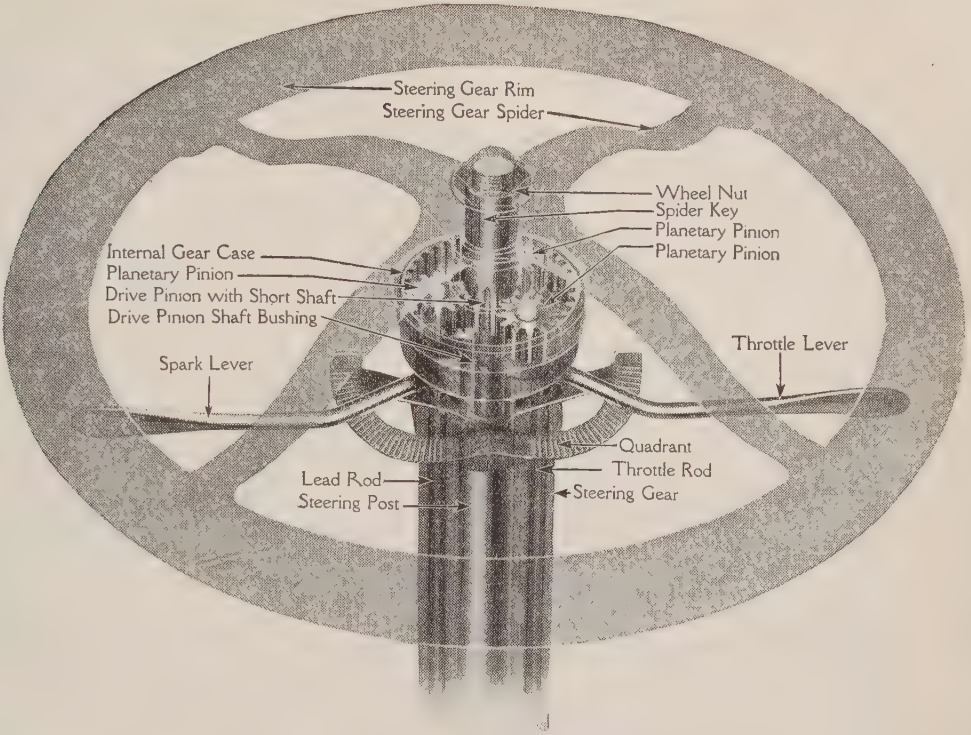

Fig. 18. The distinctive feature of the **Ford steering gear,** illustrated above, is the arrangement of the planetary reduction gears at the upper end of the steering post.

The steering wheel is keyed to a shaft about 4½″ long, which also forms the center or drive pinion. The three planetary pinions are carried on a spider at the upper end of the steering post and mesh with the drive pinion; also the internal gear case which surrounds them.

When the steering wheel is turned, the drive pinion must also turn. This causes the three planetary pinions to rotate on their axes, and as they mesh with the gear case, which is stationary, they also revolve around the drive pinion, thus forcing the steering post to turn. The difference in the number of teeth on the pinions and gear case gives the steering post but one-third of the turn of the steering wheel. This gear reduction gives the leverage required for easy steering.

way around, so that the wear comes on the opposite side of the cone, this permits a certain amount of looseness, and is not as good as the fitting of new parts.

If the balls are chipped, cracked, or pitted at all, they should be replaced by new ones. Chipped balls will break and ruin the other parts of bearings.

Testing the Wheels

The front wheels should be jacked up and tested for side play and smoothness of running. See page 905; "Testing front wheel bearings."

A sharp click, when running the front wheel, together with a momentary check in the motion of the wheel, indicates a broken ball, which should be immediately removed, before it causes trouble.

Adjustment of Front Wheels

The front wheels should be so adjusted that the wheels will come to rest—after spinning—with the tire valve at the lowest part of the wheel. Yet there should be no noticeable side play, when the spokes of the wheel are grasped with the hands and the wheel shaken.

When Timken roller bearings are used, they should be adjusted as follows: the threads on the outer bearings are the same as on the adjusting cones of the ball bearings. Tighten the outer bearing on the spindle until the wheel seems to bind, then back off one-quarter to one-half a turn so that the wheel revolves freely without end play.

Timken roller bearings can easily be installed on cars equipped with ball bearings.

Sedans, coupés, and trucks are now fitted with roller bearings.

Undue wear of the cones may be caused by adjusting the cones so closely that the bearings bind; or this may be due to lack of lubrication. The hub-caps should be filled with a soft grease every few thousand miles.

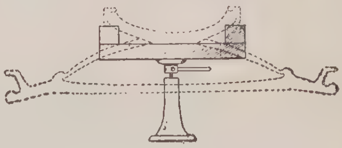

Fig. 19. One **method of jacking up the front of a car** with a block of wood. The illustration shows method and dimensions. The block should be narrow enough to go between the front axle and steering connection that crosses about 4½″ behind it.

Removing the Front Axle

Jack up the front of the car, by supporting the frame on a couple of boxes, or by chains or ropes, or as shown in Fig. 19. Remove both front wheels. Disconnect thrust rod (**B**) from arm (**SA**) (Fig. 11, page 1086). Disconnect the radius rod at the ball joint (as in Figs. 10 and 12). Remove the two spring shackle bolts at each end of the front spring.

To Disconnect the Front Radius Rod from Axle

Remove the cotter-pinned nuts. To remove the radius rod entirely, take the two nuts off the studs which hold the ball cap, and remove the lower half of the cap. See Figs. 10 and 12.

If the radius rod rattles, remove the lower half of the ball cap, and file some of the metal off the flat surfaces, or rub down (as shown in Fig. 16).

Straightening the Front Axle

In case the front axle or parts are bent, straighten them while cold. The application of heat will remove the effects of the heat treatment to which these parts have been subjected, and will dangerously weaken them.

Bringing the point of contact of the tire and ground more nearly under the spindle body bolt makes steering easier and tends to prevent tire wear. See the discussion of "camber" on page 906.

Transposing Tires

To use 30″ by 3½″ tires on the front wheels, a pair of rear wheels can be purchased and fitted in place of the original front wheels, on cars not equipped with demountable rims.

Springs

Care of springs: If the springs seem stiff, use a screwdriver to pry the leaves apart and place some graphite grease, or heavy oil, between the leaves.

Spring clips should be kept tight: If these clips are not kept tight, the strain will be put on the tie-bolt which passes through the center of the spring leaves and will break it. The tie-bolt is intended only for keeping the spring leaves from slipping out of position sideways. This is particularly true of the front spring, for if the front spring shifts sideways, it will endanger the steering of the car, and may cause an accident.

Making the Car Ride More Easily

One or more leaves can be removed from the rear spring of the runabout, to make the car ride more easily, as the same spring is used on both runabout and touring cars. The runabout does not carry so much weight. If one leaf is removed, it should be the second from the top. If severals leaves are removed, take out alternate leaves, so as to maintain the general shape of the spring as nearly as possible.

For truck use: Several leaves are sometimes added to increase the stiffness of the springs.

Alignment of Wheels

See page 903; "Alignment of wheels" for the reason why proper alignment of wheels is necessary. See also page 906 for "Alignment of Ford front wheels."

Adjustment of the front wheels can be made by turning the yoke at the left end of the drag rod, drawing the wheels into a parallel position. If inspection shows that the axle or the spindles are bent, it will be necessary to have those parts straightened or replaced before correct alignment can be secured.

THE FORD TRANSMISSION AND CLUTCH

This transmission serves the same purpose as a sliding gear or selective type of transmission, as explained under the instruction on "Transmissions."

It is mounted on a shaft which has a flange projection at one end, which bolts to the flywheel; the flywheel is bolted to a flange on the end of the crank shaft.

The planetary gears are shown as marked, (P1) (P) (K) and (S) (P) (G) (Fig. 20). These gears are mounted on studs projecting from the flywheel.

By means of bands, which are tightened around the drums, the rotation of these gears is governed as explained.

It is called a **planetary transmission,** from a fancied resemblance between the motion of the triple gears around the central shaft and the motion of the planets around the sun.

Low speed: Gear (D) is the driven member, keyed to the hub clutch drum (C), which in turn is secured to the driven shaft. By applying the brake band to drum (B), gear (F) is held stationary, pinion (P) rolls on it, and a smaller pinion (P1) causes gear (D) to turn slowly in the same direction as the flywheel, as explained later.

For high speed or direct drive, the friction clutch locks the clutch drum (C) to the engine crank shaft and the entire mechanism revolves as a unit.

For reverse: Applying the brake band to drum (V), gear (L) is held stationary, pinion (K) rolls on it, and pinion (P1) turns gear (D) slowly in the reverse direction, as explained later.

Fig. 20. Simplified illustration of the Ford transmission and clutch.

The clutch serves the same purpose as a cone or disk clutch, as described under the instruction on "Clutches," on page 20.

The clutch on the Ford is made of steel disks, as lettered. The pressure of clutch fingers (there are 3) through the ring which presses against the disks, causes the disks to take hold. When the clutch is "in," the car is on high speed (there are only two speeds forward on a Ford), and the entire transmission revolves, and the drive is then **direct** to the rear axle.

Principle of the Ford Transmission

The shaft **(S)** (Fig. 21) is connected, through the universal joint, to the drive shaft of the car. It is also fastened rigidly to the brake drum. Therefore any motion imparted to the brake drum will also be imparted to the rear axle and consequently to the rear wheels.

What Happens When the Transmission Is in Neutral

The flywheel (Fig. 21) and the shaded parts rotate. The clutch-release fork holds back the clutch spring from pressing on the clutch fingers.

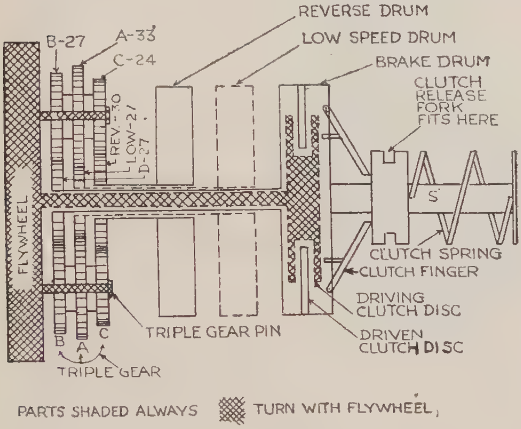

Fig. 21. Diagram of Ford Transmission.

Therefore the driving clutch disks will not be pressed against the driven clutch disks, and the brake drum will not be rotated. The low-speed drum and the reverse drum will rotate, but will have no effect.

What Happens When the Transmission Is in High

The release fork permits the clutch spring to press on the clutch fingers, thus pressing the driving clutch disks against the driven clutch disks. The brake drum will then be directly connected to the flywheel and the drive will consequently be direct. The low-speed drum and the reverse drum will rotate, but will have no effect.

The total gear ratio in high is therefore the ratio of the rear axle, which is 3.63, because the bevel-drive gear in the rear axle is so much larger than the pinion that the engine makes 3.63 revolutions for every turn of the rear wheels.

What Happens When the Transmission Is in Low

The release fork holds back the clutch spring and consequently the flywheel is not **directly** connected to the brake drum through the clutch disks.

A band is clamped around the low-speed drum (Fig. 21), thus holding the low-speed drum stationary. This drum is fastened to the gear **(LOW-21)** therefore **(LOW-21)** is stationary. Since the triple gear pins rotate with the flywheel, then triple gear **(A-33)** must rotate on the triple gear pin as it rolls around the gear **(Low-21)**.

The triple gears (A) (B) and (C) are all fastened together; consequently the rotation of **(A-33)** on the triple gear pin will cause **(B-27)** to turn on this pin. Since **(B-27)** is in mesh with the driven gear **(D-27)**, this latter gear will rotate, thus causing a slow motion of the brake drum to which it is attached. Since the brake drum rotates slowly, the car moves slowly.

Now refer to Fig. 22. Remember that gear **(D-27)** is fastened to the brake drum, and consequently to the drive shaft. The numbers on the gears correspond to the number of teeth on it, that is, **(A-33)** has thirty-three teeth, **(B-27)** has twenty-seven teeth, and so forth. The arm **(Ar)** represents the triple gear pin which is fastened to the flywheel and carries triple gears **(A-33)** and **(B-27)**. When the low-speed drum is stopped, gear **(LOW-21)** remains stationary, as just explained.

Let us see what takes place during one revolution of the flywheel. (1) The triple gear pin **(Ar)**, since it is part of the flywheel, will pass through one revolution as shown by the arrow **(S)**. (2) Consequently it will try to pull the driven gear **(D-27)** through one revolution in the same direction as shown by the arrow **(X)**. (3) Since gear **(LOW-21)** is stationary, one revolution of the triple gear pin **(Ar)** causes the gear **(A-33)** to turn in the direction shown by the arrow **(T)**. (4) But gear **(A-33)** has thirty-three teeth, while **(LOW-21)** has only twenty-one teeth; therefore gear **(A-33)** will not make quite one revolution, but will make only 21/33 of a revolution. (5) Gear **(A-33)** being fastened to **(B-27)** causes the latter to revolve the same amount, or 21/33 of a revolution, as represented by the arrow **(W)**. (6) Since **(B-27)** is in mesh with **(D-27)** and both have the same number of teeth, then **(D-27)** will try to revolve 21/33 of a revolution in the direction shown by arrow **(Y)**

As a result we find the effect on gear **(D-27)** to be as follows: The triple gear pin **(Ar)** tries to rotate **(D-27)** one revolution, as shown by the arrow **(X)**, whose length represents one revolution; the triple gears try to rotate **(D-27)** 21/33 of a revolution in the opposite direction, as shown by arrow **(Y)**, whose length represents 21/33 revolution. **Gear (D-27) will actually turn** the difference between the two, that is one revolution minus 21/33 of a revolution equals 12/33 of a revolution in the same direction as the flywheel as represented by the small arrow **(Z)**, whose length represents 12/33 of a revolution.

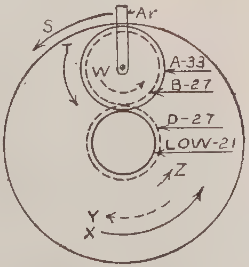

Fig. 22

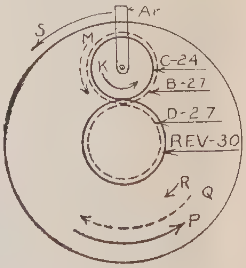

Fig. 23

Fig. 22. Diagram of Ford transmission in low speed.
Fig. 23. Diagram of Ford transmission in reverse.

The gear ratio in low is therefore 33 divided by 12, or 2.75. The rear axle has a ratio of 3.63, therefore the **total ratio** in low is 2.75 times 3.63, equals 9.98, or practically 10 to 1.

In general, owing to frictional losses in the transmission, and other causes, it may be assumed that the car will travel about three times as fast in high gear as in low. But the car will have about twice as much pulling force when low gear is used.

What Happens When Transmission Is in Reverse

The release fork holds back the clutch spring, and consequently the flywheel is not **directly** connected to the brake drum through the disks (Fig. 21).

A band is clamped around the reverse drum (Fig. 21), thus holding the reverse drum stationary. This drum is fastened to the gear (**REV**-30) therefore (**REV**-30) is stationary. Since the triple gear pins rotate with the flywheel, then triple gear (**C**-24) must rotate on the triple gear pin as it rolls around the gear (**REV**-30). The triple gears (**A**) (**B**) and (**C**) being all fastened together, the rotation of (**C**-24) will cause (**B**-27) to turn on the triple gear pin. Since (**B**-27) is in mesh with driven gear (**D**-27), this latter gear will rotate in a reverse direction, as explained later. The reverse rotation of (**D**-27) causes a reverse turning of the brake drum to which it is attached. Since the brake drum reverses, the car reverses.

Now refer to Fig. 23. Remember that gear (**D**-27) is fastened to the brake drum, and consequently to the drive shaft. When the reverse drum is stopped, gear (**REV**-30) remains stationary, as just explained.

Let us see what takes place during one revolution of the flywheel. (1) The triple gear pin (**Ar**) will pass through one revolution, as shown by the arrow (**S**). (2) Consequently it will try to pull the driven gear (**D**-27) through one revolution in the same direction as shown by the arrow (**P**). (3) Since the gear (**REV**-30) is stationary, one revolution of the triple gear pin (**Ar**) causes the gear (**C**-24) to turn in the direction shown by the arrow (**K**). (4) But gear (**C**-24) has only twenty-four teeth, while (**REV**-30) has thirty teeth; therefore gear (**C**-24) will make more than one revolution on the triple gear pin. To be exact, it will make 30/24 of a revolution, or 1 and 6/24 of a revolution. (5) Gear (**C**-24) being fastened to (**B**-27) causes the latter to revolve the same amount, or 30/24 of a revolution, as represented by the arrow (**M**). (6) Since (**B**-27) is in mesh with (**D**-27), and both have the same number of teeth, (**D**-27) will try to revolve 30/24 of a revolution in the direction shown by the arrow (**Q**).

As a result we find the effect on gear (**D**-27) to be as follows: The triple gear pin tries to rotate (**D**-27) one revolution, as shown by the arrow (**P**), whose length represents one revolution; the triple gears try to rotate (**D**-27) 30/24 of a revolution, as shown by the longer arrow (**Q**), whose length represents 30/24 of a revolution. **Gear (D-27) will actually turn** the difference between the two, that is 30/24 of a revolution, minus one revolution, equals 6/24 of a revolution, in the direction of the small arrow (**R**), whose length represents 6/24 of a revolution.

Notice that the arrow (**R**) points in the opposite direction to the arrow (**S**). Consequently (**D**-27) turns in the opposite direction from the flywheel, thus causing reverse rotation to the brake drum.

The gear ratio in reverse is therefore 24, divided by 6, which equals 4. Since the rear axle has a ratio of 3.63, the **total ratio** in reverse is 4 times 3.63, which equals 14.52 to 1, which is nearly 15 to 1. But owing to the number of gears transmitting the power when reverse is used, the actual available power in reverse is not as great as might be supposed. However, it is sometimes possible to use the reverse gear to pull the car out of a mudhole when even the low speed gear does not have sufficient power.

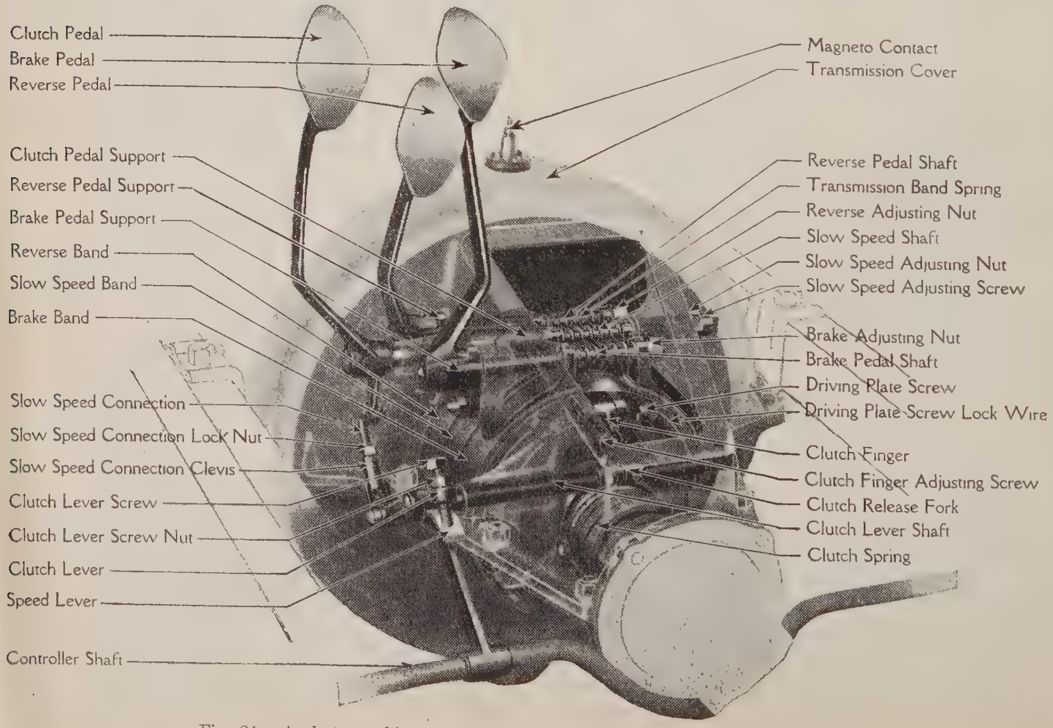

Fig. 24. A photographic view of the Ford **transmission and control pedals.**

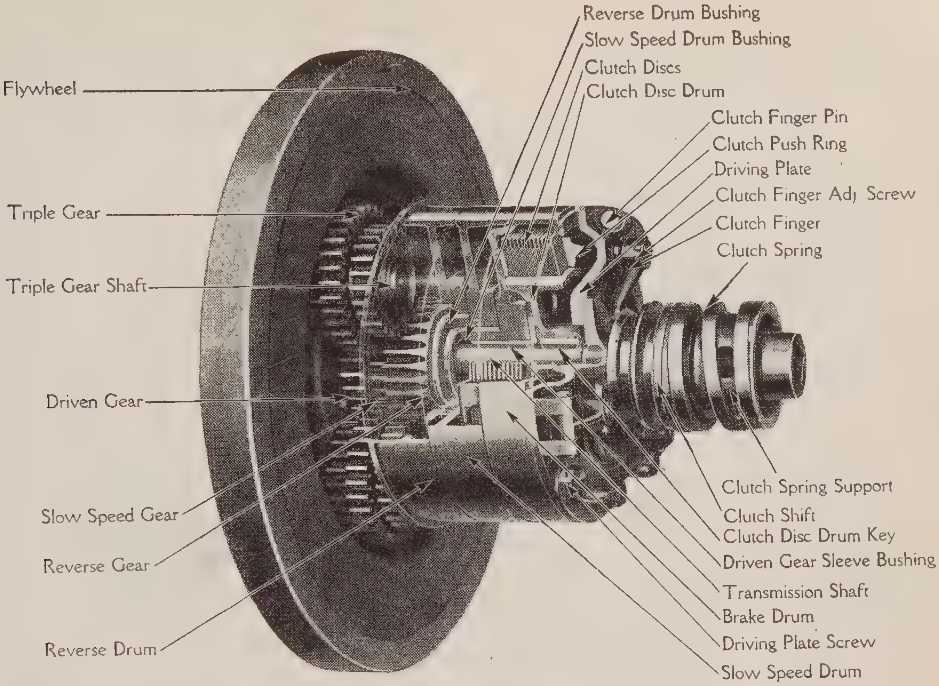

Fig. 25. A phantom view of the Ford **transmission and clutch,** showing how it is attached to the flywheel.

Clutch Control

The control of the clutch is by the left pedal at the driver's feet. If the clutch pedal, when pushed forward into slow speed, has a tendency to stick and not to come back readily into high, tighten up the slow-speed band, as directed farther on.

Should the machine have an inclination to creep forward when cranking, it indicates that the clutch lever screw (B) (Fig. 27), which bears on the clutch lever cam (C) has worn, and requires an extra turn to hold the clutch in neutral position.

When the clutch is released by pulling back the hand lever, the pedal should move forward a distance of 1¾″ in passing from high speed to neutral. See that the hub brake shoe and connections are in proper order, so that the brake will act sufficiently to prevent the car creeping very far ahead. Also be sure the slow-speed band does not bind on account of being adjusted too tight.

Clutch Slips or Drags

A slipping clutch may be due to worn main bearings, allowing the crank shaft to vibrate, or it may be due to the use of heavy oil in the engine.

When the clutch drags: This may be due to heavy or old oil. This oil collects between the clutch plates, and does not allow them to separate freely from each other, as they should, when the clutch is disengaged. An oil that is too heavy for the clutch plates is also too heavy for good use in the engine. Heavy oil will not penetrate into the closely fitted bearings, and if the oil does not get in, friction and rapid wear will result.

Heavy oils are sometimes used in Ford engines with the idea that the heavy oil will seal the gaps between worn pistons and cylinder walls, but the only effective remedy is to replace pistons and other worn parts as needed. **In winter, oil should have a low cold test,** that is, the oil should not congeal easily. If it does, the engine will be very hard to start on account of the **dragging of the clutch and the bands on the transmission drums.**

To Tighten Brake and Reverse Bands

Remove the transmission case cover and turn the adjusting nuts on the shafts to the right (Fig. 26).

The bands should not drag on the drums when disengaged, as they have a tendency to exert a brake effect, and to overheat the engine. The foot brake should be adjusted, however, so that a sudden pressure will stop the car immediately, or slide the rear wheels in emergency cases.

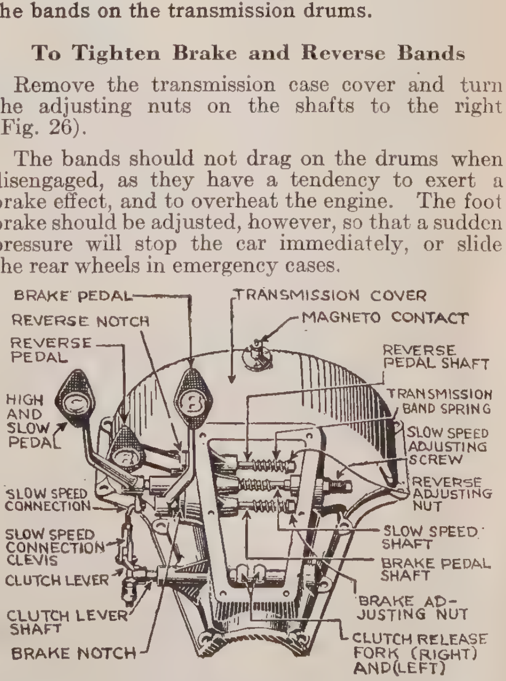

Fig. 26. **Transmission cover showing where adjustments are made.** The transmission-case cover (which bolts over the wedge-shaped opening) has been removed, thus exposing the reverse and the brake adjusting nuts.

To Tighten Slow-Speed Band

Loosen the lock nut at the right side of the transmission cover, and turn the adjusting screw (see Figs. 26 and 27) to the right.

If the reverse grabs and sticks at times, and the lining is in good condition, this is due to the adjustment on the foot pedal on the reverse, which allows the pedal to be pressed too far. This can be remedied by turning the reverse adjusting nut shown in Fig. 26.

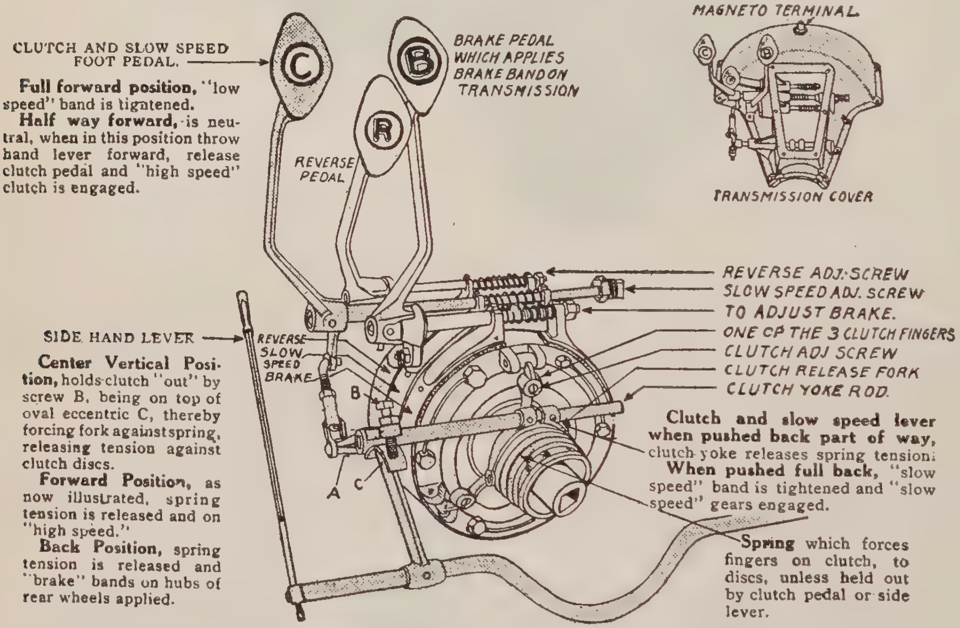
If the clutch slips in high speed, jack one rear wheel up, turn the engine so that the clutch fingers (Fig. 27) come in convenient position, remove the split pin, give half a turn clockwise to each clutch adjusting screw, and replace the pins. Do not drop the pins in the transmission case. After long wear, new disks will be needed. It will be necessary to remove the transmission cover, as explained later.

When the transmission band linings have become hard and glazed, they will not grip the drums until the pedals have been pushed very hard and all the oil has been squeezed from between the bands and the drums. Then the bands take hold with a series of jerks, and this causes a chattering and severe strains on both the transmission and the rear axle assembly.

Other evidences of worn transmission bands are:

1. The failure of the foot brake to hold in spite of all the adjustment that can be made through the cover on the top of the transmission case, without causing the bands to drag.
2. Or if the low-speed and reverse gears slip when the pedals are pushed, and the engine races, while the car does not travel as fast as it should.

On an average, the brake linings should give good service for about six months; with good driving, from ten months to a year of service may be had, counting on from five to ten thousand miles driving as a year of service.



Full forward position, "low speed" band is tightened. **Half way forward,** is neutral, when in this position throw hand lever forward, release clutch pedal and "high speed" clutch is engaged.

Center Vertical Position, holds clutch "out" by screw B, being on top of oval eccentric C, thereby forcing fork against spring, releasing tension against clutch discs. **Forward Position,** as now illustrated, spring tension is released and on "high speed." **Back Position,** spring tension is released and "brake" bands on hubs of rear wheels applied.

Clutch and slow speed lever when pushed back part of way, clutch yoke releases spring tension; **When pushed full back,** "slow speed" band is tightened and "slow speed" gears engaged.

Spring which forces fingers on clutch, to discs, unless held out by clutch pedal or side lever.

Fig. 27. Connections of **hand lever and foot pedals** to transmission and clutch.

Causes and Symptoms of Worn Transmission-Band Linings

Cause: When starting the car, the driver should press the pedal forward until the low speed begins to engage. Then the pedal should be pressed more slowly until there is no slipping of the band on the drum. When using the low-speed gear on long, steep hills, many drivers unconsciously relax the pressure on the pedal, so that the drums slip and wear the bands. Hold the pedals in firmly when the bands have once been engaged with the drums.

Another cause of rapid wear of the bands is the habit of some drivers of racing the engine at high speeds before attempting to engage the transmission bands. The best driver is the one who can use the gears and not speed up the engine any faster than will just avoid stalling. If the engine is not raced too fast, there will not be so much difference between the speed of the transmission bands and the speed of the drums. Then there will be less wear on the band linings and less strain on all parts of the car.

By driving on the throttle, as much as possible, instead of using the clutch so often, the bands will be made to wear longer.

Removing Transmission Cover

1. Remove the magneto wire.
2. Remove the starting motor.
3. Remove the 3/8" bolts holding on the transmission cover. (Use L-handle wrench No. 2322 for keeping the nuts from turning, while the bolts are turned from below, by using T-wrench No. 2320.)
4. Loosen and remove the two bolts which hold the universal ball cap to the transmission cover.
5. Loosen the lock nut on the low-speed screw and loosen the low-speed adjustment.
6. Push the emergency brake lever forward.

If the cover is hard to remove, then loosen the nuts on reverse and the brake-adjustment nut as far as they will go, and remove the slow-speed adjusting screw.

Removing Bands

Now the cover can be pulled off, and then the bands.

Place the band nearest the flywheel over the first of the triple gears. Turn the band around so that the opening faces downward. The band can then be removed by lifting up.

If the three sets of triple gears are so placed that one set is about 10° to the right of center at the top, the operation is considerably simplified. Each band is removed in the same way. It is important to shove each band forward on to the triple gears—as only at this point, is there sufficient clearance in the crank case to allow the ears of the transmission bands to be turned down.

Relining Bands

Instructions for relining the brake bands are given elsewhere. See page 893. The sizes of the linings are 5/32″ or 11/64″ thick, 1⅛″ or 1 3/16″ wide, and 23 5/16″ or 23⅜″ long.

Never use linings containing metallic reinforcements for the transmission bands. Special Ford linings should be used. Particles of wire, worn from ordinary band linings, are apt to cut through the insulation of the magneto, which is in the same compartment as the transmission. A short-circuited magneto necessitates pulling the engine out of the car for repairing.

At the Ford branches or agencies, transmission bands can be exchanged for 50 cents each. As the cost of the linings and rivets is about 40 cents, it usually pays to exchange the bands.

Use soft brass rivets: When relining the transmission bands, use soft brass rivets. If iron rivets are used, particles of iron, worn from the rivets, will be attracted to the magneto, and will tend to cause short circuits.

Iron rivets are so hard that they will cut and score the soft iron brake drums, thus making them liable to break.

To Install Bands

Simply follow the reverse of the procedure of removing the bands. When the three bands are placed in an upright position on the drums, placing the transmission cover on can be facilitated by passing a cord around the ears of the three bands, and holding them in the center. The pedal shafts can then be made to rest in the notches in the band ears.

The clutch release fork should also be placed in the rear groove of the clutch shaft.

Replacing Transmission Cover

First, tie the lugs of the three bands together tight, with a piece of wire or cord, or construct a band holder, as shown in Fig. 28.

Second, make sure that all the gaskets are in place and that none of them are defective. Broken gaskets will allow oil to escape when the engine is running. The oil is splashed around in the transmission case by the flywheel and transmission drums.

Third, loosen the nuts on the brake and slow-speed studs as far as they will go, without danger of falling off.

Fourth, compress the springs on these operating studs. This will make it much easier to replace the transmission cover.

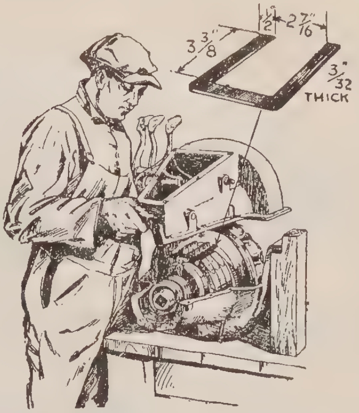


Fig. 28. **This clamp is used to hold the transmission bands together while replacing the transmission cover.** It is made of spring steel ½″ wide and 3/32″ thick, bent into the form of a U, having legs 3⅜″ long and 2 7/16″ across. One of these is clamped over the lugs on the transmission bands before replacing the cover, and is removed after the cover is bolted on. (*Motor World.*)

Fifth, replace the cover and all the bolts, and tighten them securely. It is not usually necessary to fit those around the sides with cotter pins. However, the bolts holding the universal ball cap must endure greater strains, so they should be fitted with cotter pins.

Remove the cord or wire, which was used to hold the bands in place while the cover was being installed.

Adjusting Bands

Adjust the bands so that the pedals can be pushed down to within a couple of inches of the floor boards, before the bands grip tightly. After running a couple of hundred miles, adjust the bands again, using the double-end wrench, No. 1917.

Transmission Gears

If the teeth of the triple gears are worn or chipped to such an extent that they do not properly mesh, they will cause a growling or grinding noise, especially when low or reverse gears are used.

Transmission Bearings

The transmission is supported at the rear end by a babbitt-lined bearing at the universal ball cap. If this bearing is worn, it will cause a knock in the transmission when the car is traveling over rough roads.

Worn bushings in the second speed and reverse drums throw the transmission shaft out of line; hence the gears become worn and noisy. It is advisable to install new bushings as soon as worn before they cause gear-teeth trouble, which means an ugly grinding noise.

A "chattering" noise in the transmission means that new band linings are needed. The same remedy applies when the car runs with a jerky movement.

To Remove Transmission

Take the upper part of the engine off the lower part of the crank case, as explained under "Removing power plant." Next remove the transmission cover (Fig. 28), and the crank-case cover. Then remove the four cap screws that hold the flywheel to the crank-shaft flange, using the special Ford flywheel cap-screw wrench No. 1929. The entire transmission may then be easily removed from the cylinder block assembly.

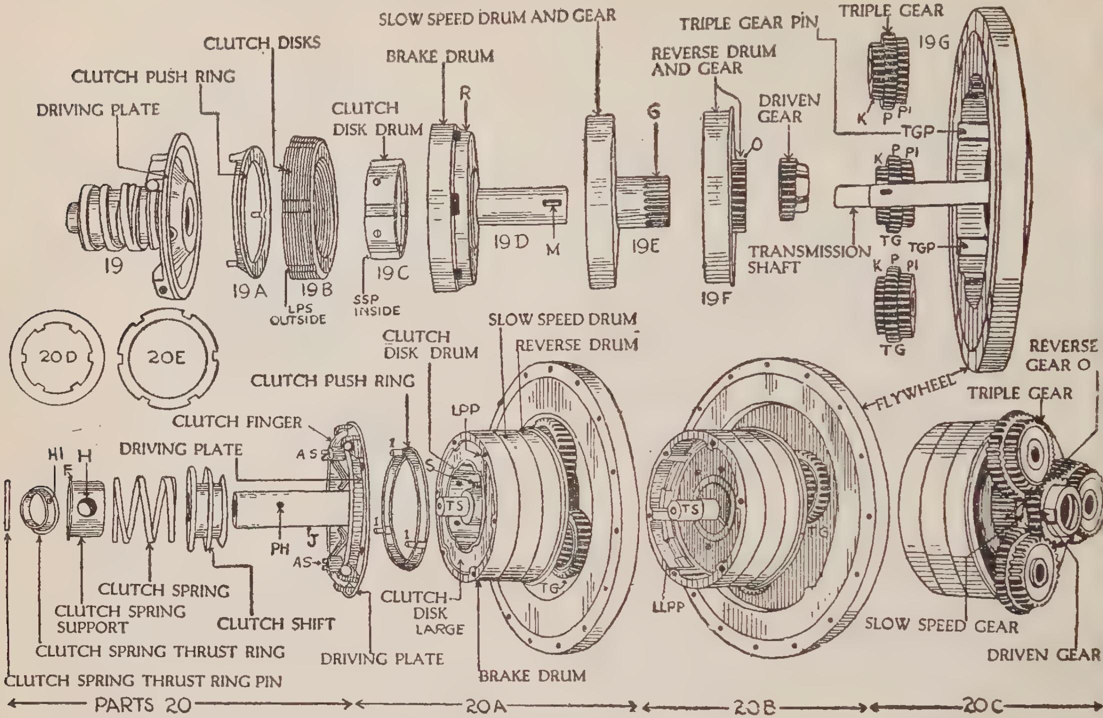

Fig. 29. **Parts of the Ford transmission:** The objects marked (19) to (19G) illustrate the parts of the transmission separated but in their respective order to be assembled.

Clutch: Note that the twelve small clutch disks or thrust plates (**20D**) and the thirteen large disks (**20E**) are placed together alternately (see 19**B**).

The projection on the small plates fits the slots of the disk-drum (19C), the latter being rigidly fastened to the transmission shaft (TS), whereas the slots in the large plates fit in projections (**LPP**) of the illustration (20**A**). The disk-drum (19C) is fastened to the transmission shaft by set-screw (S). The pressure of the "clutch push ring" (19A), due to the tension of the "clutch spring" (19) against the "clutch fingers," causes the large and small disks to grasp. The adjustment of the clutch fingers is made by screws (**AS**).

Transmission shaft (TS) and small plates (20**D**) run free in the brake drum, when the clutch is disengaged, in other words, the small plates revolve with the flywheel.

Slow-speed drum (19**E**) fits over the part (**R**) of the brake drum (19**D**). The driven gear is fastened to the hollow shaft (**M**) of the brake drum (19**D**) by means of two Woodruff keys.

Triple gears (TG), (K) are the reverse gears, (P) the slow-speed gears, and (P^1) the driving gears. These gears are fastened rigidly together in groups of three and are called triple gears on that account. There are three groups, and they revolve freely on pins (**TGP**) of the flywheel. (K) meshes with the gear on reverse drum (19F); (P) meshes with gear (G) on the hollow shaft of the slow-speed drum (19E); (P^1) meshes with the driven gear, and is keyed to the hollow shaft (M) on brake drum (19D), which projects past gear (G). The action can now be studied by referring to this illustration and the discussion of the principle previously given.

How to Assemble the Transmission

First, assemble the group of parts as shown in (20C) as follows: Place the brake drum (**19D**) so that the hub is in a vertical position; place the slow-speed drum (19E), with gear (G) up, over the shaft (**M**) of the brake drum. The slow-speed drum will then fit over (R).

Next, place the reverse drum (19F) over the hollow shaft of (19E), so that the reverse gear (O) on the drum surrounds the slow-speed gear (G).

Then fit two Woodruff keys in the shaft of the brake drum at (M), and place the "driven gear" (with teeth down) so that they will then come next to the slow-speed gear (G).

Triple gears (TG) (all three groups) should now be meshed with the driven gear, according to the punch marks on the teeth—the reverse gear or the smallest of the triple gear assembly being down.

When the triple gears are properly meshed, tie them in place with a string or cord passed around the outside of the three triple gears.

Second, assemble the parts to the flywheel as in (20B); place the flywheel on the bench with face down, and the shaft vertical.

Turn the group (20C) upside down, and place it over the transmission shaft, so that the three triple gear pins (TGP) on the flywheel will pass through the triple gears.

This will now leave the brake drum on top, as **shown in (20B), ready to take the clutch disks (19B).**

If the transmission is assembled, and if the triple gears, when in slow and reverse, growl, this is due to one of two causes: (1) The triple gears have a punch mark which should be in the center line with the driven gears. If the gears were rebushed, it is not likely that they will be placed back wrong, but if not, and the bushings are worn and loose, this may be the cause: (2) The bands may be adjusted too tight.

Assembling the Clutch

Third, fit the clutch-disk drum key in the transmission shaft; press the clutch-disk drum (19C) over the transmission shaft (TS) (20B), and put the set screw (S) in place to hold the drum.

Put a large clutch disk (20E) over the clutch drum, then a small clutch disk (20D) alternating with large and small disks until the twelve small and thirteen large disks are in place. A large clutch disk, or "thrust plate" as it is termed, will then be on top, as shown at (20A). Do not put a small disk on top.

Now place the "clutch push ring" (19A) over the clutch drum, so that it will be on top of the disks, with the pins (1) up.

Fourth group 20: Next bolt the "driving plate" in such a manner that the adjusting screws of the three "clutch fingers" will press against the "clutch push-ring pins" (1).

Fifth, it is now advisable to test by moving the clutch disks, and to see if they will move freely by hand. If properly assembled, the flywheel will revolve freely while any of the drums are held stationary.

Sixth, assemble the clutch-spring parts. Place the "clutch shift" (parts 20) over the driving plate hub **(J)**, so that the small end rests on the clutch fingers. The clutch-spring support is then slipped into the spring so that the flange **(F)** will rest on the upper coil of the spring; then insert the "clutch-spring thrust ring"[1] and press it into place. Insert the pin in the driving plate hub at **(PH)**, through the hole **(HI)** in the side of the thrust ring. This part of the work requires some "knack," but is simplified considerably by using a compressor similar to that shown on page 1137. The large holes **(H)** in the clutch-spring support facilitate the insertion of the pin.

Another easy method of compressing the clutch spring, so that the pin can be inserted, is to loosen the tension of the three clutch-finger adjusting screws **(AS)**.

When the clutch is tightened up again, the spring should be compressed to within a space of 2″ or 2 1/16″, to make sure the clutch spring does not slip.

The adjusting screws (AS) should be adjusted so that there is even tension all around the clutch disks. These screws are now provided with a slot, and it is necessary to turn them at least one half-revolution so that the slot comes in line with the cotter-pin holes; then insert the cotter pins.

Rebushing and Reaming of Transmission Drums and Gears

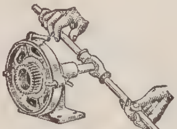
The bushings in drums and gears, when worn, can be replaced with new bushings and then reamed.

When reaming with an ordinary hand reamer, the gears are liable to wabble. Therefore, some sort of fixture should be used by which the drums can be accurately centered and located at fixed right angles, so that they may be reamed absolutely true, thus making a quiet transmission.

A reaming outfit with a centering device is shown in Figs. 30–33, which is a product of the K. R. Wilson Co., Buffalo, N.Y.

The bronze bushings in reverse gear (Fig. 30), the slow-speed gear (Fig. 31), the two bushings in the transmission brake drum (Fig. 32), and one bushing in each of the three triple gears (Fig. 33) should be replaced in case of wear.

The bushings are purposely made with the inside diameter a little smaller so that they can be reamed to an exact fit to the bearings on which they are to revolve.



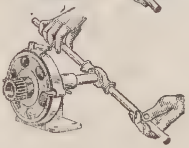


Fig. 30 (Upper)
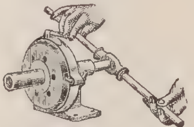
Fig. 31 (Lower)



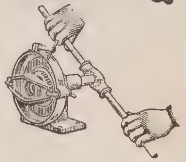


Fig. 32 (Upper)
Fig. 33 (Lower)

Fig. 30 shows a Ford **transmission reverse drum held in position in a reaming fixture,** especially designed. This fixture automatically locates the drum at right angles to the reamer, and with perfect centers. The reamers used in this machine are all especially designed, using a common standard-size arbor, the reamer proper being interchangeable on that arbor. The reamers are ground at a 45° angle in place of a long taper. This type of cutter plows through the bearing metal without being deflected off center, as in common practice with a long taper, where more cutting surface is exposed to the metal being cut.

Fig. 31 shows a Ford **slow-speed bushing being reamed** by the same process as that shown above.

Fig. 32 shows a Ford **transmission brake drum.** This drum has two bushings which must be reamed in perfect alignment. For this a special reamer with a pilot is used, the arbor being of the same size and interchangeable, as in the case of those used in Figs. 30 and 31.

Fig. 33. A Ford **triple gear being reamed,** correctly centered and at right angles; the clamp shown holds the center gear surface against the finished surface of the reaming fixture, thereby holding it in perfect alignment.

It is proper to use an arbor press for taking out or replacing bushings, as an even strain on all sides is applied. Many mechanics use a sledge hammer to force these bushings in place, with the result that they may batter over the ends of the bushings and, unless a self-centering reaming fixture is used, the reamer would have a tendency to be deflected off center, or in the direction of the least amount of metal to be removed, usually reaming out of alignment.

Bushings that are worn have no metal to ream out. Two or three years ago, there was put on the market a very powerful press for the purpose of compressing bushings, thereby making them tighter in the drums or triple gears, and also making the hole smaller. The low cost of bushings has prevented this idea from proving very successful, as the average mechanic prefers a new bushing. The cost of a press was nearly $200, a rather large investment for the ordinary repair shop for a tool doing only a limited amount of work, although it is a good investment if the business is large enough to warrant it.

Bushings should be renewed whenever they are loose and sloppy. If not renewed and properly fitted, as in the case of a planetary transmission, there will be excessive wear and noise due to imperfect meshing of the gear teeth in various positions of a revolution, with the result that the gears wear excessively and unevenly on the pitch diameters (or shoulders) of the gear, while, if held in perfect alignment by being properly fitted, they must wear evenly, as originally designed. Gears which have been allowed to become loose and sloppy on the bearings will be rounded off toward the end of the teeth, and in reality there is no special bearing surface on the gear with worn teeth.

---

[1] On the later cars the "clutch-spring thrust ring" is not used, its function being incorporated in the "clutch-spring support," the inner end of which is contracted and has four small lugs for the reception of the "thrust-ring pin."

REAR AXLE AND PARTS

The axle housing is made in two parts (Fig. 39). The later types of rear axle housings are much stronger than those made in earlier years.

Drive shaft and housing (Fig. 35): The housing or tubing encloses the drive shaft and also takes the torque or twist off the rear axle, when the car is being started or stopped, that is, in connection with the radius rods. This sometimes causes the tube to break near the rear axle.

BRAKE ROD
BRAKE ROD
LOOSEN NUTS TO REMOVE DRIVE SHAFT
POINT WHICH OCCASIONALLY BREAKS
IRON BRAKE
LOOSEN NUTS ALL AROUND TO REMOVE AXLE HOUSING

Fig. 34. Rear axle assembly.

Drive shaft and its bearings (Fig. 36): There is a roller bearing to support the shaft and pinion, and a ball-thrust bearing above the roller bearing to take the thrust of the pinion against the drive gear.

The entire rear axle and drive shaft, shown in Fig. 34, must be removed when repairs are to be made to the differential, or the drive gears, or when new axle shaft is installed. The Ford rear axle is a "plain live" type of axle, see page 15.

To test for wear or play in the rear-axle drive system, jack up one of the rear wheels and notice if the rear wheel can be turned 4" or more. If so, it is likely that there is wear in the rear-axle gears, or in the universal joint, or both. They must be replaced. While working around the universal joint, **tighten all nuts** on the radius rod, front and rear.

To Remove Rear Axle

Jack up the car and remove the rear wheels. Take out the four bolts connecting the universal bolt cap to the transmission case. Then disconnect the brake rods. Remove the nuts holding the spring perches to the rear axle housing flanges. (It is sometimes easier to remove the shackles which connect the spring to the spring perch.) Raise the frame at rear, and remove entire axle. (See Fig. 34.)

Disconnecting Universal Joint

The two plugs from the top and bottom of the ball casting must be removed. Then turn the shaft until the pin comes opposite the hole. Drive out the pin and force the joint away from the shaft. (See Figs. 37 and 45.)

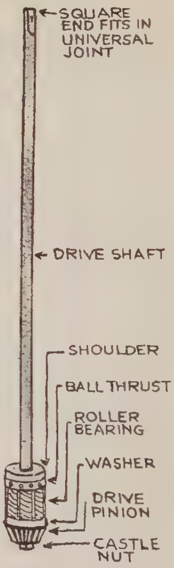

Fig. 36

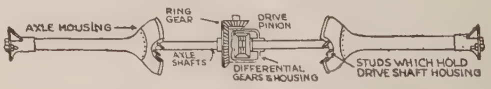
Fig. 35. Propeller or drive shaft enclosed in a housing or tube; Fig. 36. Propeller or drive shaft and parts; Fig. 37. Universal joint; Fig. 38. Brake drum on rear wheel.

To Disassemble Rear Axle

See Figs. 34 and 39. Disconnect the universal joint first, then the radius rods at the front end; then loosen the nuts on the studs holding the drive shaft to the rear axle (Fig. 34). Next, remove the nuts holding the axle housing together over the differential, as in Fig. 39. The axle housing in two parts is then removed from the axle shafts.



AXLE HOUSING
RING GEAR
DRIVE PINION
AXLE SHAFTS
DIFFERENTIAL GEARS & HOUSING
STUDS WHICH HOLD DRIVE SHAFT HOUSING

Fig. 39. Axle shafts, axle housings, and differential.

To Remove Axle Shafts

Follow the plan in the preceding paragraph, and as in Figs. 34 and 39. Take the inner part of the differential casing apart, by removing the bolts which hold the two halves together as in Fig. 40, and draw axle shaft through casing at the center.

When replacing the axle shaft, be sure the rear wheels are firmly wedged on at the outer end, and that the key is in proper position. With a new car the hub caps should be removed and the lock nut tightened. In fact, it is essential that the rear wheels be kept tight.

If the rear axle or wheel is sprung by skidding or striking a curb, or if the axle shaft is bent, replace it.

Removing Drive Pinion

The pinion end of the drive shaft, to which the pinion is attached, is tapered to fit the pinion tapered hole which is keyed on to the shaft, and then is additionally secured by a cotter-pinned "castellated" nut. Remove the castle nut, and drive the pinion off (Figs. 35 and 36).

No adjustment is provided. Fit new parts if worn.

The Differential

There is no adjustment on the Ford differential between the pinion and drive gear. New parts are usually fitted.

Removing differential gears: The gears are keyed on to the axle shafts, and are held in position by a ring or split washer, which is in two halves and fits in a groove in the rear axle shaft (Fig. 40).

Force them down on the shaft, away from the end to which they are secured; drive out the two halves of the ring in the grooves in the shaft with a screwdriver or chisel; then the gears can be forced off the end of the shafts.

Fig. 40. Differential, drive pinion, and axle shafts.

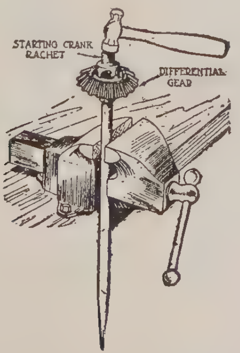

Fig. 41. **Removing the differential gear from the axle shaft.**

One method for doing this is shown in Fig. 41. The Ford differential gears can be removed from the shafts by placing an old starting-crank ratchet in the face of the gear, and driving it with a hammer till the gear is below the half-moon key. The key is then removed and the gear driven off.

Rear Wheels

The rear wheels are fitted with pressed-steel brake drums to which the emergency or hand brake operates. See Figs. 42, 34, and 38.

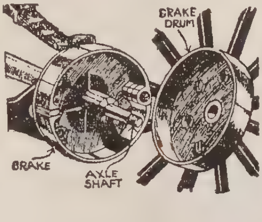

Fig. 42

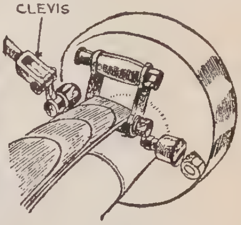

Fig. 43

To remove rear wheels, take off the hub cap, remove the cotter pin, unscrew the nut, and with a wheel puller remove the wheel from the tapered shaft to which it is locked with a key.

Hand Brakes

The cast-iron brake shoes will wear if used very much. This brake is usually used for holding the car when at rest on an incline, and not for slowing down the car.

Brake shoes, lined with asbestos fabric can be obtained from accessory dealers, and will last longer than plain cast-iron shoes.

To replace these brake shoes, (1) remove the rear wheels; (2) unscrew the nut and bolt on which the brake shoes are pivoted to the axle housing. The brake shoes can now be pulled off.

Put the springs in place on the new brake shoes; then place the open ends of the brake shoes over the cams, and swing the brake shoes into place.

Replace the wheels, and tighten the axle-shaft nuts securely, before putting the cotter pins in place.

Equalize the rear hub brakes, by removing the cotter pins and pulling out the clevis pins (see Fig. 43), and then turning the clevises on the brake-connecting rods until the two brakes grip equally. Be sure that the clevises catch enough threads on the brake rods to give strength.

Universal Joint and Shaft Bushing

The universal joint and the driving shaft front bushing (Fig. 44): When this bushing becomes worn (which will take a long time, if the grease cup is turned regularly), it will be necessary to have the new bushing forced in in the shop, and then reamed to fit the axle shaft.

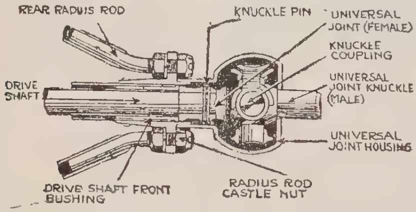

Fig. 44. The universal joint and parts.

Grease Leaks from Rear Axle

Grease leaks from the rear axle: These are the result of too much grease. One and a half pounds of grease is plenty, but a small amount should be added every thousand miles. See also page 1085.

Another reason for the leakage is, that in this construction Hyatt roller bearings are used, which tend to permit leakage of fluid or semi-fluid lubricants. The ring gear (or main differential gear) takes up too great a quantity and distributes it to the shafts. The centrifugal action of these shafts carries the lubricant to the outer end, and **if the felt washers are not in first-class condition,** the grease works out to the brake drums.

Worn thrust washers (T) (Fig. 40) allow the axle shafts and differential to shift from side to side and pump the grease out. This usually causes the grease to appear around the left wheel first, as that wheel is nearer the drive gear.

Worn thrust washers will cause the gears to grind. The noise will change as the car turns corners to right or left, and the weight of the car is shifted from side to side.

Fig. 45. **Remedying excess of oil leakage out of wheel bearings:** The oil from the transmission works down the drive shaft, through the universal joint, through the differential, out at the axle ends, causing an excess of oil on the brakes.

To overcome this, place a felt washer at **(F).** (Note the Ford stock numbers on these felt washers.) Then place steel washers (see illustration for size), as shown in the illustration.

To put these washers in place, remove the rear axle and rear half of the universal joint, then remove the front universal cover ball-cap cover. Put the felt and metal washer on, as shown, by placing them over the transmission shaft. Then put No. 2829 washer on after the cover is removed. Note the pin which will hold the washers in place. The washer 2510B and steel washer are easily applied when the universal joint is apart. Reassemble carefully.

Worn thrust washers require that the rear axle be removed from the car and taken apart before new washers can be inserted. Ball-bearing thrust washers are now made for Ford rear axles, and it is claimed that they wear longer. They should give less friction, and should therefore be useful for speedsters and racing.

The felt washers become worn and hard with use. They can be replaced—after removing the wheels—without taking the axle system off the car.

Two felt washers should be pushed on the axle shaft near the roller bearing next to the differential. A third felt washer should be placed near the outside end of the axle shaft, just inside of the outer roller bearing. These felt washers are cheap, and easily replaced, and, if only one pound of grease is used, will usually cure the rear-axle grease leakage.

If light grease or oil is used it will leak out rapidly. If the grease is too stiff and heavy, the gears will simply cut a groove through the grease and the bearings will not be lubricated. Mobilubricant is often used for Ford rear axles, as also Kaoga No. 2.

A Special Transmission

A four-speed transmission is made for Fords by specialty concerns. One concern supplying these is the Laurel Motors Corpn., Anderson, Ind.

Gear Ratios and Special Gears

The standard ratio is 3 7/11 to 1 on high gear or direct drive. Changes can be made by purchasing the differential ring gear and drive pinion (Fig. 46) from Laurel Motors Corpn., Anderson, Ind., or from Detroit Radiator Specialty Co., Detroit, Mich., or from Fulton-Houston Co., 1146 S. Michigan Ave., Chicago. It is necessary to change both gears.

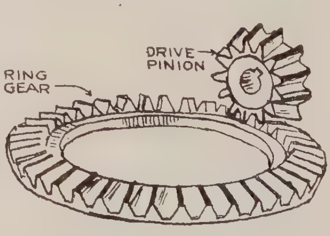

Fig. 46. Special gears for Ford rear axle.

For racing use 2 4/7 to 1; **for fast roadsters** use 2¾ to 1; **for general use** for level country, use 3 to 1; **for general use** in average country, use 3 7/11 to 1; **for trucks,** use 4 to 1, or 4.2 to 1.

For racing on dirt tracks, where a quick pick up is required, the 3 to 1 is recommended. The 2¾ to 1 and 3 to 1 are interchangeable. The number of teeth are as follows for various ratios:

2¾ to 1; gear 36 teeth, pinion 13.
3 to 1; gear 39 teeth, pinion 13.
3 7/11 to 1; gear 40 teeth, pinion 11.
4 to 1; gear 40 teeth, pinion 10.

Average speeds: 2¾ to 1; 60 to 65 m.p.h.; 3 to 1, 50 to 60 m.p.h.; 4 to 1, varies according to weight; average 25 to 35 m.p.h.

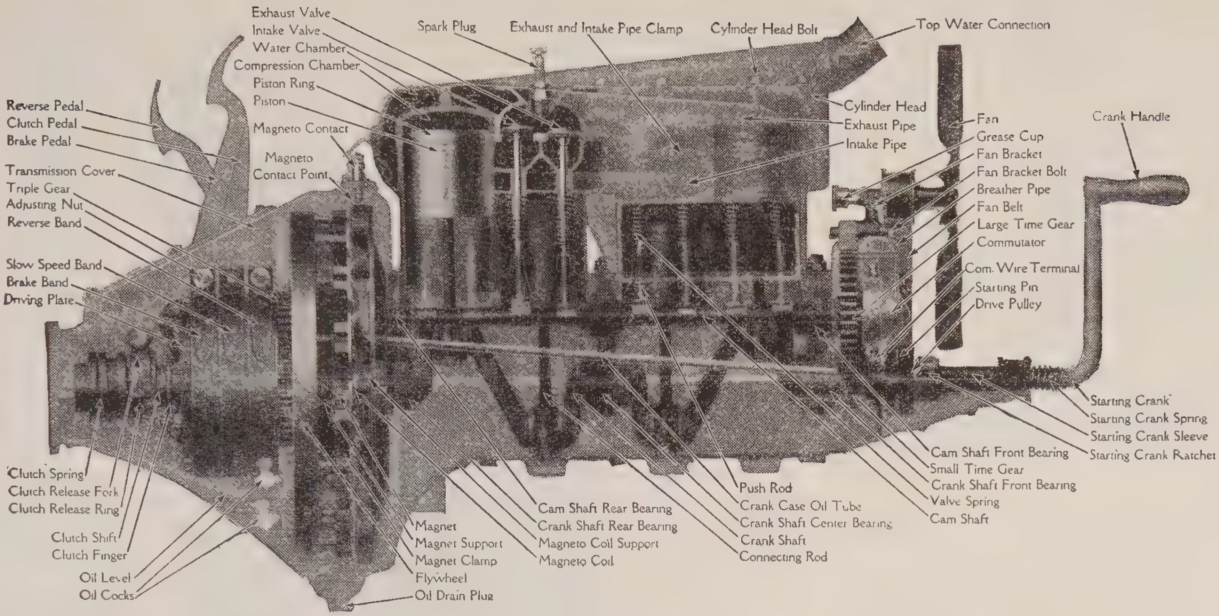

Fig. 47. Ford power plant, consisting of engine, transmission with clutch, and magneto in one unit, thus termed a **"single-unit power plant,"** as used on the model "T" Ford car and truck.

Specifications of Ford Engine

Engine: 4-cylinder, L-head type, with mechanically operated valves on the side. Bore $3\frac{3}{4}''$; stroke $4''$; $22\frac{1}{2}$ h.p. Cylinders are "in block" type.

The cooling is by means of thermo-syphon circulation.

Ignition: Source of electric supply is an inductor type of magneto, one part being attached to the flywheel and the other part stationary. The current is carried to a commutator, thence to four high-tension coils, thence to the spark plugs. (The Ford electric starting and lighting system is explained farther on.)

Lubrication: Gravity and splash. The flywheel, in revolving, picks up the oil and throws it by centrifugal force into the catch basin; from here it is led by $\frac{3}{8}''$ copper piping (the crank-case oil tube as shown above) to the timing gears and then to the oil splash trough under the front cylinder.

Location of valves: The front valve to the left of the fan, is No. 1 cylinder exhaust; then No. 1, inlet; then No. 2, inlet, No. 2, exhaust; No. 3 exhaust is next, then No. 3 inlet; then No. 4 inlet and then No. 4 exhaust. Note that the exhaust valves are next to the water jackets and nearest to the port openings, where the cooling action is most effective.

Gasoline feed system is gravity.

Carburetion: The Holley model "G," and sometimes Kingston model "Y" and "L-4."

FORD POWER PLANT; INTERNAL AND EXTERNAL PARTS

Internal Parts of the Ford Power Plant

By referring to Figs. 47, 48, and 49, the complete **internal construction of the Ford engine** will be made clear, and will be found fully explained.

Engine: Note in Figs. 48 and 49 that there are four pistons. The crank shaft is of the 180° type. When pistons Nos. 1 and 4 are up, Nos. 2 and 3 are down.

The Ford **engine fires** 1, 2, 4, 3—that is, if, say, No. 1 was starting down on the firing stroke, No. 2 would be coming up on compression and would fire next; No. 4 would be going down on suction, because it would fire after No. 2; No. 3 would be coming up on the exhaust (see table, Fig. 49).

Cam-shaft speed: The cam shaft runs at half the speed of the crank shaft, because the cam-shaft gear is twice the size of the crank-shaft gear (see timing gear Fig. 48; note the small gear on the end of the crank shaft and the larger cam gear on the end of the cam shaft).

The cam-shaft gear has 42 teeth and is 5⅓″ in diameter. The **crank-shaft gear** has 21 teeth, and is 2 2/3″ in diameter.

Transmission: Of the planetary type. It gives two speeds forward and one reverse. When driving on high speed, the drive is direct and the entire transmission revolves with the drive shaft. When running on low speed, the gears inside of the low-speed part of the transmission are in action; the same when reversing.

The transmission is attached to the end of the crank shaft, and is enclosed in a housing which covers transmission, flywheel, and magneto.

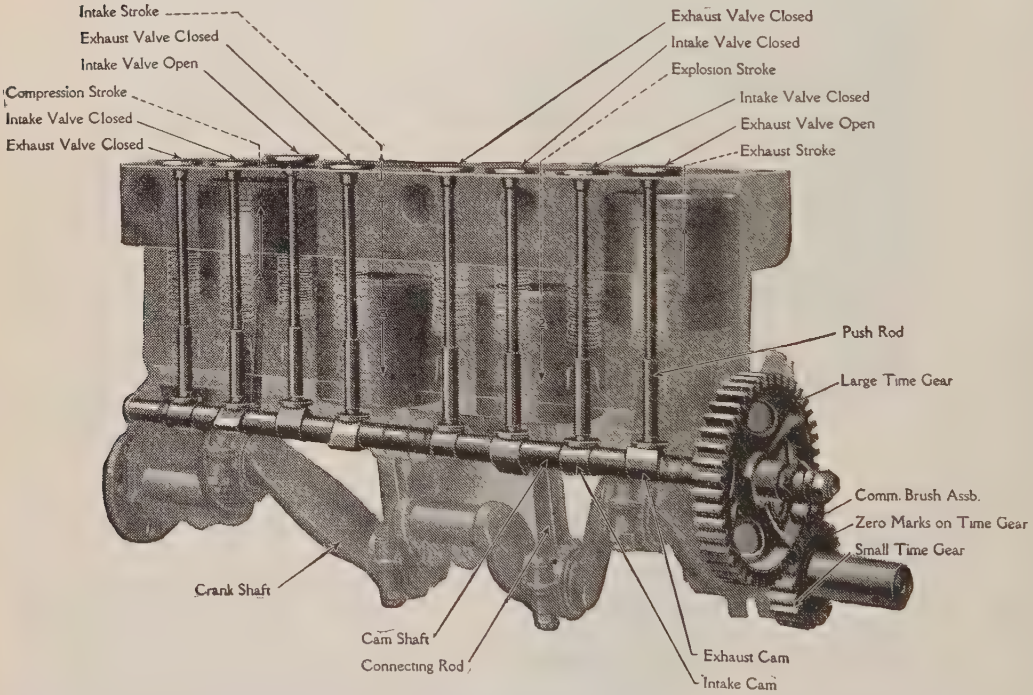

Fig. 48. **A view of the relation of the Ford crank shaft and small timing gear** which drives the cam shaft through the large timing gear, also the cam shaft, cams, and valves. As the large timing gear is twice the size of the small driving gear, **the** cam shaft will, of course, revolve at one-half the speed of the crank shaft.

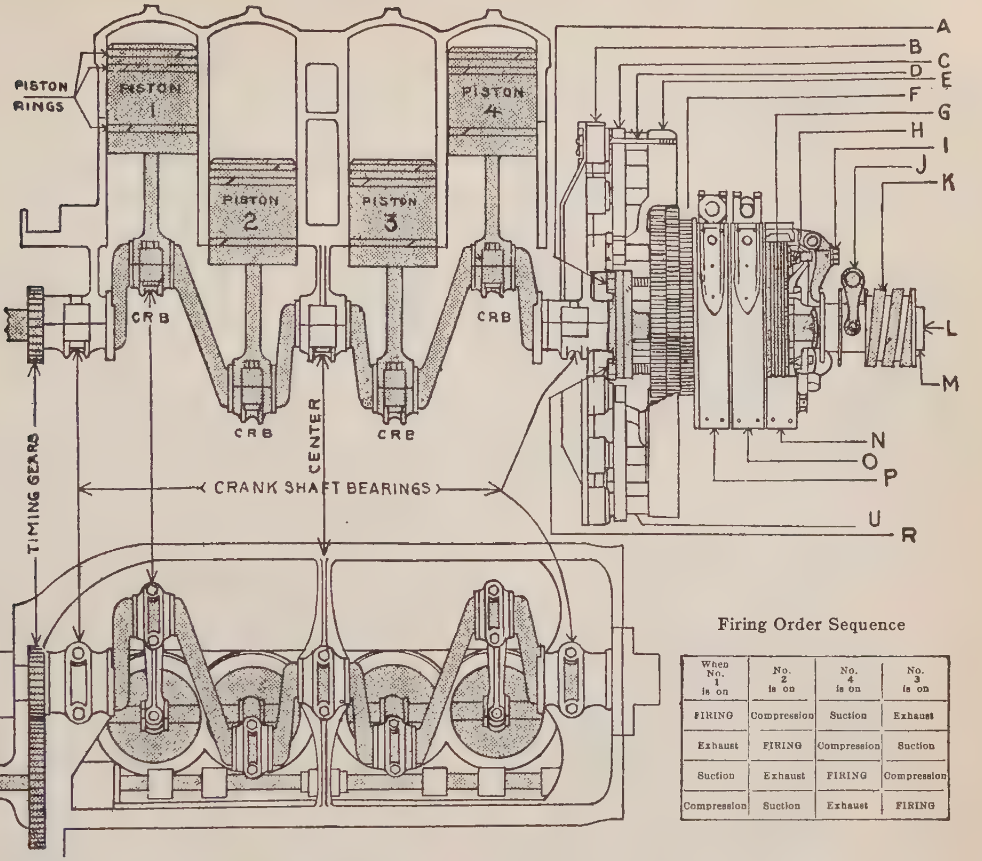
The firing order is 1, 2, 4, 3. No. 1 cylinder is next to the gears, or the front of the engine. **No. 2 piston is going down** (see arrow point) **on the explosion stroke.** Note that the nose of the cam does not raise either of the valves, therefore the intake and exhaust valves are closed.

No. 4 piston is almost at top of its compression stroke and will be the next cylinder to fire, and the piston will then go down on the explosion stroke. Note that both valves are closed.

No. 3 piston is going down on the intake stroke, drawing in a charge of gas, as the inlet valve is open, but the exhaust valve is closed. The piston of No. 3 will go up on the compression stroke, at which time the inlet valve will be closed and will fire after No. 4.

No. 1 has almost completed its exhaust stroke. The exhaust valve is open. The intake valve is closed. Immediately that the exhaust valve closes, which is exactly on top, then the inlet valve will open and it will go down on the intake stroke next, then on the compression stroke up, then on the explosion stroke. **Therefore No. 1 will fire after No. 3.**



Firing Order Sequence

When No. 1 is on	No. 2 is on	No. 4 is on	No. 3 is on
FIRING	Compression	Suction	Exhaust
Exhaust	FIRING	Compression	Suction
Suction	Exhaust	FIRING	Compression
Compression	Suction	Exhaust	FIRING

Fig. 49. **View of the Ford engine, explaining the firing order and the location and names of parts as follows:** (A) Flange on the end of the crank shaft, bolted to the flywheel. (B) Magneto coils or spools, of which there are sixteen. They remain stationary. (C) Magnets on the flywheel, of which there are also sixteen. They revolve with the flywheel. (D) Bolts supporting the magnets. (E) Flywheel, bolted to the flange on the crank shaft. (F) Planetary gears, called the "sun and planet" type. (G) Clutch disks. (H) Ring which presses against the clutch disks when the fingers are pressed on by yoke (J), which causes the clutch adjusting screw (I) to press against ring (H), thereby pressing the clutch disk plates (G) together, which then causes the drive shaft (L) to transmit power through the drive shaft to the rear axle. (I) Adjusting screw for pressure of the finger against the ring and clutch. There are three of these and three fingers. (J) Yoke which throws the clutch "in" and "out" by movement of the side hand lever (Fig. 27). (K) Spring which forces the collar against the fingers. (L) Transmission shaft connecting with the universal joint, thence to the drive shaft. (M) Collar supporting the thrust of the rear of the spring. (N) Transmission brake band, applied by movement of the foot lever, marked (B) (Fig. 27). (O) Slow-speed band applied by the foot lever marked (C). The same lever operates the clutch. (P) Reverse band applied by the foot lever, marked (R). **Note that in Fig. 49** there are only four cams shown on the cam shaft. There are eight cams, as in Fig. 48. (Error in drawing.)

Removing the Ford Power Plant

1. Remove the hood.
2. Drain the radiator.
3. Loosen the bolts holding the top hose connection.
4. Loosen the bolts holding the side hose connection to the cylinder block.
5. Loosen the radiator-to-dash stay rod.
6. Remove the nuts and washers from the two bolts holding the radiator to the chassis.
7. Remove the radiator.
8. Loosen the cap screw holding the commutator. Place the commutator case and wires to one side.
9. Remove the spark plug and magneto wires.
10. Remove the spark plugs.
11. Remove the cylinder head. (This makes the engine lighter and easier to lift.)
12. Remove the four bolts holding the universal ball cover.
13. Turn off the gasoline and disconnect the feed pipe from the carburetor.
14. Remove the nuts from the studs holding the inlet and exhaust manifolds.
15. Take off the inlet manifold, with the carburetor attached.
16. Take off the exhaust manifold, with the exhaust pipe complete.
17. Remove the two bolts holding the pans to each side of the base, and knock the pans down out of the way.
18. Loosen the nuts holding arm (A) (Fig. 10, page 1086) on the lower end of the steering post.
19. Remove the three bolts holding the steering column to the chassis.
20. Loosen the dashboard, and pull the dash and steering column up out of way. (Note. It is not necessary to loosen the dash or steering gear on 1917 and later cars. The engine is brought forward until clear of dash; then lifted up to the right, to clear the steering post.)
21. Remove the nuts from the front radius-rod ball joint (see Fig. 12, page 1086).
22. Loosen and remove the bolts holding the engine to the frame at the front end.
23. Loosen and remove the bolts which hold the side crank-case arms to the frame, and then the power plant can be lifted out.

External Parts of the Ford Power Plant

The illustrations, Figs. 47, 48, and 49, on preceding pages gave internal views of the Ford power plant. The following illustrations (Figs. 50, 51, 52, and 53) show the **external construction** and the location of parts.

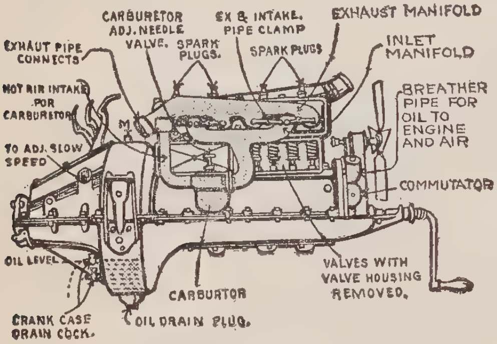


Fig. 50. **Right side of Ford model "T" unit power plant.** Showing inlet and exhaust manifold and valves.

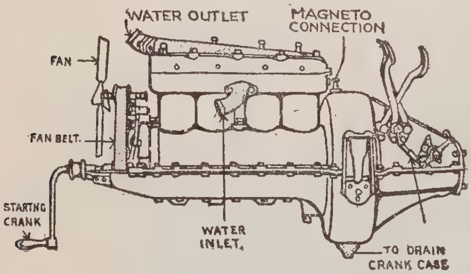

Fig. 51. **Left side.** Showing cooling water inlet and outlet. Note cylinders are "in-block" a typical unit power plant.

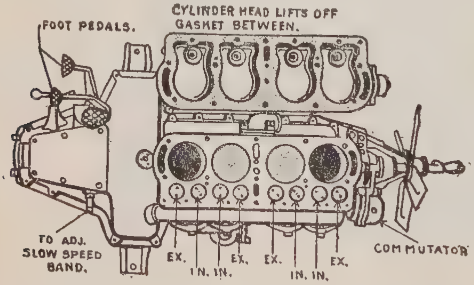

Fig. 52. **Top view.** Cylinder head removed showing cylinder bores, pistons, and heads of valves in their seat. Note which are exhaust and which are inlet valves.

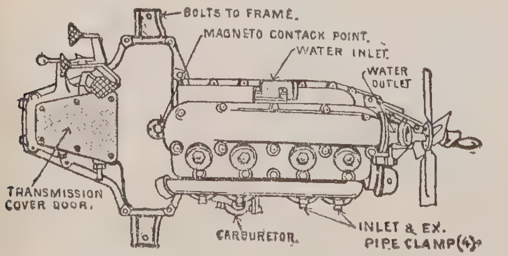

Fig. 53. **The cylinder head is detachable** and can be removed by taking off fifteen 7/16" x 2 9/16" cap screws on top of the cylinder. Underneath the head there is a gasket.

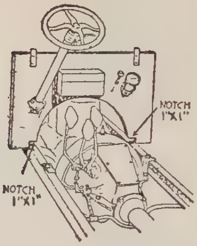

Fig. 54. To remove the Ford engine from the frame without raising the body from the frame, take a hacksaw and cut out a square 1" by 1" on each side of the dash. (*Motor World.*)

Ford Pistons and Rings

The subjects of Ford pistons and rings are treated elsewhere in this book.

See pages 811, 812 for "Questions and Answers on Ford pistons," also "Measurements of Ford pistons," "Piston replacement," and "Ford piston rings." See also page 823 for "Reboring Ford cylinders," and page 812 for "Ford oversize pistons and rings."

"Running in" the Engine

After the engine and car have been overhauled, new rings fitted, etc., it is a good plan to jack up the rear wheels, in the manner shown in Fig. 55, and to put about 1¼ gallons of lubricating oil in the crank case. Put water hose in the radiator and run the engine for several hours in order to work the rings and bearings "in." Note that when "running in" an engine, the water should be kept running constantly.

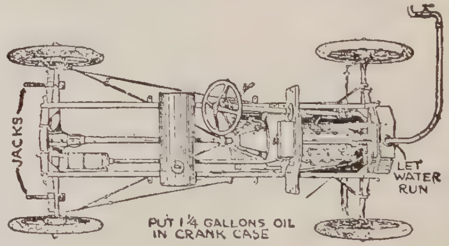

Fig. 55

When doing this work, the engine is usually out of the frame of car. Therefore another plan would be to place the engine on a stand made for the purpose, and to run the engine from a belt from the line shaft. This is a suggestion for a repair shop with considerable work. See page 789.

Note on page 785 that there are different methods described for fitting main bearings to the crank shaft as follows:

1. By spotting-in and scraping.
2. By boring, then reaming, then spotting-in and scraping, then running-in in oil.
3. By boring, reaming and burning-in, then running-in in oil.
4. By boring, then reaming, then running-in in oil.

Note on pages 821, 817 that there are different methods described for enlarging cylinders and fitting oversize pistons, as follows:

1. By boring.
2. By reaming.
3. By lapping.
4. By grinding.

COMPRESSION AND THE VALVES

If the compression is poor, and the pistons and rings fit well, the valves may need grinding or adjusting. The compression can be tested when the engine is warm, by pulling up slowly on the starting crank. The compression should be springy and elastic, but not as lively as that of other cars, on account of the drag and friction in the Ford transmission. See pages 766, 765, "Testing compression."

Removing Valves for Grinding

Drain the radiator. Remove the cylinder head and the valve covers on the right side of the engine. Use the valve-lifting tool (Fig. 35, page 770) to compress the valve springs, and pull the pins out of the ends of the valve stems. The valves can then be pulled out.

Valve Grinding

This subject is fully dealt with elsewhere. See pages 56, 57, 770: "Valve grinding."

When the valve seat is worn badly or seamed, it is then advisable to have it reseated with a valve-seating tool. Care should be exercised against making too deep a cut, otherwise the retiming of the valve will be necessary. See pages 773, 57; "Reseating valve seats."

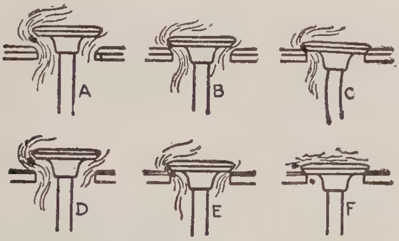

Fig. 56. **An ideal valve seat is a narrow edge,** as it is more easily ground and will last longer than a wide one. The illustrations show the action of the valve on a piece of carbon which might locate on the seat. **A wide seat holds the carbon,** which will soon burn and warp the valve, while a **narrow seat** cuts the carbon, keeping the seats clean. (A) grain of carbon passing through exhaust valve with wide seat; (B) the exhaust valve with a wide edge has just closed, the grain of carbon lodging between valve and seat; (C) the exhaust valve with a wide edge is closed, and the grain of carbon warps the valve and stem. (D) grain of carbon passing through the exhaust valve with a narrow seat. (E) exhaust valve with a narrow edge has just closed, the grain of carbon trying to lodge between valve and seat; (F) narrow edge of valve seat cuts grain of carbon, one part passing into the exhaust manifold, the other remaining in the combustion chamber to be burned during the next power stroke, or removed during the next exhaust stroke.

Oversize Valves and Worn Valve Guides

The play between the valve stem and the valve guide may be checked by placing the valve in the valve guide of the cylinder block, raising it about ¼″ and moving it from side to side. If there is very little play and the valve stem shows considerable wear, try a new valve with a standard stem. If this does not take up the play sufficiently, ream the valve guide for a 1/64″ oversize valve stem (Fig. 57) with a 21/64″ reamer (Fig. 58).

Fig. 57

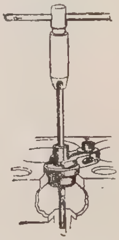

Fig. 58

Fig. 57. For valve 1/64″ oversize. See page 773; "Ford valves" for sizes of standard valves.

Fig. 58. A valve-guide reamer. When reaming the valve guides it is necessary to ream true; therefore a guide is necessary. The guide is shown clamped to the cylinder head. The reamer is then passed through the guide and turned by a hand tap wrench.

CHECKING VALVE TIMING BY PISTON TRAVEL

When valves are ground, the engine should be checked for valve timing.

The method of determining when the valves open and close is as follows: With the spring assembled, close the valve. When it is closed, hold it with the fingers,

Twist back and forth on the head while someone cranks the engine slowly. The instant the valve will turn, it has started to open. In the same way the valve may be closed, the valve turning until it has seated.

Another way to check the opening and closing is to insert a .001″, or less, feeler, or a thin piece of paper, between the stem and push rod. The instant the feeler will not move the valve has opened. The instant it will move after being held tight the valve has closed.

On a new engine, the valves in No. 1 cylinder may be checked by the **piston travel,** and the rest of the valves may be checked by the **air gap clearance** between the end of the valve stem and the tappet rod. This gap should be between .022″ to .028″, the distance being measured with a feeler or thickness gauge.

On the 1913 and later model "T" Ford engines, the valves open and close as in Figs. 59, 60, 61, and 62. (See next page.)

Prior to 1913, the inlet opened 7/64″ past top and closed ⅜″ past bottom. The exhaust opened ⅜″ before bottom, and closed 1/64″ past top. These figures may vary slightly on different engines, especially on old engines with worn parts.

The intake valve should be timed accurately on the opening, and the exhaust should be timed on the closing, since, in an engine whose cam shaft may be worn, it is not always possible to have both the opening and closing check accurately with the figures given.

On old engines, the valve tappet rods (also called push rods) become worn in the center (Fig. 63) (see next page) owing to the continual tapping against the valve stem.

If the engine were timed by the gap alone, it might be considerably out of time, as the feelers (thickness gauge) would bridge the actual point of contact on the tappet rod.

All valves on a worn engine should therefore be timed or checked by the **piston travel.**

Inlet valve opens 1/16 in. (piston travel) after top center on 1st stroke (as piston is 5/16 in. above cyl. when at top — it is now ¼ in. above.)

Inlet valve closes 9/16 in. after bottom center on 2d stroke. Measurement from top of cyl. to top of piston being 3⅛"

Exhaust valve opens 5/16 in. before bottom center on 3d stroke. Measurement from top of cyl. to top of piston being 3⅜"

Exhaust valve closes on top center of 4th stroke.

Note when piston is at top of stroke it is 5/16 in. above cyl. casting.

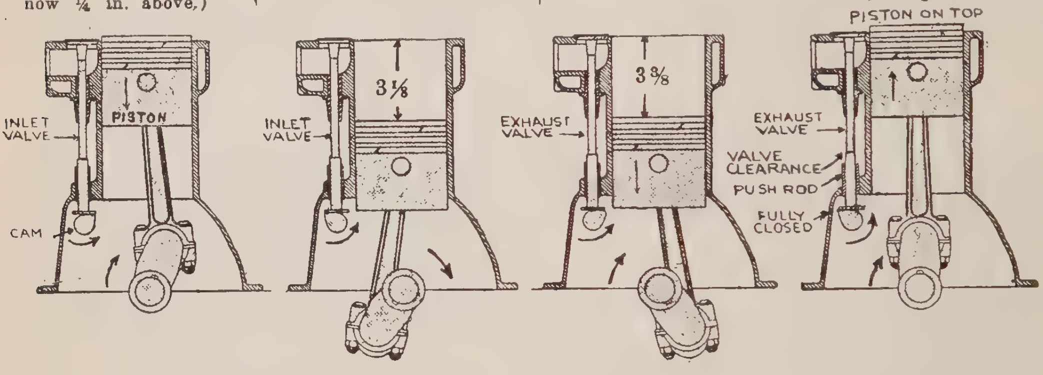

Fig. 59 Fig. 60 Fig. 61 Fig. 62

Figs. 59 to 62. **Illustrating the positions of the pistons when the valves open and close.** A method of checking the valve timing by the **piston travel.**

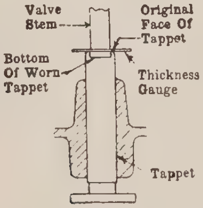

Fig. 63. Showing how the tappet rod becomes worn in time.

It is possible to tell if the tappet rods are worn by removing the springs and feeling the top of the tappet rod. New rods are straight across the face. Worn rods have a depression in the center of the face, as in Fig. 63.

Worn tappet-rod guides cannot be replaced on the Ford engine. The remedy is to ream out the worn guide and to install an **oversize** tappet rod. Worn guides cause a great deal of noise, as each time the cam strikes the lower end of the tappet it slaps the tappet against the worn guide.

VALVE TIMING AND VALVE CLEARANCE

Valve Timing

The method of accurate valve timing on a Ford model "T" engine is to time the valves by the **piston travel.** The measurements are given in Figs. 59 to 62.

As the valves are properly timed at the factory it is not necessary to retime them **unless the cam shaft, time gears, or valves were removed in overhauling.**

In this case, the time gears must be meshed properly, as follows: Place the top of the piston of No. 1 cylinder within approximately ⅝" of the top of the cylinder block by turning the crank shaft in the direction of rotation.

Turn the cam shaft (with gears out of mesh), until the exhaust cam is at a point where the exhaust valve is near closing (Fig. 64); the exhaust cam should point away from the (0) mark on the camshaft and crank-shaft gear, which is directly opposite or in line with the center of the point or nose of the cam. At this point, the tooth of the crank-shaft gear, indicated by the (0) mark, will mesh **between** the two teeth of the cam-shaft gear (large gear) at the (0) mark.

After meshing the gears in this manner, the inlet valve of No. 1 cylinder should be closed and the exhaust valve open.

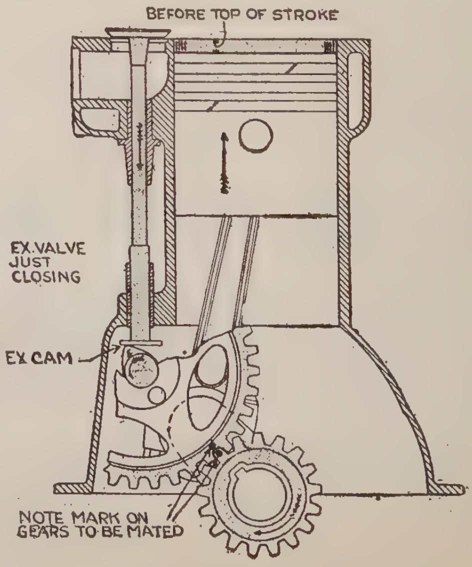

Fig. 64. **Meshing of timing gears by zero marks.**

When the gears are meshed as described, the exhaust valve of No. 1 cylinder (Fig. 64), is just at the point of closing, but is not fully closed; but by the time the piston reaches the top of its stroke the exhaust valve will be fully closed, as in Fig. 62.

When the gears are meshed as above with the zero marks together, the piston will be ¾″ from top dead center; or, in other words, since the piston is 5/16″ above the block when at top dead center, when the zero marks on the timing gears are together the top of the piston should be 7/16″ below the top of the cylinder block.

As the exhaust valve of No. 1 cylinder is just closing, as shown in Fig. 64, and will be closed just as soon as it completes its exhaust stroke, then No. 1 piston will start down on the **suction** stroke.

By referring to the table at the lower right-hand corner of Fig. 49, page 1101, it will be noted that when No. 1 piston starts down on the suction stroke, then No. 4 will be the next cylinder to **fire** (No. 4 will fire with the spark lever retarded when No. 1 is about ⅛″ down on the suction stroke). Therefore if No. 4 is the next to fire, the roller of the commutator should be set on No. 4 segment, or just ahead of the No. 4 segment, with the spark lever fully retarded (if the spark lever was fully advanced, the roller would be well on to the segment.)

Setting the commutator: There should be no difficulty in setting the commutator roller in the proper position on the cam shaft, as it is held in place by a retaining pin similar to a nail, and the pin can be inserted only when the hole in the roller lines up with the one in the shaft. As the hole in the cam shaft is not drilled clear through, there is only one place where the roller can be set, and the pin inserted.[1]

The retaining pin is held in place by a collar which fits over the head, and is in turn held by the lock nut on the end of the cam shaft. See page 1113 for the method of timing ignition.

If the cam-shaft gear is removed at any time from the shaft, in replacing the gear see that the dished side is out and that the first cam (exhaust cam) points in the opposite direction from the (0) mark on the cam-shaft time gear, as in Fig. 64.

To check valve timing, when the cam shaft or the gears have not been removed, first remove the cylinder head and check the inlet valve opening and exhaust valve closing of each cylinder by following the measurements in Figs. 59 to 62.

These measurements may not check accurately. If they are out to any great extent, see if the camshaft, bearings, push rods, or valves are worn. If not, and the gears are meshed correctly, then the variance may be in the manufacturing limit. See **that the valve clearance** is properly adjusted before checking the valve timing.

Spiral or helical tooth timing gears are now used.

Valve Springs

A weak valve spring can usually be detected by the following method: Remove the valve plate (Fig. 65) and insert a screw driver between the coils of the spring while the engine is running. If the extra tension thus produced causes the engine to pick up speed, the spring is weak and a new one should be replaced.

Valve springs consist of 11¼ coils of No. 104 music wire, complete spring is 2⅞ inches long and 31/32 inch outside diameter.

If the valves fail to seat properly, it may be due to weak or broken springs. Weak inlet springs would probably not affect the running of the engine, but weak exhaust valve springs cause uneven action, which is difficult to locate.

It will cause a lag in the engine due to the exhaust valve not closing instantly, and the result will be, a certain percentage of the charge under compression escapes, greatly reducing the force of the explosion.

Valve Clearance

The correct clearance between push rod and valve stem is .022″ to .028″. The gap should be measured, of course, when the cam point, or nose of the cam is not lifting the valve, but when the push rod is on the heel of the cam, that is, when the push rod is at the lowest point. The correct clearance is naturally half-way between these two measurements.

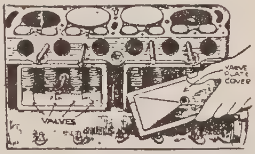

Fig. 65. Removal of valve cover to adjust clearance.

If clearance is greater, the valve will open late and close early, resulting in uneven running of the engine. In this case, **the push rod is worn or the valve stem is too short,** and a new valve should be substituted, and a push rod (tappet) also, if necessary. The old valve can be "drawn out" by peening the lower end to lengthen it, but this is not considered the best practice. Valve adjusters may be used, as shown in Fig. 66.

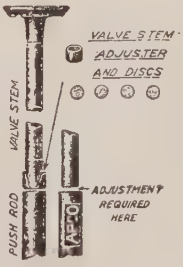

Fig. 66. **Valve clearance adjusters:** When the space between the end of the push rod and the end of the valve stem is more than 1/32″, a clicking noise is the result. As the Ford valve has no means of adjustment, it is remedied by either installing new valves and push rods or using adjusters as shown. (Apco Co., Providence, R.I.)

A reamer, 29/64″, is used to ream the push rod or tappet guides 1/64″ **oversize.**

If the clearance is less, the valve will open early and close late, or if there is no clearance at all, it will remain partially open all the time. In this case, the stem is **too long,** and a small amount of stock should be ground from the end of the valve stem.

When fitting new push rods, new valves should also be fitted.

When fitting new valves, they should be ground in. See page 770: "Grinding valves."

Valve clearance on Ford engine is non-adjustable.

---

[1] In the older models the hole in the cam shaft is drilled clear through. In this case, place the roller on the No. 4 segment, as directed above, and insert the retaining pin, paying no attention to the hole in the opposite side of the shaft.

CONNECTING-ROD BEARINGS

The connecting rod in the Ford engine is clamped tight to the wrist pin, and is termed the "oscillating type." See also page 795: "Adjusting connecting rods."

Loose connecting-rod bearings cause a rattle, or light knock, especially at light loads and high speeds. Heavier loads seem to steady the connecting rods.

Long wear, pounding due to carbon, a spark too far advanced, or forcing the engine to labor on high gear, as well as a lack or poor quality of oil, are the chief causes of loose connecting-rod bearings. If this condition continues, the crank shaft will eventually crystallize, and may break.

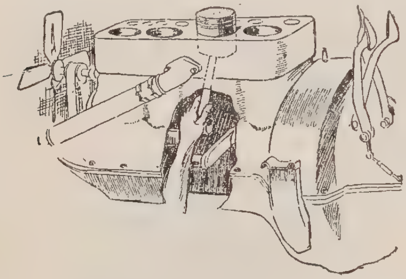

Fig. 67. **Removing the connecting rod and piston.** One method of getting at the piston is to take off the cylinder head, remove the cover from the bottom of the crank case, and, by reaching through this, remove the bolts holding the connecting-rod lower bearings in place. After the connecting-rod bearing caps are removed, the piston can be pushed up through the top of the cylinder.

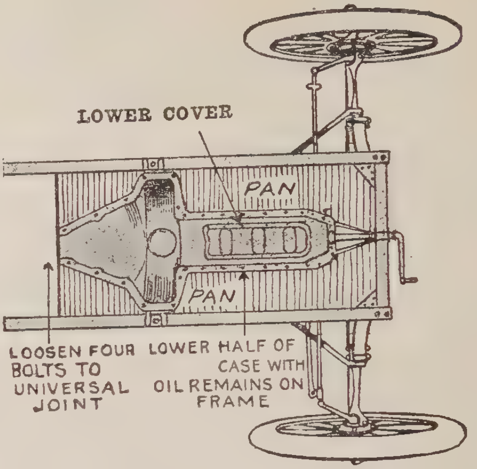
The method of removing the piston is clearly illustrated.

To remove the piston pin, loosen the connecting-rod clamp screw.

Adjusting Connecting-Rod Bearings

The connecting-rod bearings may be adjusted without taking out of the engine, as follows: (1) drain off the oil; (2) remove the crank-case lower cover plate on the bottom of the crank case, exposing the connecting rods; (3) punch or file a mark on one side of the bearing cap, so that it may be replaced in the same position; (4) remove the first connecting-rod bearing cap and draw-file the ends, just a little at a time; (5) replace the cap, being careful to see that the punch or file marks are on the correct side, and tighten the bolts until it fits the shaft snugly; (6) test the bearing for tightness by turning the engine over by the starting handle; (7) now loosen the bearing and proceed to fit the other bearings in the same manner; (8) after each bearing has been properly fitted and tested, tighten the cap bolts.

There is a possibility of getting the bearings too tight, and under such conditions the babbitt is liable to cut out quickly, unless the engine is run slowly at the start. After adjusting the bearings, jack up the rear wheels and let the engine run slowly for about two hours (keeping it well supplied with water and oil) before going out on the road.



LOWER COVER
PAN
PAN
LOOSEN FOUR BOLTS TO UNIVERSAL JOINT
LOWER HALF OF CASE WITH OIL REMAINS ON FRAME

Fig. 68. All parts of the Ford engine can be removed in one unit, and the **lower part or the oil pan can be left on the frame,** as it seldom needs to be removed.

To remove the lower crank-case cover, it is necessary to take out fourteen capscrews (5/16" x 7/16"). Be careful not to destroy the gasket, and watch for oil in pockets under the connecting rods. Note that the lower crank-case cover is the part to which the upper arrow points.

Removing No. 4 Connecting-Rod Cap

Bring the No. 4 connecting rod about half-way up on the up-stroke. Remove the cotter pin and nut from the right connecting-rod bolt. Now turn the crank shaft over, by means of the starting crank until the connecting-rod cap is about half-way down on the other side. Pull out the other cotter pin and remove the nut from the bolt. The Ford socket wrench No. 2322 can be used, if a couple of inches are cut off from the handle; or the Walden wrench No. 5810 is specially made to reach this nut, and is very useful for this purpose.

Be careful that the nuts and parts do not fall into the transmission case, and mark the connecting-rod cap with a center punch before taking it off, so that it can be replaced in exactly the same position.

It is a good plan to stuff a rag into the transmission case while removing or replacing connecting-rod nuts and cotter pins. If they are accidentally dropped, they may then be easily recovered. The rag used should be free from lint or grit.

When the connecting rods become worn, they may be returned, prepaid, to the nearest Ford agent or branch house for exchange at a price of $1.00 each to cover the cost of rebabbitting. It is not advisable for any owner or repair shop to attempt the rebabbitting of connecting rods or main bearings, for without a special jig in which to form the bearings, satisfactory results will not be obtained. The constant tapping of a loose connecting rod on the crank shaft will eventually produce crystallization of the steel, with the result of a broken crank shaft; and possibly other parts of the engine may be damaged.

CRANK-SHAFT MAIN BEARINGS;[1] CAM-SHAFT REMOVAL, ETC.

Crank-Shaft Main Bearings

Wear of the main bearings of the crank shaft will be evident by a rather heavy pound or thud, especially when the engine is pulling hard under a heavy load.

Wear of these main bearings may be due to long use; not enough, or poor quality of oil, allowing the engine to knock; carrying the spark too far advanced, or carbon in the cylinders; a sprung crank shaft; or failure to drain out the old oil regularly.

The rear main bearing carries the heaviest load and is usually the first to show signs of wear. This rear bearing supports the flywheel, the magneto, and one end of the transmission, in addition to supporting the crank shaft against the thrust of the pistons.

---

[1] See also pages 787, 789 on fitting Ford engine bearings.

Looseness in the rear main bearing may be detected by running the engine on No. 4 cylinder and having the throttle wide open. This will show up a loose main bearing.

The rear main bearing cannot be tightened without taking the engine out of the car, as explained under Fig. 69. The middle bearing can be tightened without taking the engine out of the car, but it seldom needs adjusting unless the other bearings need it also.

Unless the bearing is burned out or badly worn, the center and front bearing can be taken up by removing the bottom cover without removing the engine. Remove the cotter pins from the bolts between No. 2 and No. 3 cylinders, and while one man has a wrench on the nuts, another man beneath the car turns the bolts out. If there are shims, loosen the bolts just enough to pull the shims out with a pair of pliers. If there are no shims, remove the cap, and file. Be sure to mark the caps, if they are removed.

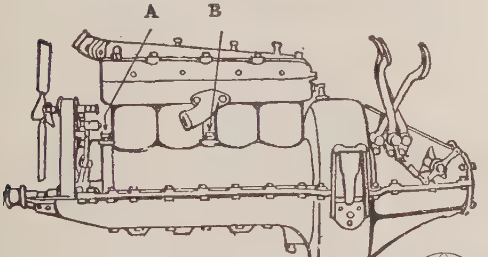


Fig. 69

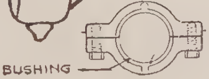

Fig. 70

Fig. 69. **To remove the center and front main bearing,** remove nuts at **(A)** and **(B)**, and draw the long crank-shaft bearing bolts (½" x 6 1/16" x 20 threads) out from the bottom, when the lower bearing caps can be removed. It is not necessary to remove the engine from the frame.

To remove the rear main bearing, it is necessary to remove the engine from the frame. If a special Ford wrench No. 1929 is used, one flywheel bolt, holding the flywheel to the end of the crank shaft (see Fig. 49, page 1101) can be removed without further dismantling; then remove the two bearing nuts from the lower part and the bearing cap will lift off.

To remove the cylinder head: Disconnect the water hose from the top plate, after first draining the radiator; disconnect the spark-plug wires. Remove the cap screws holding the head to the cylinders, and lift off. This can be done without removing the engine from the frame. (See also Fig. 52, page 1102.)

Fig. 70. Illustration showing the **main bearing cap** and **bearing bushing,** which is babbitt lined. Shims between the bearing cap and upper bearing not shown. The three main bearings on crankshaft are babbitted. On the old 1910 models, the upper halves of the main bearings were plain iron and not babbitted.

Adjusting Main Bearings[1]

First: Take the engine out of the car. Remove the crank case, transmission cover, cylinder head, pistons, connecting rods, transmission, and magneto coils. Remove the three babbitted caps and clean the bearing surfaces with gasoline. Prussian blue is then applied, or red lead, to the bearing surfaces of the crank shaft, which will enable one to determine whether a perfect bearing surface is obtained when fitting the caps.

Second: Put the rear cap in position first, and tighten it up as much as possible, being careful not to strip the bolt threads. The bearing, when properly fitted, will permit the moving crank shaft with one hand. If it cannot be turned with one hand, contact between the bearing is too close, and the cap requires shimming up, one or two thin shims usually being sufficient.

If the crank shaft moves too easily with one hand, the shims should be removed or the steel surface of the cap filed off, thereby causing it to set closer.

Third: After the cap has been removed, note whether the blue or red "spottings" indicate a full bearing the length of the cap. If "spottings" do not show a true bearing surface, the babbitt should be scraped and the cap refitted until it fits properly. (See Index under "Adjusting main bearings.")

Fourth: The rear cap can now be laid aside and the adjustment of the center bearing can be made in the same manner. The operation can be repeated with the front bearing.

Fifth: After you have obtained the proper adjustment of each bearing, the babbitt surface should be cleaned carefully and a little lubricating oil placed on the bearings and on the crank shaft; then draw the caps up as close as possible—making sure that the necessary shims are in place. There is no danger of getting the cap bolts too tight, as the shim under the cap and the oil between the bearing surfaces will prevent the metal being drawn in too close a contact. Put oil on the bearing surfaces, otherwise the babbitt is apt to cut out when the engine is started before the oil in the crank case can get into the bearing. When the crank case and transmission-cover on the engine are replaced, a new set of felt or cork gaskets should be fitted to prevent oil leaks.

Note. **If the upper main bearings are worn considerably,** and adjustment is made by drawing them up tight against the worn surface, by filing and fitting the bearing caps, this may cause the crank-shaft gear to mesh tighter with the cam-shaft gear, thus resulting in a singing noise in the gears.

Crank-Shaft End Play

As a result of wear by the end thrust on the outer end of the rear main bearing, this will in time cause sufficient play to permit the magnets to strike the magneto coils.

The remedy is a new main bearing; or, refer to this subject elsewhere; see page 786: "End play in main bearings."

To Remove Crank Shaft

First remove the connecting rods and the main bearings; disconnect the bolts holding the flywheel to the flange of the crank shaft, using the Ford special wrench No. 1929.

Removing the Cam Shaft

It is sometimes necessary to remove the cam shaft in order to install new push rods, or to replace worn cam-shaft bearings, as the bearings are sometimes the source of knocks that are difficult to locate.

It is a comparatively easy matter to remove the cam shaft when the engine is out of the car, but, contrary to the opinion of many owners of Ford cars, it is also fairly easy to remove the cam shaft without removing the engine.

---

[1] See also page 784 on "Adjusting Bearings."

Procedure for cam-shaft removal: Remove the pin which holds the fan-belt pulley on the crank shaft (see Fig. 71). Drive the fan-belt pulley forward. Remove the cap screws which hold the cylinder front cover to the cylinder block. Remove the commutator brush assembly, after driving out the pin which holds it to the cam shaft. Now the cylinder front cover can be removed. Next, remove the two cap screws in the side of the cylinder block which hold the cam-shaft bearings in place.

It may now be possible to pull out the cam shaft with its bearings, but if not, the plate on the lower part of the crank case should be removed, after the cap screws which hold this plate to the crank case have been taken out.

Then a drift, or brass bar can be used to drive the cam shaft out from below, holding the end of the brass bar against one of the cams and striking the other end of the bar with a hammer. Care should be taken not to punch a hole through the cast-iron cylinder block while doing this part of the work.

After the cam shaft has been removed, the push rods will drop down and can be removed through the opening in the bottom of the crank case. Be sure to remove all the push rods.

Installing New Push Rods (Tappet Rods)

Place the new push rods in the guides. Small holes, near the top of each push rod, will now be noticed. After putting the push rods in place, slip nails, or a piece of wire, through these holes, to keep them in position while the cam shaft is being replaced. Then the cam shaft and its bearings can be driven in, and the cap screws (which hold the bearings) tightened.

The marks on the small crank-shaft gear and on the large timing gear should be placed together, and the valves tested to make certain that the valves open and close at the proper time. Then the front cylinder cover plate should be replaced, and the timer brush assembly, and also the timer cover; then the fan-belt pulley and the starting-crank pin, and finally the fan belt. (*Fordowner.*)

Removing Starting-Crank Ratchet

Drive out the pin which passes through the starting crank and ratchet (see Fig. 71). Pull the starting crank forward and out of the ratchet. It may be necessary to support the crank by a block and to drive off the ratchet by means of a drift placed against the shoulder of the ratchet.

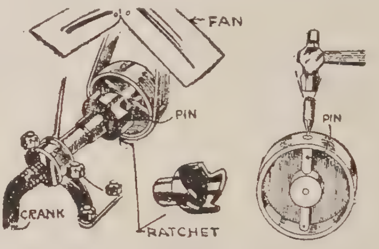

Fig. 71. Method of drawing out pin in fan-belt pulley with which the starting-crank ratchet engages.

Removing Fan Pulley

Remove the ratchet, as explained above. Drive out the pin in the fan-belt pulley, as shown in Fig. 71. Move the pulley forward off the crank shaft.

CAUSES OF ENGINE KNOCKS; CARBON; OVER-LUBRICATION

Causes of Engine Knocks

1. **Carbon** is the most frequent cause of engine knocks.
2. **The spark too far advanced** will waste power and cause a knock.
3. **Loose connecting-rod bearings** will cause knocks.
4. **Worn crank-shaft main bearings** cause knocks.
5. **Piston slap,** due to a loose piston, will cause knocks.
6. **Worn or broken piston rings** will cause a light knock.
7. **The piston striking the cylinder-head gasket.**
8. **Loose cam-shaft bearings.**
9. **Valve tappets out of adjustment,** or badly worn, will cause noise.

How to Distinguish Knocks

1. **The carbon knock** is a clear, hollow sound, most noticeable in climbing sharp grades, particularly when the engine is heated. It is also indicated by a sharp rap immediately on advancing the throttle.
2. **Too advanced a spark** will be indicated by a dull knock in the engine.
3. **The connecting-rod knock** sounds like the distant tapping of steel with a small hammer, and is readily distinguished when the car is allowed to run idly down grade, or upon speeding the car to twenty-five miles an hour; then, when suddenly closing the throttle, the tapping will be very distinct.
4. **The crank-shaft main bearing knock** can be distinguished when the car is going uphill, as a dull thud.
5. **The loose piston knock** is heard only upon suddenly opening the throttle, when the sound produced might be likened to a rattle. (See also pages 777, 460: "Engine knocks.")

Overheating of Engine

This subject is fully treated under the "Digest of Troubles," page 460, and under the discussion of the "Cooling" subject, page 152.

Water Pump for Ford Engine

Overheating of the engine as a result of long runs or where there are many hills to climb, or a tendency on the part of the radiator to steam, can be remedied in many instances by attaching a water pump which will more rapidly circulate the water in the cooling system.

The **Cluley water pump** for the Ford operates from a double-flanged pulley on crank shaft, and independent of the fan. There are several good features to this particular pump. It can easily be attached. (Address Cluley Auto Supply Co., Fullerton Bldg., St. Louis, Mo.)

Before and After Carbon Cleaning

First: Drain the water off by opening the pet cock at the bottom of the radiator; then disconnect the wires at the top of the engine and also the radiator connection attached to the radiator. Remove the fifteen cap screws which hold the cylinder head in place. Take off the cylinder head and, with a putty knife or screwdriver, scrape from the cylinder and piston heads the carbonized matter (as in Fig. 72), being careful to prevent the specks of carbon from getting into the cylinders or other openings.

If carbon gets into cylinder-head cap-screw holes, it might prevent the cap screws from drawing up the cylinder head tightly, or it might cause the cap screw to be broken off. To avoid this, put the cap screws back in the holes before removing the carbon.

In replacing the cylinder-head gasket, turn the engine over so that No. 1 and No. 4 pistons are at top center; place the gasket in position over the pistons and then put the cylinder head in place. Be sure to draw the cylinder head cap screws down evenly (i.e., give each one a few turns at a time); do not tighten them at one end before drawing them up at the other. See Fig. 66, page 733.

Removing Carbon

Carbon removal is most easily done with a putty knife, after the cylinder head has been removed.

The flexible putty knife follows the surface better than the stiff and narrow blade of a screwdriver.

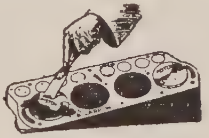

Fig. 72. Removing carbon.

Do not get the carbon in the openings into the water jacket. This would tend to impede the flow of the water and might cause overheating of the engine. The openings into the water jackets and the holes for the cylinder-head bolts can be plugged with wooden plugs, or pieces of cloth, until the scraping has been completed. (See also page 763.)

Over-Lubrication of Cylinders

When the spark plug is constantly oily or fouled and constantly missing, and an excess of smoke is emitted out of the exhaust, this indicates that too much oil is working past the piston rings, or at least that too much oil is passing into the combustion chamber from the crank case.

Causes of Over-Lubrication

1. The oil level in the crank case may be carried too high. It should not be above the upper petcock in the crank case. (See Fig. 3, page 1083.)
2. The front spring may be sagged. If the front end of the engine is lower than the rear, the oil will not drain back into the sump until there is too much oil under the front piston. A heavier pad between the front spring and the frame will level the engine.
3. The cylinder bore may be worn oval by the side thrust of the connecting rods on the pistons, or the cylinder walls may be grooved and scored. All four cylinders should be rebored at the same time, and fitted with oversize pistons.
4. The points of the spark plugs may be too close together, thus allowing oil to short-circuit them too easily. Bend the points slightly farther apart (not over 1/32″), and bend the side electrode upward, so that the oil will drain off to one side and not collect between the points.
5. For leaky piston rings see pages 828 and 815.

A broken piston ring will be indicated by a click or light knock, by loss of compression, and by smoke from the oil filler pipe or crank-case breather.

Well-fitted pistons and rings will almost invariably cure trouble caused by over-lubrication of the cylinder. If it does not, and none of the foregoing is the cause, then the engine is afflicted with what is termed "piston pumping oil," which is explained on page 168, and the remedy is to doctor the rings and piston.

GASKETS FOR FORD POWER PLANT

Cylinder-Head Gaskets

There is a copper-asbestos gasket between the cylinder head and the cylinder block. There is practically no water pressure on this gasket, but there is a cylinder pressure, of from 60 lbs. on the compression stroke, to 250 lbs. on the firing stroke, which must be withstood by the gasket.

As the cylinder-head bolts contract when cool, and expand when hot, there are varying degrees of pressure on the gasket; so the cylinder head must be securely seated to keep the cylinder head gasket from blowing out. (See also page 733: "Gaskets.")

The gasket is composed of asbestos fabric, between sheets of brass and copper. (See also Index under "Gaskets.") If examined closely, one end of the gasket will be found to have a different curve from the other. When the gasket is placed on the cylinder block, with its edges coinciding with the edges of the block, the right side of the gasket will be turned upward, and no further trouble will be experienced.

Shellac should not be used on either side of the cylinder-head gasket, or on any of the other gaskets on the engine. If shellac is used, it will not be possible to remove the gasket without spoiling it. But if grease is used, the grease will hold the gasket in place when the parts are being assembled, and it will cause no trouble when the engine is again taken apart. In this manner the cylinder-head gasket can be used several times.

3279: for magneto contact, 1½" x ¾" x 3/64".

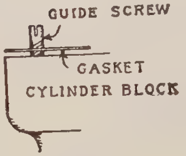

Fig. 76

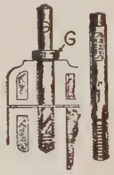

Fig. 77

Fig. 76. **Guide screws are handy for correct replacement of cylinder-head gasket.** They are made from cap screws with the head cut off and slotted. Place one at the front and rear diagonally opposite. Then place the gasket over the guide screws and replace the cylinder head. The screws can then be removed.

Fig. 77. **Cylinder-head cap screws are sometimes broken off when being tightened.** Ordinarily, this involves the removal of the cylinder head and the attempt to drill out the broken part of the bolt. It is not easy to hold the drill perfectly true, so that the threads will not be damaged, but by the use of the drill guide (G) furnished with the set, the drill can be held perfectly central, without the necessity of removing the cylinder head. Then the threads can be cleaned out with the 7/16" tap, and the new bolt installed. The cylinder bolts must be kept rather tight, or water may escape around the cylinder-head gasket. (See also page 716 for "Ezy Out").

If the cylinder-head cap-screw threads become stripped, it is not advisable to drill a hole in the head for an "oversize" screw; drill a cylinder-block tap and set in not less than a ⅝ x 18 thread blind plug, then drill and tap for a standard cap screw (7/16 x 14). 7/16 means the size of screw, and 14 means the number of threads to the inch.

FORD IGNITION

The electric system of a Ford model "T" car can be classified into two divisions:

1. The ignition system.
2. The starting and lighting system.

The ignition system consists of:

1. A low-tension magneto of the inductor type, which is the source of electric current for the ignition.

   Note. When the Ford is equipped with a starting and lighting system, the current is taken from either the battery, generator, or magneto.

2. A high-tension coil which transforms the low-tension current to a high-tension current.
3. Spark plugs, of which there are four.
4. An ignition commutator.

Ignition Circuit

The ignition circuit, when the magneto is used as a source of electric supply, is shown on page 249 and in diagram IV, page 1126.

The Ford magneto is fully described elsewhere in this book; therefore see page 248: "Ford magneto." The magneto is located as shown in Fig. 78 below.

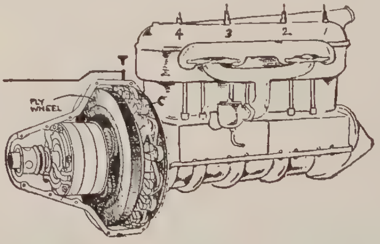

Fig. 78. An exaggerated illustration showing the magneto location. Note the coils (C) which are stationary, and the magnets (A) which rotate. When the flywheel revolves, the sixteen magnets revolve in front of the sixteen coils.

The Ignition Coil Box

The coil box contains four high-tension (vibrator type) coil units. The units can be removed from the box in case one is damaged. Connections to the coils are in the rear in Fig. 79.

The principle and construction of this coil is clearly shown and explained on page 222.

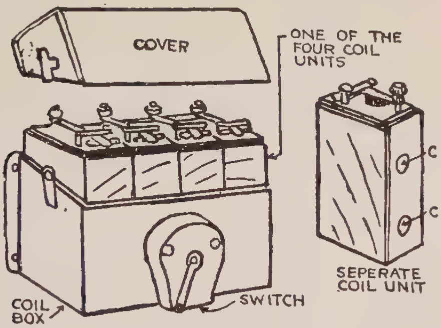

Fig. 79. The coil box containing four high-tension coil units. A separate unit is shown to the right.

The Ignition Commutator

The commutator is of the roller type. It is placed on the end of the cam shaft, that is, the roller mechanism is attached to the end of the cam shaft and revolves with it. Therefore the roller revolves at half the speed or revolutions of the crank shaft.

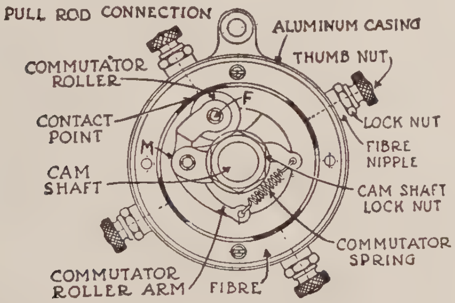

Fig. 80. The ignition commutator.

The roller makes contact with the insulated contact points, of which there are four, and which do not revolve. When the roller comes in contact with one of the four insulated contact points, the coil unit connected with it becomes operative. As the roller leaves the contact, the coil becomes inoperative.

To advance or retard the time of spark, the housing is connected at the "pull-rod connection" (Fig. 80) with the spark lever on the steering wheel.

Ignition Troubles

Ignition troubles on the Ford may be divided into four classes.

1. Spark-plug troubles.
2. Commutator troubles.
3. Coil units out of order.
4. Magneto out of order.

Spark-Plug Troubles

This subject is fully treated on pages 233–239.

When tightening spark plugs, never draw a spark plug down tight into a hot cylinder head. When the cylinder head is hot, the diameter of the spark-plug hole is slightly enlarged, while the spark plug which is comparatively cooler is nearer its normal diameter. When the engine becomes cool, the cylinder head shrinks on to this plug, making it almost impossible to remove it. Correspondingly, if the repairman finds a tight spark plug he may be able to remove it by running the engine until it becomes thoroughly warm.

If considerable trouble is experienced with plugs sticking, it is advisable to wipe the threads with some flake graphite which has been mixed with a little oil, before screwing them into the cylinder head.

Ignition Commutator Troubles

If misfiring occurs when running at high speed, and is not due to the spark-plug gap, inspect the commutator.

Removing commutator: Remove the cotter pin from the spark rod and detach the latter from the commutator at the "pull-rod connection" (Fig. 80).

Loosen the cap screw which goes through the breather pipe on top of the timer gear cover. This will release the spring which holds the commutator case in place, and this part can be removed.

Unscrew the cam shaft lock nut; withdraw the steel brush cap and drive out the retaining pin. The brush can then be removed from the cam shaft.

Inspection and Repair of Ignition Commutator and Wiring

The surface of the circle around which the roller travels should be clean and smooth, so that the roller makes a perfect contact at all points. If the roller fails to make a good contact on any one of the four contact points, its corresponding cylinder will not fire. In case the fiber, contact points, and roller of the commutator are badly worn, the most satisfactory remedy is to replace them with new parts. Or possibly the trouble is caused by short-circuited commutator wires.

The spring should be strong enough to make a firm contact between the roller and contact points, even though slightly worn or dirty.

Other causes of misfiring may also be an improperly seated valve, or a short circuit in the commutator wiring.

Weakness in the valves may be easily determined by lifting the starting crank slowly the length of the stroke of each cylinder in turn, a strong or weak compression in any particular valve being easily detected. It sometimes happens that the cylinder-head gasket (packing) becomes leaky, permitting the gas under compression to escape, a condition that can be detected by running a little lubricating oil around the edge of the gasket and noticing whether bubbles appear or not. Another source of leakage is around spark plugs. Test in the same way (see page 239).

How a short circuit in the commutator wiring may be detected: Should the insulation of the primary wires (running from coil to commutator) become worn to such an extent that the copper wire is exposed, the current will leak out (i.e., a short circuit) whenever contact with the engine pan or other metal parts is made. A steady buzzing of one of the coil units will indicate a "short" in the wiring. When driving the car, the engine will suddenly lag and pound on account of the premature explosion. Be careful not to crank the engine downward against the compression when the car is in this condition, as the "short" is likely to cause a kick-back.

How an "open" (broken wire or loose contact) in the commutator wiring may be detected: Take a dry cell or storage battery and connect one lead from it to ground of the car. Connect the other lead to the **battery terminal** of the coil box (see Fig. 81) and turn the ignition switch to (B) side.

Note. In cars equipped with a starting and lighting system, this procedure is unnecessary; just turn the ignition to the battery.

Now short one commutator thumb nut (see Fig. 80) to the engine by means of a piece of wire. If the coil buzzes, it indicates that this wire is in proper condition. Short the remaining thumb nuts one at a time. If the coil fails to buzz, it indicates that there is an "open" in the circuit leading to this thumb nut. Examine the contacts at both ends of this wire, and also examine the spring contacts inside the coil box. If these items prove satisfactory, the wire is broken at some point. **Be careful if the engine is warm,** as the shorting of one of the thumb nuts may cause the engine to start.

To repair wiring, when a short is discovered, tape may be used to insulate the bare spot, but it is usually better to install a complete new set of timer wires, as they are quite inexpensive. The price of timer wires for cars not equipped with a starting and lighting system is 60 cents; for cars with a starter the price of timer wires is 90 cents.

If a broken wire is discovered, it is best to install a new set of timer wires. However, if you are out on the road and cannot obtain a new set, a separate wire may be run from the terminal of the coil that fails, to its respective thumb nut on the commutator (see method of wiring given below).

To install timer wires: When a broken, badly shorted, or oil-soaked timer wire is discovered, it is best to install a new set. (1) Remove the old timer wires by disconnecting them from the coil terminals and the commutator thumb nuts; (2) thoroughly clean the contacts at the commutator thumb nuts; (3) take a new set of wires and connect them to the coil terminals according to the color scheme shown in Fig. 81; (4) connect the other ends of the wires to the commutator thumb nuts, as shown in Fig. 81, according to the same color scheme, that is, the black wire on No. 1, the red on No. 2, the green on No. 4, and the blue on No. 3; (5) note that all four wires pass under the priming rod, that Nos. 1 and 3 pass behind the commutator spring, and that No. 3 passes behind the commutator pull rod, thus protecting them from the fan belt and excess chafing; (6) to connect the light wires see Fig. 100 for cars not equipped with starters, and see Fig. 102 for cars with starters.

Fig. 81. **Method of wiring the Ford commutator** (when the car is equipped with a starter and lighting system, the coil box has no battery terminal. The change is made in the lighting and ignition switch).

The parts of a commutator most likely to get out of order are: the roller, the spring, or the fiber lining and contacts in the commutator shell.

Replacing the brush (commutator roller assembly): See "Timing of ignition" on page 1113.

Cold weather effect on a commutator: It is a well-known fact that in cold weather even the best grades of lubricating oil are apt to congeal to some extent. If this occurs in the commutator, it is very apt to prevent the roller from making perfect contact with the contact points imbedded in the fiber. This makes difficult starting, as the roller-arm spring is not stiff enough to brush away the film of oil. To overcome this, as well as any liability of the contact points to rust, we recommend a mixture of 25 per cent kerosene with the commutator lubricating oil, which will thin it sufficiently to prevent congealing, or freezing, as it is commonly called. You have probably noticed in starting your car in cold weather that perhaps only one or two cylinders will fire for the first minute or so, which indicates that the timer is in the condition described above; as a consequence a perfect contact is not being made on each of the four terminals.

Ignition Coil Units

The four coil units on the Ford are contained in a metal box with a slanting cover (see Fig. 79) which enables them to be taken out of the box, without removing it from the dash. Some of the 1914 and 1915 metal coil boxes had straight covers, but when this type is used on a cowl dash (1916 or 1917 body), the units cannot be taken out without taking the box off the dash.

The earlier wood box coils were much inferior to the present type, and the Ford Motor Co. makes an exchange proposition on these wood box coils which should be carefully considered before replacing defective coil units in wood-coil boxes or installing new points.

Adjusting vibrators: With the spring held down, the gap between the vibrator points should be slightly less than 1/32". Then set the lock nut so that the adjustment will not shake loose. Each coil unit should be adjusted to take about 1½ amperes, as measured by an ammeter. See also the K.W. Ford coil adjustment (Fig. 2, page 222, and also page 188).

Hard starting, due to vibrator adjustment: If there is **too much tension** on the vibrator springs' the weak current generated by the magneto at cranking speeds will not be sufficient to cause the vibrators to buzz, and it will be difficult to start the engine. **Too little tension** will not let the vibrators respond quickly, and the engine will run unevenly.

A defective coil unit: This can be detected by noticing if the vibrator buzzes without producing a spark at the plug. Then the suspected unit can be exchanged with another unit to make sure that the trouble is actually in the coil unit. A punctured condenser is indicated by a heavy spark at the vibrators and a weak spark at the spark plug.

If the engine has a tendency to miss when driving over rough roads, this may be due to the coil units not fitting tightly in the coil box. The bouncing of the car makes the coil units touch the metal cover of the box and causes misfiring.

Sometimes, misfiring is due to the wooden lining of the metal coil box being damp and allowing the electric current to leak across from one terminal to another.

Testing coil units and dressing contact points is fully treated on pages 222, 223, 224, 225.

Timing the Ignition

We will assume two conditions under which to time the ignition:

1. Engine in disassembled condition.
2. Engine in assembled condition.

Timing Ignition; Engine Disassembled

This should be done immediately after meshing the timing gears and **checking the valve timing,** as explained under Fig. 64, page 1104.

The next operations are:

1. Replace the timing gear cover.

2. **Place the commutator roller assembly in position on the end of the cam shaft.** This roller can be placed in only one position on the cam shaft on the later models (see Fig. 82 below), that is, the slot in the roller assembly should line up with the hole in the cam shaft which is drilled only part way into the shaft. In the earlier models the hole was drilled clear through the cam shaft, thus permitting two positions of the roller. In this case, be sure that the roller points downward when the zero marks on the timing gears are together. In the later models, this is the only position in which it is possible to replace the roller.

3. Insert the retaining pin.

4. Replace the steel brush cap over the roller assembly hub.

5. Screw the lock nut on the cam shaft.

HOLE IN CAMSHAFT LINES UP WITH SLOT IN HUB

Fig. 82. Timing or setting the Ford ignition. The commutator case is shown in a retarded position.

By reading the matter on page 1104 (Fig. 64), it will be noted that when the zero marks on the timing gears are together, No. 1 piston has not quite reached the top of the exhaust stroke, and the exhaust valve is just at the point of closing; consequently No. 4 piston has not quite reached the top of the compression stroke, and in this position (which is ¾" before top dead center) No. 4 is not quite ready to fire as yet. Therefore, when the zero marks on the timing gears are together, the commutator roller should nearly, but not quite, make contact with No. 4 segment on the commutator case after the latter is replaced.

6. **Adjusting the position of the commutator case:** Place the commutator case with wires attached over the roller assembly.

7. Clamp in position by means of the commutator spring shown in Fig. 81.

8. Turn the engine over slowly by means of the crank until No. 1 piston passes upper dead center and then descends ⅛" on the suction stroke. The top of the piston will then be 3/16" above the cylinder block, as shown in Fig. 82. No. 4 piston will then be in a similar position on the power stroke. With spark retarded, No. 4 should now fire.

9. Turn the commutator case until the roller just makes contact with No. 4 segment, as shown in Fig. 82. If the ignition switch is turned on the battery, the coil will buzz when contact is made.

10. The length of the commutator pull-rod can be adjusted by turning the ball-and-socket joint on its thread, or by bending the rod itself. This length should be adjusted so that the pull rod will fit into its hole in the commutator case (when the spark lever is fully retarded, up) without disturbing this position of the case. Insert the cotter pin in the commutator pull-rod.

When the spark lever is advanced, the roller will make contact when the piston is ⅜" from top dead center on the up or compression stroke.

Timing Ignition; Engine Assembled

When the engine is in an assembled condition, the ignition may be timed as follows:

1. In the earlier models, turn the crank shaft until the exhaust valve on No. 1 cylinder just starts to close. Place the commutator roller in position so that it points downward. In the later models, this is not necessary, as the roller can only be placed on the cam shaft in one position.

2. Install the commutator case with wires.

3. Place the spark lever three notches down (almost retarded).

4. Adjust the length of the pull-rod so that the pull-rod connection is ¼" to the left of the fan bracket bolt, as shown in Fig. 82.

Ford Magneto

How magnets are located on the flywheel: The like poles of the magnets are placed together, that is, N to N, and S to S, as shown in Fig. 83 (see also page 248).

Before assembling the magnets (if disassembled), test them and chalk mark the N poles. After assembling, test their correctness by passing a compass around the flywheel, close to the outside of the magnets. The needle should reverse as each pair of poles is passed. If they are placed wrong, the needle will turn cross-wise and tremble.

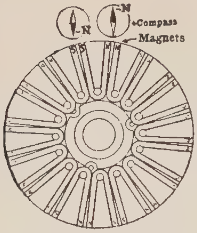

Fig. 83. **The magnet poles of the magneto** are placed with **like** poles together, and are mounted on the flywheel.

To test: The S pole of the magnet will attract the N pole of the compass needle, and the N pole of the magnet will attract the S pole of the compass needle.

Cause of Weak Magnets

1. Dirty contact as in Fig. 84.
2. End play in bearings, caused by a worn crankshaft bearing which permits the magnets to rotate at too far a distance, which makes the current weak.
3. A grounded magneto coil will weaken the current.

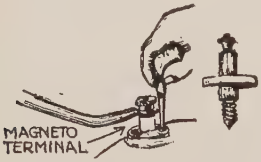

Fig. 84. Dirt on the magneto terminal contact will cause dim lights and misfiring. It can be removed and cleaned.

Indications of Weak Magnets

See the tester described on page 1117.

(1) Dim lights. (2) Frequent backfires, or explosions in the muffler when running—possibly blowing the muffler up.

The magneto is often blamed for trouble that lies elsewhere in the electrical system. A weak current will often be caused by dirt or waste collecting beneath the terminal contact spring on the crankcase cover. To clean, remove the three screws holding the binding post, remove the post and spring, and clean as shown in Fig. 84.

Check up the wiring for short circuits or grounds.

To reach the magnets, it is necessary to remove the engine from the car. The common method of doing this is to remove the radiator, dash, and steering gear, and to lift the engine out complete. By this method the base of the engine is left in the chassis, and the dash and steering gear are left undisturbed. Two experienced men can readily remove an engine and place it on the bench in thirty minutes by this method.

Note. **Before removing the engine,** make sure that the trouble lies in the magneto. This may be done by trying to run the car on the battery ignition, when cars are equipped with storage batteries. When cars are not equipped with batteries, use dry cells, connecting one lead to ground and the other to the battery terminal of the coil box (Fig. 81); then turn the ignition switch to the (B) side. If the engine will now run, it indicates the trouble to be in the magneto, but if the engine will not run, the trouble may be elsewhere.

To Remove the Engine without Removing the Crank Case[1]

1. Drain the radiator.
2. Remove the four bolts at the universal joint.
3. Remove the rear spring shackles and pull the rear axle back. (The rear of the car must first be blocked up.)
4. Disconnect the radiator stay rod.
5. Remove the two bolts holding the radiator to the frame, and remove the radiator.
6. Unsnap the commutator and place it to one side.
7. Remove the spark-plug wires.
8. Shut off the gasoline and remove the feed line from the carburetor.
9. Disconnect the exhaust manifold from the exhaust pipe, and remove both intake and exhaust manifolds from the engine.
10. Remove the fan-shaft bracket and timing gear case.
11. Remove the two bolts holding the pans to each side of the base, and knock the pans down out of the way.
12. Remove the base bolts.
13. Remove the transmission case after loosening the reverse, low, and brake-transmission bands, and removing the starting motor, if so equipped.
14. Lift the engine from the frame and place it on the bench. The lifting may be done with a hoist. It is quicker and easier, however, if three men take hold of it and lift it out by hand. One should straddle the engine at the rear and the other two should be at each side at the front.

To Find Amount of End Play in Crank Shaft

Before removing the transmission from the engine, test for crank-shaft end play as follows:

1. Force the transmission as close as possible to the engine.
2. Place a thickness gauge between the core of coils and the face of the magneto clamps.
3. Pull the transmission as far as possible away from the engine block.
4. Measure again with the thickness gauge.
5. The difference between the two measurements is the amount of end play of the crank shaft.

When there is more than .008″ end play, a new bearing cap should be fitted.

End play up to .015″, while detrimental to a smooth-running engine, should not cause a weak magneto.

Tearing Down the Engine and Testing the Magneto[2]

1. Clamp the engine on the bench.
2. Test the magnets on the flywheel, as shown in Fig. 85. The block of steel should just hang by a corner. The weight of this test block happens to be the same as that of the Ford cam-shaft gear. Failure to hold indicates weak magnets.

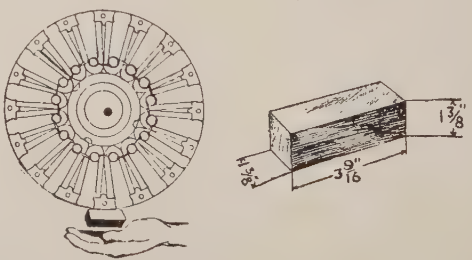

Fig. 85. Method of testing strength of Ford magnets.

---

[1] For another method of removing the engine see page 1101.

[2] See the tester described on page 1117.

3. Remove the bolts holding the flywheel and transmission to the crank shaft.
4. Remove the flywheel, magnet, and transmission unit, placing the latter face down on the bench.

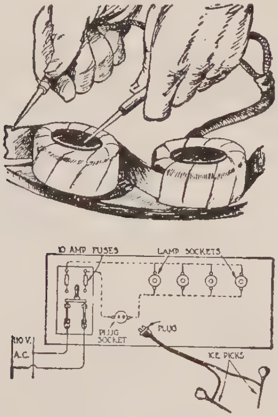

Fig. 86. Testing Ford magneto coils for grounds.

5. If trouble is suspected in the magneto coils, these may be tested, as shown in Fig. 86. The two test points are connected to a 110-volt alternating current line (Fig. 86). The main ground of the coils is disconnected, and each coil is tested for shorts, grounds, or open circuit (see also Fig. 87).
6. Chisel the heads from the ends of the brass magnet-retaining screws at the rear of the flywheel; when reassembling, use new screws.
7. Turn the flywheel transmission assembly over and set it upright in a square box placed on the bench.
8. Remove the wires holding the central magnet-retaining bolts.
9. Using a bit brace screwdriver, unscrew the outside magnet screws.
10. Using a bit brace socket wrench, unscrew the central retaining bolts. Clean all parts.

Fig. 86 shows a testing outfit using four 32 c. p. carbon lamps.

Testing Magneto Coils for Grounds

Connect five or six dry cells to a 6-volt lamp (Fig. 87). Attach one end of the terminal from the lamp to the magneto terminal (T).

Then unsolder the grounded end of the winding at coil (C-2) and raise it so that it will not be in contact with the magneto frame.

With the other wire from the battery, touch the iron frame (Y); if the lamp lights, then somewhere there is a ground of one of the spools in contact with the frame.

The next step will be to find out in what particular portion of the winding the ground exists.

Attach the test wire (W) to the metal part. This can easily be done by inserting the end under nut (Y), or by temporarily making a soldered joint at the point where the permanent ground was formerly attached. If there is a ground, the lamp will then light.

Loosen the coils, one at a time, and shake them vigorously, or move them up and down. This will cause the light to flicker, or go out and on when you reach the coil or section where the ground is located.

The ground can sometimes be removed by cleaning out the dirt and metallic particles and revarnishing with a special oil-proof varnish which can be obtained of Ford agents. Common shellac will not do.

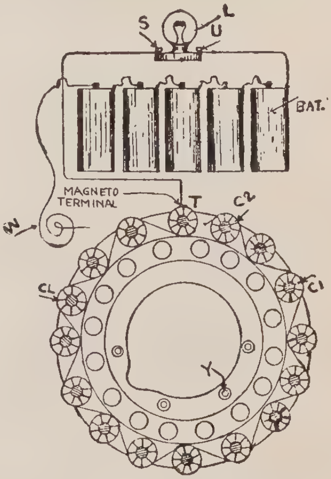

Fig. 87. Testing magneto coils for grounds.

In replacing the defective magneto coil with another from an old magneto, soak it well in oil-proof varnish and press it firmly on the stud. Let it dry thoroughly before installing in the engine. It is to be understood that the replacement of a single coil is an emergency measure only, as it is better practice to replace the entire set.

Note. The illustration (Fig. 87) shows the coil plate reversed. The bolt holes and recess for the cam shaft should be on top.

Building up the Magnets

If the magnets are found to be weak by the test shown in Fig. 85 (see also the tester described on page 1117), new magnets should be installed.

1. Place the new magnets on the flywheel in the same order that they were in the box in which they were shipped from the factory, that is, so that the legs that do not attract each other are together. This means that like poles, or N and N and S and S poles are placed together (see Fig. 83, page 1114).
2. Catch all the central retaining bolts in place, but do not tighten.
3. Slip the outside spools under the magnet ends.
4. Drop the magnet clamps on to the magnet ends, and catch the brass screws into their threads.
5. Using a brace screwdriver, bring all the screws down snug.
6. Pinch the ends of the magnets in with a pair of pliers until the sides of the magnets rest against the spacer on the clamps.
7. Tighten the outside brass screws.
8. Tighten the central retaining bolts.

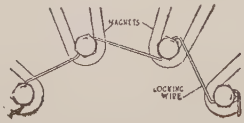

Fig. 88. Method of locking bolts by running a wire through the heads.

9. Using stovepipe or brass wire, lock the central bolts in position. The wire should be inserted as shown in Fig. 88 (when the holes are about in the position shown), as this creates a tendency to tighten instead of to loosen the bolts.
10. Knock the four corners of each magnet clamp down over the magnets, so that they cannot interfere with the coils later.
11. Test the magneto clamps for high spots. To do this, lay a straight-edge (such as a steel rule) across any three clamps. If the straight-edge "rocks," the center clamp is high. Move the straight-edge around the magneto so that each magneto clamp will at one time be in middle, thus testing each clamp.
12. Turn the assembly over, and head the brass screws at the rear of the flywheel. Before assembly, the engine should be inspected for loose or worn bearings, and if any are found, they should be cleaned and adjusted.
13. Inspect the magneto coils for high spots in a manner similar to that described for magnets under (11).

Dead Points on Old-Type Magneto

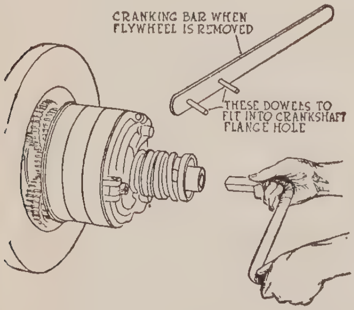
On the older model Fords which did not have the ¾″ magnets, there were certain dead points where, if the spark lever was placed in certain notches in the quadrant, the engine would not respond with increased speed. On the late magnetos, as the magnets pass from one end to the other as it revolves, there is no dead point.

Later Magnets ¾ Inch

To install ¾″ magnets of the latest type so that electric lights can be used, as the crank-case and the transmission cover are similar, the necessary parts include No. 3250-D magneto-coil assembly, one set of ¾″ magnets, sixteen magnet clamps No. 3277, and sixteen magnet clamp screws. (Former magnets were ⅝″.)

Assembling the Magneto

1. Test the crank-shaft flange for burrs or high spots.
2. Replace the flywheel-transmission assembly on to the crank-shaft flange, and secure it with the two opposite flange bolts. Draw these bolts up snug.



CRANKING BAR WHEN FLYWHEEL IS REMOVED
THESE DOWELS TO FIT INTO CRANKSHAFT FLANGE HOLE

Fig. 89. Cranking the engine with the transmission in place.

3. Using the crank as shown in Fig. 89, turn the flywheel and note whether the magnets interfere with the coils. The magnets are set 1/32″ from the coils.
4. The clearance or air gap between the coils and magnets should be .030″, which is almost 1/32″. However the allowable limits are from .025″ to .040″. **If the gap is too wide,** put the necessary shims behind the coil support. **If the gap is too narrow,** take out some shims. The steel shims are .015″, and the paper ones are .005″. The clearance may be measured with a thickness gauge.
5. Replace the two other flange bolts.
6. Tighten all the flange bolts. A short piece of round stock, wedged through one of the holes in the coil flange and caught behind the magnets, holds the crank so that the bolts may be drawn tight.
7. Again using the crank, as shown in Fig. 89, crank the engine quite fast. While cranking, short-circuit the magneto-contact point with the cylinder block, using a screwdriver. A fat blue spark shows the magneto to be in proper condition.
8. Place the locking wires in the crank-shaft flange bolts.

Replacing the Engine

Before replacing the engine in the base, the base should be thoroughly cleaned. The rivets holding the supports to the base should be tested to see that they are tight. All bolts should be inspected.

1. Place the standard Ford felt packing on each side of the engine base, setting it in heavy oil.
2. Lift the engine up, and set it in place. Be careful not to slide it around any more than necessary. Three men can do this easily.
3. Line up the holes in the base with a small drift.
4. Replace the front gear cover.
5. Drive all the base bolts through their holes, from the bottom up, and catch the nuts on to the threads. Two men, one with a speed wrench on the nuts and the other holding the bolts, can quickly fasten the engine to the base.
6. Slide the transmission bands in place.
7. Bring the lugs all together at the top, and wire them together tightly with a single strand of stovepipe wire, or use a clamp similar to that shown in Fig. 28, page 1093.

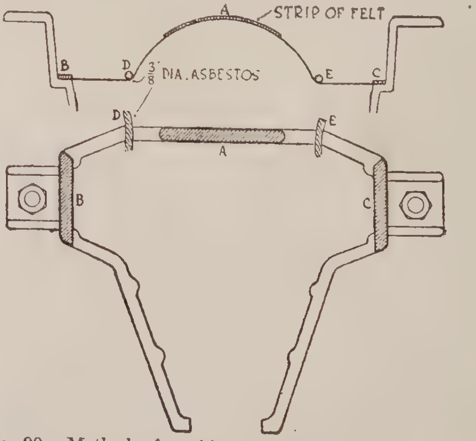


Fig. 90. Method of packing transmission-case joints to prevent leakage of oil.

8. Place the short lengths of felt gasket at (A) (B) and (C), as shown in Fig. 90. Place ⅜″ asbestos wicking and grease in the corners at (D) and (E).
9. Then place the standard Ford felt transmission gasket in place. The double-thickness felt and the asbestos wicking stop up the points that tend to leak.

10. Slide the transmission housing in place. Using a screwdriver, pry the bands into place.
11. Knock the housing down flush, and tighten the two rear retaining bolts.
12. Using a thin socket, or check-nut wrench, tighten the transmission bands.
13. Replace the balance of the housing bolts, and bring them up snug.
14. Slide the rear axle and drive shaft back into place, and secure them there.
15. Assemble the engine fittings, such as fan, commutator, wiring, and manifolds.
16. Replace the radiator assembly, hood, and floor boards. (*Motor World.*)

To Test the Air Gap with a Ford Magneto Tester

Another method for testing the strength of the magneto, which also determines the air-gap space, can be found very easily with the **tester** shown in Figs. 91 and 93, as explained below.

To test the air gap space and strength of the magneto on a car:

1. Test the output of the magneto with the tester (Fig. 91), with the engine running at moderate speed.
2. Remove the transmission cover and place a thickness gauge, 1/32″, between the magnet and the coil core. If the gap is 1/32″, but the magneto has tested out as **weak,** the magnets need recharging.
3. After remagnetizing the magnets (which can be done without taking the engine down; see below), test the magneto again with the engine running at moderate speed. The tester should show **strong;** if it does not, the probabilities are that the magneto coil is short-circuited.

If some of the magneto coils become short-circuited, or if the magnets are weak, the tester will read low. In other words, it tells you instantly, without removing the magneto from the engine, if the magneto is in proper condition. If not in proper condition, it is time to take the magneto out and to remedy the trouble. If it tests satisfactorily, it is time to look elsewhere for the trouble, and you will thereby save the time and trouble of removing the magneto in error.

The meter scale is very simple. It has two readings (see Fig. 91). One is marked "1914," meaning that on all magnetos before 1915, the needle should come to this mark. The other is marked "1915," meaning that on all cars after 1915, the needle should reach this mark. (The Ford magnets were enlarged in 1915.)

Example of a Ford Magneto Tester[1]

The Ford magneto generates "alternating" current. An ordinary "direct"-current ammeter, as used for testing batteries and generators, will not operate. Therefore a special meter, as shown in Fig. 91, is designed for testing the Ford magneto.

If the engine will not run at all, and the ignition is the fault, an easy way to determine if the trouble is due to the magneto, is to connect a storage battery, or five or six dry cells, to the battery side (**B**) of the coil (Fig. 92), and to turn the switch to (**B**), or to the right side.

If the engine then starts, and runs satisfactorily, but will not start on the magneto, with the switch to the left, or (**M**) side, you may know that the magneto is not supplying current. This may be due to dirty or loose magneto terminals (**T**) or to a weak magneto, due to weak magnets, or to grounded magneto coils.

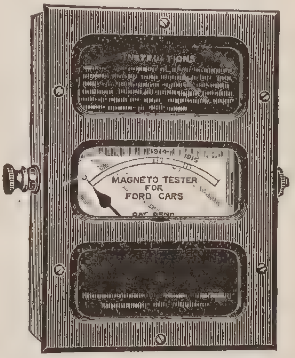

Fig. 91. Ford magneto tester. Note how the scale is marked. See text.

The Ford magneto can be tested with a special magneto tester, as shown in Figs. 91 and 93. This instrument is nothing more than an ammeter, but one provided with a "reactance coil" (**R**) (Fig. 93), which enables the meter to indicate a constant current at all engine speeds. In other words, the meter is so designed that it will indicate if the magneto is giving its proper output at any speed of the engine, while testing.

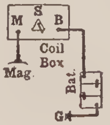

Fig. 92

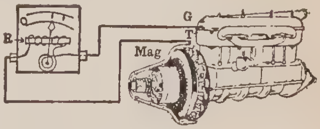

Fig. 93

Fig. 92. Method of connecting the battery to the ignition coils.

Fig. 93. Method of connecting Ford tester.

This instrument can be used to test the strength of the magneto while the engine is being run on a battery, if the engine fails to start on the magneto.

If engine starts on the magneto, but continually misses, and if the trouble is not due to other causes, then the tester can be used to see if the magneto is delivering its proper current, while the engine is being operated on the magneto.

The connection for testing would be the same in both cases (Fig. 93), except that, when the engine is running on the battery, the wire from the ignition coil to the magneto is removed, and the switch is placed on (**B**) side (Fig. 92).

The clearance or air gap of Ford magnets is the distance the magnets are from the core of the magneto coils. This should be as stated on next page. If they are farther away, the amperage and voltage will be less; if closer, the amperage and voltage will be greater, but there is danger that the magnet will strike the coil core.

The tester is a great help when assembling the magneto on the bench. The "air-gap" can be adjusted to the point of greatest output, if you have the meter to test with as you assemble. The flywheel can be turned by hand fast enough, so that the instrument will give a steady reading.

---

[1] This tester can be secured of A. L. Dyke, Granite Bldg., St. Louis, Mo. Price $11.00.

Adjusting air-gap clearance: The clearance, or air gap, between the coils and magnets should be .030″, which is almost 1/32″. The allowable limits are from .025″ to .040″. **If the gap is too wide,** put the necessary shims behind the coil support. **If the gap is too narrow,** take out some shims. The steel shims are .015″, and the paper ones are .005″.

If the needle fails to reach this mark, remagnetize the magnets.

If then the magneto fails to test up to this mark, and the missing still occurs, and is not due to loose terminals, and runs satisfactorily with a battery, then you may know you have a "grounded" magneto coil. The magneto must be removed, the defective coil located, another put in place, and the "air-gap" clearance must be given as described above.

Remagnetizing Ford Magnets

There are various methods of remganetizing Ford magnets. The usual and proper method of remedying weak magnets is to replace them with new ones. The Ford Co. does not advise everyone to attempt this work. This however necessitates taking down the engine and then reassembling. This makes a costly job, and is a big job. Therefore different methods of recharging magnets without removing them from the car will be given.

Remagnetizing by electromagnet and battery:[1] It is not necessary to remove the flywheel from the engine when remagnetizing Ford magneto magnets with the device shown in Fig. 94. Simply remove the transmission-case cover so that the ends of the magnets are available. Use a compass to determine the N pole of each magnet, and chalk them; also chalk the S pole of the remagnetizer. Place the S pole of the remagnetizer so that it will be on the N pole of the magnets.

Turn the flywheel over after remagnetizing one magnet, and remagnetize each magnet separately.

After remagnetizing, check the polarity of all magnets with the compass again.

The connections are shown in Fig. 94. The storage battery can be either a 6 or 12-volt battery. It is possible to use 6 or 8 dry cells, if connected as in Fig. 95.

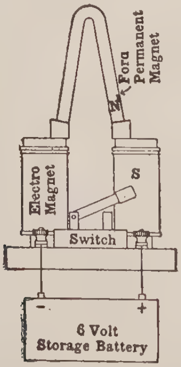

Fig. 94. Electromagnet using a storage battery for remagnetizing Ford magnets.

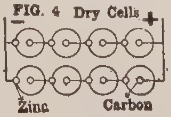

Fig. 95. Dry cells can be used instead of a storage battery, if connected as shown.

Magnets of all types of magnetos can be charged with this remagnetizer. When remagnetizing magnets which are separated from the magneto, it is important to place a "keeper" across the magnets until placed on the magneto. It is also advisable to rap the magnet a few times with a piece of wood while being remagnetized. See also page 312: "Remagnetizing Magneto Magnets."

Remagnetizing with storage batteries: Five or six, 6-volt storage batteries should be about right. Refer to Fig. 96.

To prepare the magneto for recharging, first disconnect the wire (A) which goes from the magneto terminal on the transmission cover to the coil on the dash.

Next remove the transmission cover (B), so that you can look at the magneto. Locate the brass studs on the rim of the fly wheel which hold the magnets in place, and have someone turn over the engine very slowly until one of these brass studs is in line with an imaginary line drawn about 1″ or so from the magneto terminal, to the left of the latter and paralleling the frame.

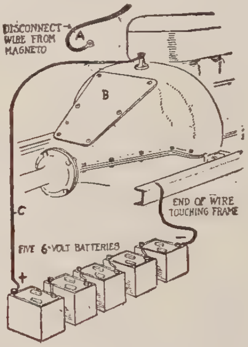

Fig. 96. Remagnetizing Ford magnets with storage batteries.

Another method is to place an ordinary small compass on the transmission cover about 1″ from and to the left of the magneto terminal, at the same time turning the engine slowly until the needle of the instrument is parallel with the engine.

The N pole end of the needle should point toward the engine when in this position.

Connections: Connect a wire from the positive (+) terminal of the battery to the magneto terminal on the engine, as shown at (C) (Fig. 96).

Next connect a wire from the negative terminal on the battery, and make and break the circuit by striking the free end of the wire on some metal part of the engine.

Permanent connection should not be made, but only thirty or so momentary contacts, which, it is said, will recharge the magnets much more satisfactorily than if permanent contact is made. (*Motor Age.*)

Dry cells can be used if necessary. Use 48 connected in series-multiple, as shown in Fig. 97. Connect the positive (+), or carbon poles, with the terminal.

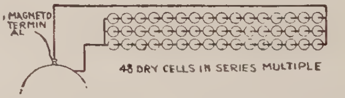

Fig. 97. Remagnetizing Ford magnets with dry cells.

Resistance wire can be used. Use 13 ft. of nichrome No. 16 wire, or 8 ft. of No. 18. If German silver, use 35 ft. of No. 16 or 22 ft. of No. 18—in series, as shown in Fig. 98.

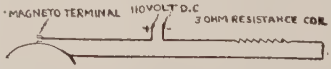

Fig. 98. Method of remagnetizing Ford magnets with 110-volt direct current and resistance.

110-volt direct current can be used. To use this it will be necessary to use a resistance lamp bank, as shown in Fig. 99. Use twenty-eight 32 c.p. carbon filament lamps. Connect the positive pole with the magneto terminal. Connected as shown, this gives 27½ amperes. To find the positive pole, or polarity of any circuit, see page 564, "Polarity, how to find."

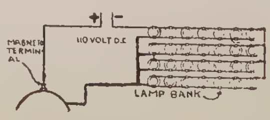

Fig. 99. Method of remagnetizing Ford magnets with 110-volt direct current and lamp bank.

---

[1] Can be secured of A. L. Dyke, Granite Bldg., St. Louis, Mo. Price $9.50 with Ford attachment and full instructions.

LIGHTING CIRCUITS ON FORD CARS NOT EQUIPPED WITH STARTERS

Two lamps can be connected in series to operate from the magneto, as shown in Fig. 100 below.

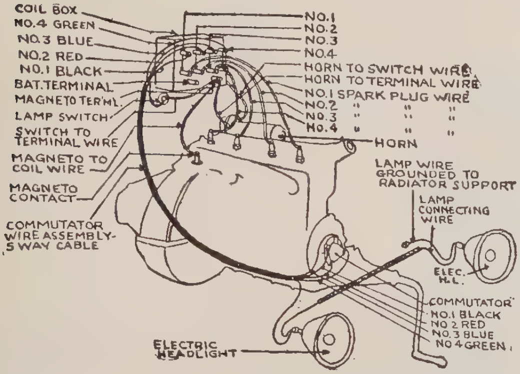

Fig. 100. **The wiring** above shows the ignition and also two lamps in series which take current from the magneto **on Fords that are not equipped with a starting and lighting system.** The horn switch or button is on the steering post.

The lamps are 9 volts, therefore, two being in series, they would require 18 volts, which voltage is taken from the magneto. Note that the lighting circuit is from the magneto contact or terminal to a connection on the rear of the coil, thence to the lamp switch, thence to the two lamps in series, thence to ground. **A complete lighting circuit where the starting and lighting system is used** is shown in Diagram V, page 1127. All details are shown in the illustration.

The bulbs supplied on present Ford cars for the electric head lamps are 9 volts, 2 amperes, and best results will be obtained by securing lamps of this voltage and amperage when replacement is necessary. (See Fig. 100.)

If a lamp burns out, it will be necessary to replace it by removing the lamp door.

Should the door be removed, care should be exercised not to touch the silver-plated reflector or the bulb with anything but a soft, clean rag, preferably flannel.

To focus the lamps, turn the adjusting screw in the back of the lamp in either direction until the desired focus is obtained.

21 or 27 c.p. is standard for headlights. For side lamps, 4 c.p.; for dash or tail lamps, 2 c.p.

The model "T" Fords are fitted with an 18-volt magneto, and therefore a 9-volt lamp in series would really last longer than 8-volt lamps in series, but the light would not be quite so bright. The older model magnetos gave 12 to 16 volts; therefore 6 to 8-volt lamps were used—connected in series.

Nitrogen bulbs, type C, are best (see pages 432, 433), but are more expensive.

When lamps are connected in parallel, 12 to 16-volts, one ampere, 15 c.p., type B bulbs can be used.

Proper voltage: You should get good lights at eight miles per hour, and the bulbs should come up to full candle-power at about twelve miles per hour.

If the bulbs do not come to full candle-power, and cast a yellowish light, you should use a bulb of smaller voltage.

If the bulbs burn too brightly, throwing an exceedingly white light at slow speeds, the bulbs are of too low a voltage, and a higher voltage should be used. In this case, the life of the bulb would be very short.

Dry cells for starting: The (B) side of the switch can be used for batteries (dry or storage) for starting and after starting, the switch is placed on the (M) or magneto side (see Fig. 92). The Ford Co. claims, however, that the magneto gives current at a very low speed and that batteries are not necessary. (If dry cells are used, use five or six.)

Storage battery for ignition and lights can be connected in place of dry cells as shown in Fig. 92.

In connecting a storage battery, **the battery terminal should never be connected to the magneto terminal** post on the dash, as this will demagnetize the magnets.

Wiring: The timer and light wires are enclosed in a loom as furnished by the Ford Co. Extra wires used should be No. 16 flexible lamp cord, run through metal tubing or flexible loom.

To Install a Storage Battery when a Ford Is not Equipped with a Starting and Lighting System

For ignition, horn, and lighting, one terminal of the storage battery can be connected to the battery terminal in rear of the coil box (see Fig. 81). The other terminal is grounded to the frame of the car or engine (make clean contact and draw tight with a bolt).

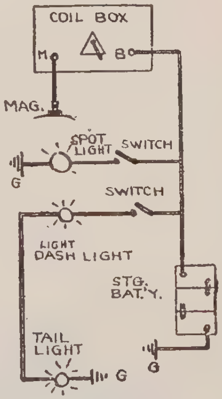

Fig. 101. Method of wiring a storage-battery system to Fords not equipped with starting and lighting system.

The wire to the (B) connection on the coil should have three branches (see Fig. 101). One branch should connect, through a single-pole switch, to a 3-volt lamp on the dash. Then the wire from this dash lamp should proceed to a 3-volt tail-lamp at the rear of the car. The remaining wire from the tail-lamp should be connected to the metal of the chassis frame. This places the dash and tail-lamp in series, so that if the tail-lamp should burn out or become disconnected, the dash lamp would also be extinguished, thus warning the driver.

Another wire should be connected, through a single-pole switch to the spot-light, the remaining wire from the spot-light being grounded.

The third branch wire from the battery should be connected to the binding post on the left-hand corner of the coil box, looking from the radiator toward the dash. When the switch on the coil box is turned toward the binding post, to which the battery wire is connected, the battery will be con-

Fig. 102. **Wiring diagram of the Ford model "T," including the Ford electric starting and lighting system.** This diagram is of value to the repairman when installing new wires. See pages 1125–1127 for two-color wiring diagrams showing the different circuits.

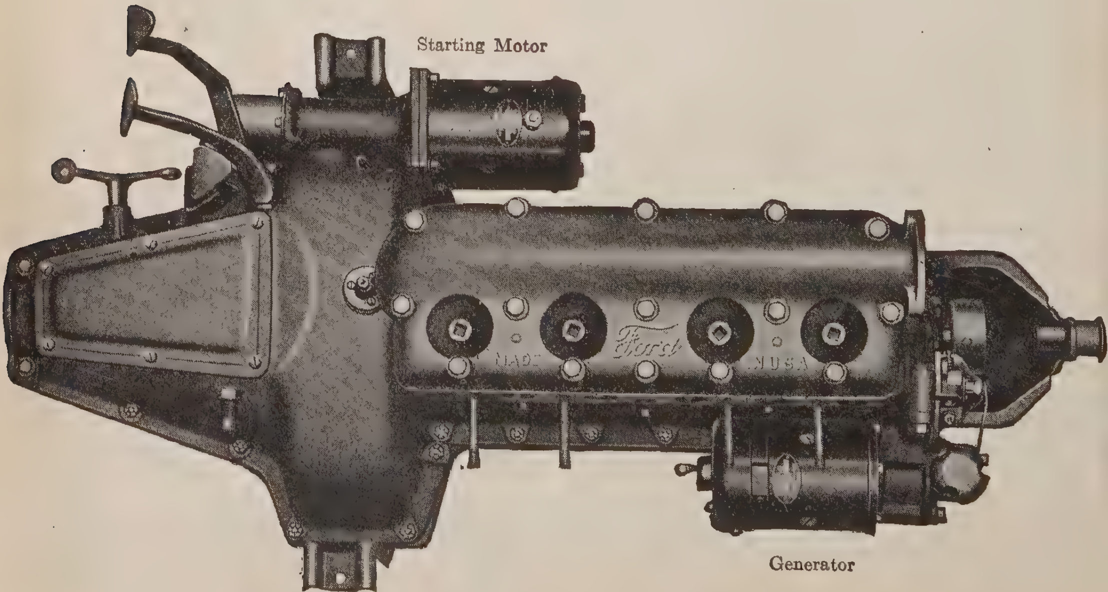

Fig. 103. Top view of Ford single-unit power plant, showing the location of the starting motor and generator.

nected for easy starting, and no other switch need be used.

The bulb for the spot light should be rated at 6 volts. The bulbs for the dash and tail-lights should be each rated at 3 volts. If desired, the bulb for the dash may be rated at 2 volts, and the bulb for the tail light at 4 volts. But they must be of the same amperage. Only two switches will be needed.

The usual voltage of storage batteries is 6 volts; therefore lamps of this voltage should be used.

The number of hours a battery will operate depends upon the number and size of lamps used and the ampere-hour capacity of the battery (see page 522).

When the battery is exhausted, it must be taken to a charging station and recharged. There is a device known as the Warner battery charger, which, it is claimed, will rectify the magneto current from alternating to direct, and the battery can be charged from the magneto with it (see page 1139).

THE F. A. STARTING AND LIGHTING SYSTEM AS INSTALLED ON FORD SEDANS AND COUPES

Parts and Location

The starting and generator system is a two-unit type, and consists of the following parts: generator, cut-out, combination switch, fuse, terminal block, ammeter, starting motor, storage battery, wire, headlamps with headlight bulbs and dimmer bulbs. The combination switch, ammeter, and priming rod are mounted on the cowl (Fig. 102).

The Starting Motor

The starting motor is mounted on the left-hand side of the engine and bolted to the transmission cover (Fig. 103). When in operation, the pinion on the Bendix drive shaft (Fig. 104) engages with the teeth on the flywheel, which is a ring gear with teeth cut in it and bolted to the flywheel and held in place by the brass screws which hold the magnets (see Fig. 105).

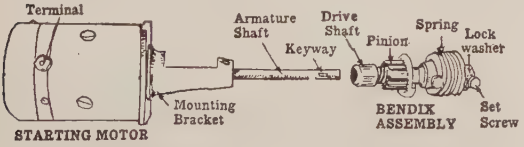

Fig. 104. Starting motor with Bendix drive parts removed from the armature shaft.

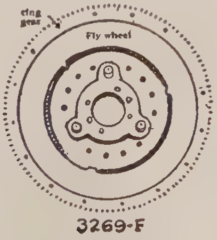

Fig. 105. Steel ring gear bolted to the flywheel for the starting motor.

To Start the Engine

The spark and throttle levers should be placed in the same position on the quadrant as when cranking by hand, and with the ignition switch turned on. Current either from a battery or magneto may be used for ignition. When starting, especially if the engine is cold, the ignition switch should be turned to "battery." As soon as the engine is warmed up, turn the switch back to "magneto." The magneto was designed to furnish ignition for the model "T" engine, and better results will be obtained by operating in this way. Special attention must be paid to the position of the spark lever, as a too advanced spark will cause serious backfiring, which in turn will bend or break the shaft in the starter.

The starting motor is operated by a foot button, conveniently located in the floor of the car at the driver's feet. With the spark and throttle levers in the proper position, and with the ignition switch turned on, press on the push button with the foot. This closes the circuit between the battery and starting motor, causing the pinion of the Bendix drive shaft to engage with the teeth on the flywheel, thus turning over the crank shaft.

When the engine is cold it may be necessary to prime it by pulling out the carburetor priming rod, which is located on the instrument board. In order to avoid flooding the engine with an over-rich mixture of gas, the priming rod should be held out for only a few seconds at a time.

If Engine Fails to Start

If the starting motor is turning the crank shaft over and the engine fails to start, the trouble is not in the starting system. In this event, release the button at once so as not to discharge the battery unnecessarily, and inspect the carburetor and ignition system to determine the trouble.

If Starting Motor Fails

If the starting motor fails to act, after pushing the button, first inspect the terminal on the starting motor, the two terminals on the battery, and the two terminals on the starting switch, making sure that all of the connections are tight; then examine the wiring for a break in the insulation that would cause a short circuit. If the wiring and connections are correct, and the starting motor fails to act, test the battery with a hydrometer. If the hydrometer reading is less than 1.225, the trouble is no doubt due to a weak or discharged battery. See also pages 562, 556: "Testing a storage battery."

Operation of Generator

The generator is mounted on the right-hand side of the engine and bolted to the cylinder front-end cover. It is operated by the pinion on the armature shaft, engaging with the large time gear (spiral gear) (see Fig. 106).

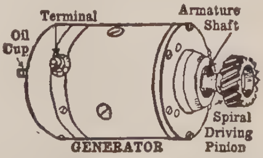

Fig. 106. Generator for Ford.

The charging rate of the generator is set so as to cut in at engine speeds corresponding to 10 m.p.h. in high speed, and reaches a maximum charging rate at 20 m.p.h. At higher speeds the charge will taper off, which is a settled characteristic of battery charging. See also page 516.

Cutout Action

This operation of cutting in and cutting out at suitable speeds is accomplished by the cut-out.

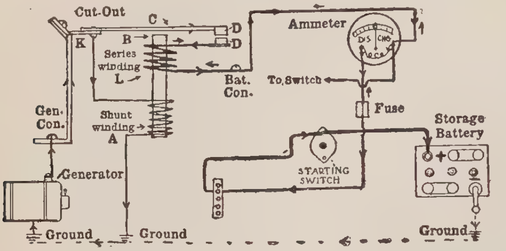

Fig. 106A. **When the engine is started and running slow,** the current flow from the generator begins to build up magnetic strength in the iron core (B), through fine wire shunt winding (A). Note that connection to the battery is open at (D).

When the car speed reaches 10 m.p.h. on high gear, the generator current is then strong enough for the shunt winding (A) to magnetize core (B), and blade (C) is drawn to (B), which closes contact points (D). The generator voltage is then 6.8 volts, or slightly more than that of the battery (battery is 6 volts). Therefore the generator **charges the battery** with current passing through the coarse wire series winding (L), through the ammeter to the battery. The generator current is now passing through (L) and (A) in the same direction.

When the engine slows down to less than 10 m.p.h., the generator voltage is then less than the battery voltage. Therefore the battery current begins to flow, or to **discharge** in the **opposite** direction (see outside arrows), through series winding (L), and this is why it is called a "reverse-current" cutout. This action **opposes** the generator current passing through shunt winding (A), which is weak, with the result that core (B) loses its magnetism, or is demagnetized, and releases blade (C), through the tension of spring (K), thus opening the circuit between the generator and battery. This action is repeated over and over as the engine speeds up and slows down, and (C) vibrates accordingly. See also pages 519, 520.

Oiling Starting Motor and Generator

The starting motor is lubricated by the Ford splash system, the same as the engine and transmission. The generator is lubricated by a splash of oil from the time gears. In addition, an oil cup is located at the end of the generator housing, and a few drops of oil should be applied occasionally. Do not use too much oil.

Ignition System

See pages 1125, 1126, which give details and circuits.

Note. The introduction of a battery current into the magneto will discharge the magnets, and whenever repairing the ignition system or tampering with the wiring in any way, do not fail to disconnect the positive wire from the battery. The end of this wire should be wound with tape to prevent its coming in contact with the ignition system or metal parts.

The Ampere Meter

The ammeter is located on the instrument board or cowl, and the reading is 20-0-20, 0 or zero being in the center, and 20 to the left indicating the "discharge" side, and 20 to the right or "charge" side (Fig. 107). The needle is on the "charge" side when the generator is charging the battery, and on the "discharge" side when the lights are burning and the engine is not running above 10 miles per hour.

At an engine speed of 15 miles per hour or more, the meter should show a reading of 10 to 12 amperes, even with lights burning.

If the engine is running above 15 miles per hour and the meter needle does not go to the "charge" side, first inspect the terminal posts on the meter, making sure that the connections are tight. Then disconnect the wire from the terminal on the generator, and, with the engine running at a moderate speed, take a pair of pliers or a screwdriver and short-circuit the terminal stud on the generator to the generator housing. If the generator is in proper order, a good live spark will be noted. (Do not run the engine any longer than is necessary with the terminal wire disconnected.) Next inspect the wiring from the generator through the meter, to the battery, for a break in the insulation that would result in a short circuit.

Next short-circuit around the cutout by connecting the battery lead directly to the generator terminal. If the ammeter now shows charge, the trouble is in the cutout, and a new one should be installed. Repairing Ford cutouts has not proved a satisfactory practice.

If, after these tests, the trouble is not remedied, then remove the dust cap from the end of the generator. Procure a fine grade of sandpaper which has been slightly oiled. Do not use emery cloth, as emery is a conductor of electricity. With the engine running, hold the sandpaper against the commutator with the fingers until all dirt has been removed and a bright surface attained. See also page 491: "Cleaning commutator."

Lighting System

The lighting system consists of two headlights and a tail-light operated by a combination lighting and ignition switch (Fig. 108) located on the instrument board. The headlamp bulbs are of 6–8 volt, **double filament** type. The major filament is 18 c.p., and the minor filament is 2¾ c.p. The small bulb used in the tail-light is of 6–8 volt, single-contact, 2 c.p. type.

All of the lamps are connected in parallel, so that the burning out or removal of any one of them will not affect the other. Current for the lamps is supplied by the battery.

Do not connect the lights to the magneto, as it will result in burning out the bulbs and might discharge the magnets. (See Diagram V, page 1127.)

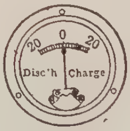

Fig. 107

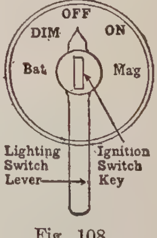

Fig. 108

The ignition and lighting switch is shown in Fig. 108. **The ignition switch** is a key, and **the lighting switch,** a lever.

How to Remove Starting Motor

When removing the starter to replace the transmission bands, or for any other reason, first remove the engine pan on the left-hand side of the engine, and with a screwdriver remove the four small screws holding the shaft cover to the transmission cover.

Upon removing the cover and gasket, turn the Bendix drive shaft around so that the set screw on the end of the shaft, as in Fig. 104, is in the position shown.

Immediately under the set screw is placed a lock washer, designed with lips or extensions opposite each other on the outside diameter. One of these is turned against the collar and the other is turned up against the side of the screw head. Bend back the lip which has been forced against the screw, and remove the set screw. As the lock washer will no doubt be broken or weakened in removing the starter, a new one must be used when replacing it. These washers may be obtained from the nearest branch.

Next, pull the Bendix assembly out of the housing, being careful that the small key is not misplaced or lost. Remove the four screws which hold the starter housing to the transmission cover, and pull out the starter, taking it down through the chassis. This is why it was necessary to remove the engine pan.

In replacing the starter, be sure that the terminal connection is placed at the top. If the car is to be operated with the starter removed, be sure to put the transmission cover plates in position. These plates may also be obtained from the nearest branch.

How to Remove Generator

If it is found necessary to remove the generator, first take out the three cap screws holding it to the front end cover, and by placing the point of a screw-driver between the generator and front end cover, the generator may be forced off the engine assembly. Always start at the top of the generator and force it backward and downward at the same time.

Plates may be obtained from the nearest branch to place over the time gear, if the engine is to be operated with the generator removed.

To Operate Engine; Generator Disconnected from Battery

If for any reason the engine is run with the generator disconnected from the battery, as on a block test, or when the battery has been removed for repair or recharging, be sure that the generator is grounded to the engine by running a wire from the terminal on the generator to one of the valve-cover stud nuts. A piece of wire 1/16″ or more in diameter may be used for this purpose. Be sure that the connections at both ends of the wire are tight. Failure to do this when running the engine with the generator disconnected from the battery will result in serious injury to the generator. Never ground the generator through the cutout.

Battery

This is a 6-volt, 13-plate "Exide," type 3-XC-13-1.

To Test Ford Generator

Clamp the generator lightly in a vise (Fig. 109). Turn the armature by hand to see if it revolves freely. If it does, attach one wire from a 6-volt battery to a bolt of the vise (one generator terminal is grounded), touch the other battery wire to the generator terminal to see if the generator will run as a motor.

If it does, and draws less than 6 amperes, the generator is probably in good condition.

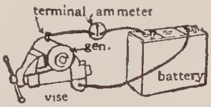
If it draws more than 6 amperes, take a piece of No. 00 sandpaper and hold it against the commutator until a bright surface is obtained. See page 491.

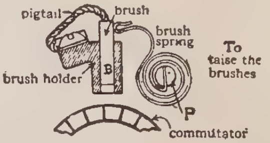
Installing New Generator Brushes

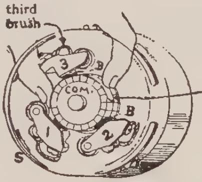
Examine the brushes and see that they are not too short and that they are clean and bear properly on the commutator. If loose, heat will be generated.

To fit new brushes, cut a strip of No. 00 sandpaper. Pull the spring back (Fig. 110) and pull the brush up by the pigtail, after which the spring is allowed to rest on the brush. Insert the sandpaper, sand side up (Fig. 111), and hold it so that it will conform to the commutator, and move it together with the commutator back and forth under the brush, the brush having been dropped on the sandpaper. Remove the brush and see if it is properly seated to the curvature of the commutator, and replace the brush.

Fig. 111 shows the method of sanding the third brush (3) and Fig. 112 shows the method of sanding the two lower brushes. (1) (2).







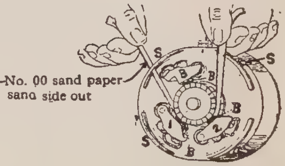


Fig. 109 (upper)
Fig. 111 (lower)

Fig. 110 (upper)
Fig. 112 (lower)

Setting Generator Brushes

The Ford generator uses the third-brush system of current regulation. When brushes seat properly, the lower brushes (1) (2) should be set on the **neutral point.** Start the lower and loosen the three upper screws (S) which hold the brush-ring to the head. Raise the third brush as in Fig. 110.

Connect the battery wire to the generator terminal. If the armature revolves, the brushes are not set on the neutral point. Turn the ring against the direction of rotation until the armature ceases to turn or until it revolves in the opposite direction. If it turns in the opposite direction, bring the ring back until the armature will not revolve in either direction, even when started by turning the shaft by hand. The brushes are now set on **neutral** point.

Tighten the screws which hold the ring to the head; lower the third brush (3) and try it for running.

If it turns over properly, drawing less than 6—preferably less than 4—amperes, the generator should be assembled to the engine, and proper connections made through the cutout to the battery.

Setting the Third Brush

The next operation is to set the third brush. The third brush may be moved back and forth on the brush ring. It is clamped to the ring by means of a bolt which is also used as a post (P) (Fig. 110) for the brush spring. To move the third brush, together with its holder, loosen the nut on this post until the holder may be moved back and forth. The third brush should be set in such a position as to give a charging rate of 10 to 12 amperes when the car is running at about 20 miles per hour on high gear. See also page 516.

Changes on Engine

The following changes have been made on engines of enclosed cars, to accommodate the starter motor and generator.

Transmission cover changed to take starter. Ford No. is 3376B.

Cylinder block changed. Ford No. 3000C.

Cylinder block front cover, changed. Ford No. 3009C.

Cylinder block front cover liner. Ford No. 3013.

Timing gear cover. Ford No. 3017.

Flywheel with ring gear. Ford No. 3269F.

The ring gear bolts to the flywheel and has teeth cut in it to take the starting-motor gear. See Fig. 105.

Price of Ford Coupé and Sedan

See page 1080.

Note. A complete instruction is devoted to the Ford electric starting and lighting system (see Instruction 45). See also pages 1125–1127, showing five two-color circuit-wiring diagrams.

FORD MODEL "T" ELECTRIC CIRCUIT WIRING DIAGRAMS INCLUDING FORD STARTING AND LIGHTING SYSTEM

The wiring diagram (Fig. 102, page 1120) is suitable for the repairman when installing new wires.

The circuit diagrams following show the different circuits, which are printed in red. These diagrams should give the repairman an idea of the wires in which any particular trouble might lie.

Wiring: The single-wire system, i.e., the metal part of the car, acts as the second wire, and is usually called the "ground." The frame is always connected to the (−) negative terminal of the battery.

There are eight circuits, each of which may be traced separately as follows:

1. Charging circuit (generator to battery as shown by the arrow points).
2. Starting-motor circuit.
3. Tail-lamp circuit.
4. Headlight circuit (bright).
5. Headlight circuit (dim).
6. Ignition from battery.
7. Ignition from magneto.
8. Horn circuit.

Electric Currents in Ford System

The generator delivers 6 to 8 volts direct current, with a maximum of 12 amperes.

The battery delivers 6 volts (direct current).

The starting motor requires about 225 amperes at 4 volts.

The magneto generates alternating current from 5 to 26 volts, with a maximum of 9 amperes.

The coil secondary current in the ignition circuit carries a current of extremely low amperage at 15,000 to 25,000 volts.

Tracing Trouble in Electrical Equipment

Trouble in the electrical system may be either **electrical** or **mechanical.**

Mechanical troubles very seldom occur, and when they do, they are located either by the resulting noise or during inspection for electrical trouble.

There are only four kinds of electrical trouble:

1. Weak source of current.
2. Open circuit.
3. Short circuit.
4. Crossed circuit.

The weak source may be the battery, the magneto, or the generator, and the trouble may be due to mechanical or any of the electrical troubles in that part.

An open circuit occurs where there is a gap in the wires of a circuit. This gap may be caused by a switch not functioning properly, a poor electrical contact between the wires and terminals, misplaced fiber insulators, dirty contact points, or a broken wire.

The importance of clean, tight contacts, particularly in the low-voltage circuits, cannot be too firmly impressed on the repairman's mind, as it is one of the most prevalent sources of trouble in an electrical system, often causing unnecessary drain on the battery when the system is apparently functioning properly..

A short circuit obtains when the current returns to its source without traveling through all the wires it is supposed to. This is caused by a bared wire coming in contact with some other uninsulated part of the circuit. These conditions may occur in the wiring or inside the separate devices.

Crossed circuits occur where the current from one circuit runs into another circuit through bared wires touching or wires misplaced in assembly.

The first thing to do in tracing trouble is to determine the circuit or circuits affected, and then, by breaking that circuit into several sections, the trouble may be located as being in one of them, which should be carefully inspected for the typical faults enumerated above.

If the trouble occurs in two separate circuits, it is reasonable to suppose that its source lies between the common connection and the supply of current. For instance, if upon trying the lights and the ignition on the battery, neither one will act, the trouble must lie between their common connection at the switch and the battery. If the horn will not sound and the car will not run smoothly with the ignition switch on the magneto side, the trouble probably lies between their common connection on the terminal block and the magneto.

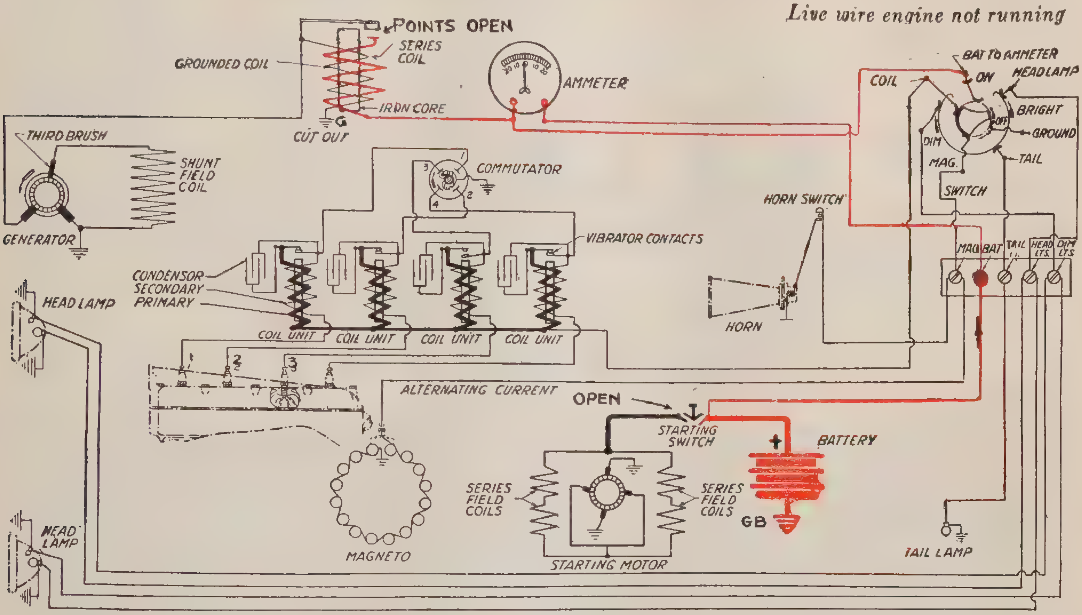
Live Wires

In diagram I the wiring diagram of cars equipped with the starting and lighting system is shown; the wires shown in red are alive at all times (excepting when the battery is disconnected), and should be inspected occasionally to see that their insulation is in good condition and that the wires are in such a position that they will not chafe on any metal parts.

These wires are used on the other circuits as shown on pages 1125, 1126, 1127. However, if the batteries require recharging frequently, it is probably due to open circuits or a slight ground in these wires. As stated above, open circuits result from loose or dirty connections, as well as from parted wires.

If the top of the battery is allowed to become wet, dirty, or covered with acid spilled when testing, the current will leak across and gradually discharge the battery. The top of the battery should therefore be wiped occasionally with a rag moistened with household ammonia.

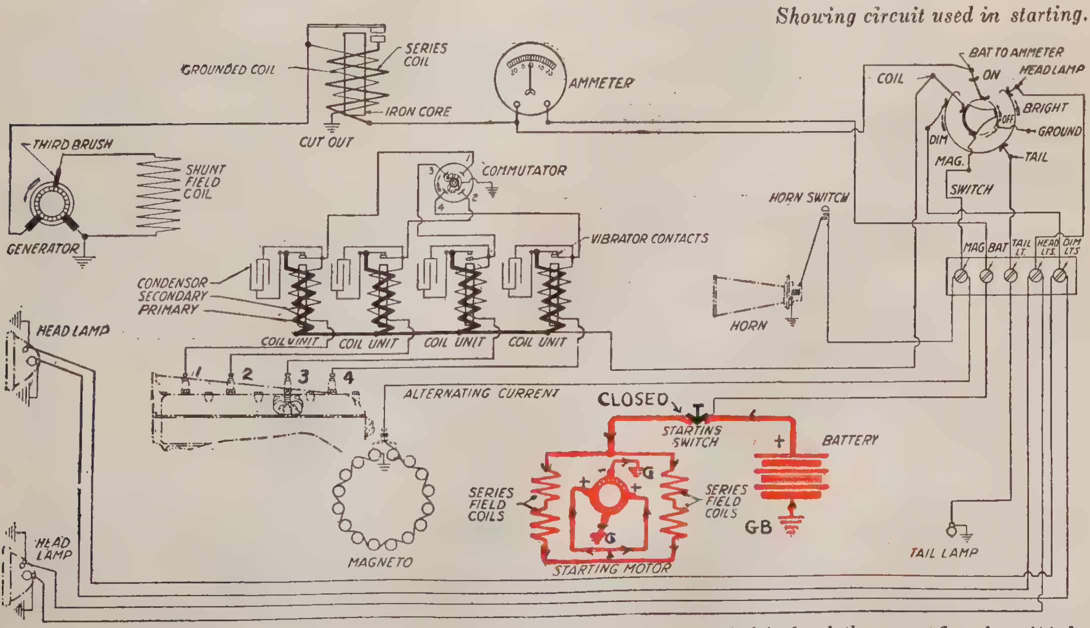
See Instruction No. 45 which gives complete details for testing all parts of the Ford electric system.



Live wire engine not running

Diagram I. **Live-wire circuit when the engine is not running** (see red wires). Note that the negative (−) terminal of the battery is grounded to the frame of the car at GB.

The red wires show the live wires, which is from the positive (+) of the battery to the terminal block (see also Fig. 102, page 1120). The circuit is then through the ammeter to the switch. Also note that one end of the cut-out series coil connects with the ammeter, but the other end is open at the open cut-out points. It will be observed that there is no complete circuit.



Showing circuit used in starting.

Diagram II. **Starting-motor circuit** (see red wires). When the starting-motor switch is closed, the current flows from (+) of the battery to the starting-motor field-windings, to the (+) brushes on the commutator of the armature, through the armature, out the (−) brushes, to ground (G), to the grounded (−) terminal of the battery (GB).

Charging Circuit

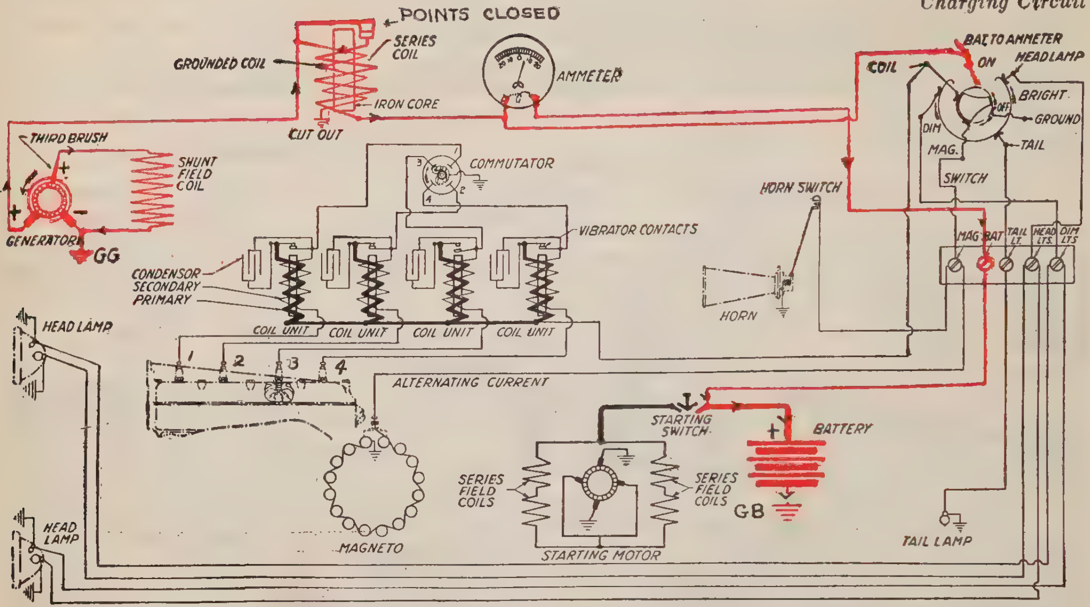


Diagram III. **Generator charging circuit** (see red wires). When the engine is running at sufficient speed (above 10 m.p.h. car speed, see instruction on Ford, page 511), the cut-out points close. The reason they close is that the current from the (+) brush of the generator passes through the shunt winding (grounded coil) on the cut-out, to ground, thence back to the (−) grounded brush of the generator (GG).

The charging current then passes from the (+) brush of the generator, through the cut-out points, through the series coil winding of the cut-out, through the ammeter, to the terminal block, to the (+) terminal of the battery, through the battery, to the (−) grounded terminal (GB) of the battery, to the (−) grounded brush of the generator (GG).

The ignition circuit, of course, must be on during this time, but is not shown in colors. If the ignition switch is on the battery side of the switch (BAT. see Fig. 108, page 1122) and the generator is charging the battery, then the ignition current would be taken from the generator ahead of the ammeter, where it is connected.

If, however, the generator is not charging the battery and the engine is running slow and the cut-out points are open, and the switch is on the battery side, then the current for ignition would be taken from the battery, first passing through the ammeter.

If the switch was on the magneto side (**MAG**; see Fig. 108, page 1122), then current for ignition would be taken from the magneto, as shown in Diagram IV.

Showing Ignition and Horn Circuits, the Ignition Switch being on the Magneto Side

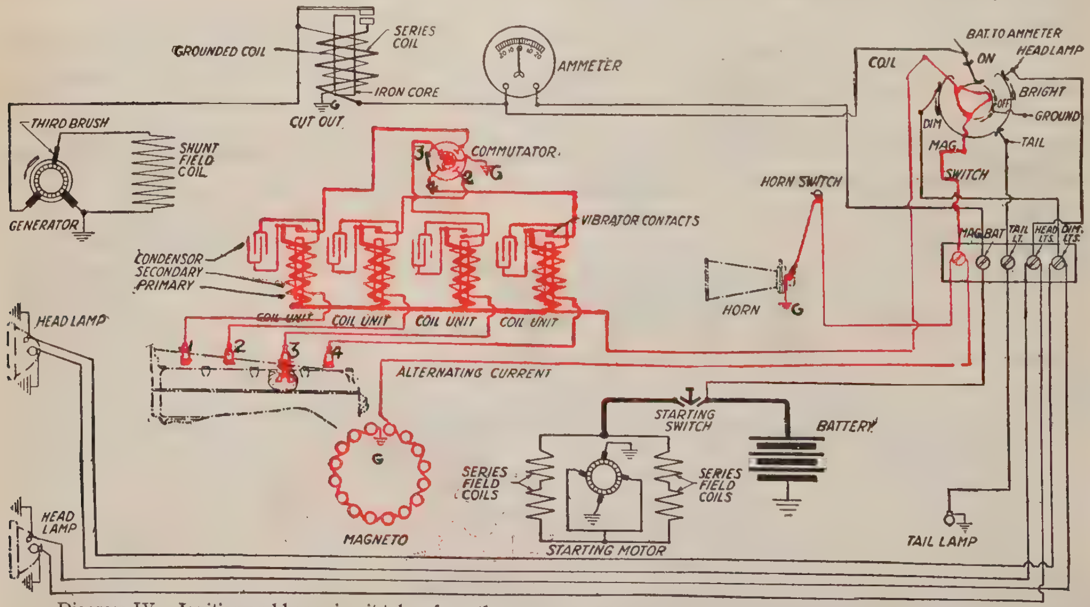

Diagram IV. **Ignition and horn circuit taken from the magneto:** The magneto ignition circuit is from the magneto terminal, to the terminal block, to the ignition switch which is now on the magneto side, to the primary coil winding (large red wire on coil), through the coil vibrator points, to the commutator segment (the one on which the roller is on contact), to ground (G) of the commutator, to ground (G) of the magneto.

The secondary current would be from the small red wire on the coil, to the spark plug (say No. 3 is firing), to ground of the engine, to ground of the commutator (G), to the secondary, where it is connected at one end of the right contact point.

Bright Head Lights and Tail Light

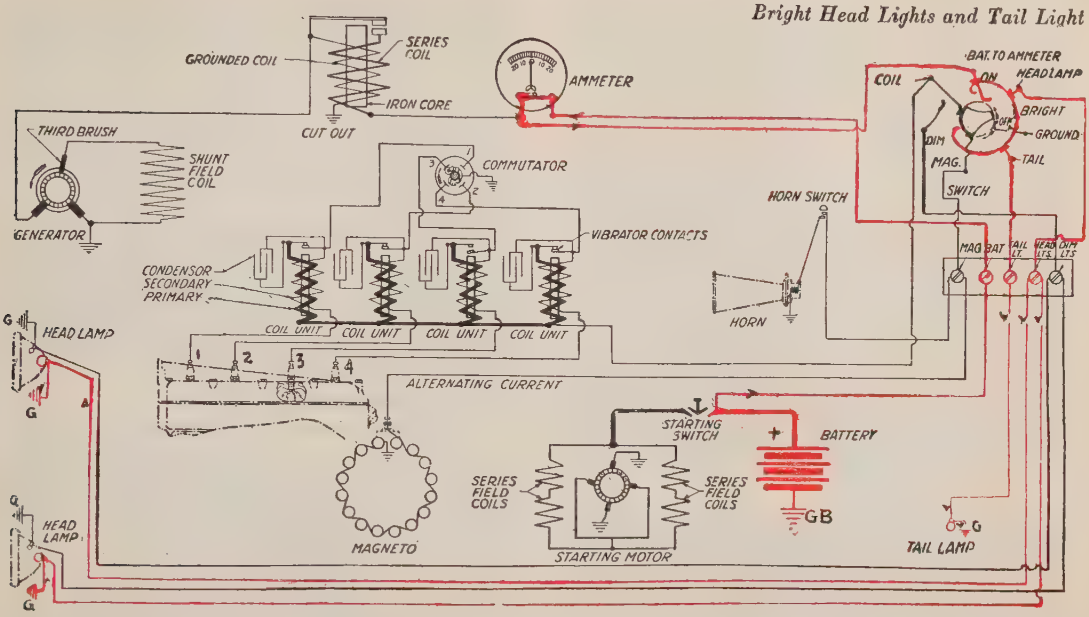

Diagram V. **Headlight (bright) and tail-light circuit** (see red wires): In this example, the generator charging circuit is open, and the engine could be running at a very slow speed or not at all, and the lighting switch lever is turned to "on" (see external view of switch, Fig. 108, page 1122); then the headlights (bright) and tail-light circuit take current from the battery, starting at (+) of the battery, to the terminal block, to the ammeter, to the switch, to the headlamps and tail lamp, to ground (G), to ground (GB) of the battery.

If dim headlights are desired instead of bright headlights, the lighting switch lever is turned to the "dim" side, which cuts out the 18-candlepower bright lamp filament and cuts in the 2¾ candlepower dim lamp filament (for double-filament lamps see page 433.

If the generator is charging the battery, the lights would be taken from the generator just ahead of the ammeter.

FORD CARBURETORS

The carburetor is located on the right side of the engine as shown in Fig. 50, page 1102. The external connections are shown in Fig. 7, page 105.

Two types of carburetors are furnished on Ford cars: the Holley, made by Holley Bros. Co., Detroit, Mich., and the Kingston, made by Byrne, Kingston & Co., Kokomo, Ind. There is very little difference in the adjusting of these two carburetors, but there is considerable difference in their repair, so they are here considered separately.

Dash Carburetor Adjustment

Both Holley and Kingston carburetors are of the automatic type, having but one adjustment. The carburetor adjustment knob (now a wire rod) is on the dash (Fig. 113). Turning this to the right—or in a clockwise direction—tends to give a weaker mixture and to save gasoline. But turning this knob to the left opens the spray nozzle and gives a richer mixture, which makes starting easier. In Fig. 113 the different positions are shown at (A) (B) and (C).

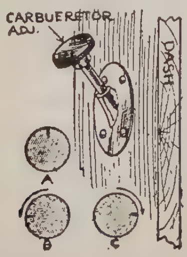

Fig. 113. **Carburetor dash adjustment.** A—is the position for correct mixture; B—for rich mixture; C—lean mixture. Adjustments in this direction save gasoline.

Carburetor Needle-Valve Adjustment

After the new car has been thoroughly worked in, a file mark or notch should be made on the face of this knob, so that the driver can determine the setting. (A) indicates the position at which the engine runs most satisfactorily. In cold weather, it will probably be necessary to turn the knob at least a quarter-turn to the left, as at (B)—especially when starting.

As gasoline vaporizes more readily in warm weather, the driver will find it economical to reduce the quantity of gasoline in the mixture by turning the carburetor adjustment to the right (as far as possible without reducing speed), as indicated at (C). This is particularly true when taking long drives where conditions permit a fair rate of speed being maintained, and accounts for the excellent gasoline mileage obtained by good drivers.

Carburetor Adjustment

This subject is treated separately for the Kingston and the Holley carburetors.

Starting the Engine in Cold Weather

The usual method of starting the engine when cold is to turn the carburetor dash adjustment one quarter-turn to the left in order to allow a richer mixture of gasoline to be drawn into the cylinders; then hold out the priming rod, which projects through the radiator, and turn the crank from six to eight quarter-turns in quick succession.

Another method of starting a troublesome cold engine is as follows: Before throwing on the magneto switch, (1) close the throttle; (2) hold out the priming rod and give the crank several quick turns, then let go the priming rod (being careful that it goes back all the way); (3) place the spark lever in about third notch and advance the throttle lever several notches; (4) throw on the switch (being sure to get it on the side marked "Magneto"); (5) give the crank one or two turns, and the engine should start.

After the engine starts, it is advisable to advance the spark eight or ten notches on the quadrant and to let it run until thoroughly heated up. If you start out with a cold engine, you will not have much power and are liable to "stall."

The advantage of turning on the switch last, or after priming, is that when you throw on the switch and give the crank one quarter-turn, you have plenty of gas in the cylinders to keep the engine running, thereby eliminating the trouble of the engine starting and stopping. After the engine is warmed up, turn the carburetor adjustment back one quarter-turn.

When cars are equipped with a starter, and difficulty is experienced in getting the engine started, do not run down the battery by continually using the starter, but follow the method outlined above.

To Facilitate Starting

Some drivers make a practice of speeding up the engine by opening the throttle just before stopping, by turning off the coil switch. This leaves the cylinders fully charged with gas.

Pulling out the priming ring, and thus causing a very rich mixture to be drawn into the cylinders, is another method of stopping the engine that will make it easier to start in cold weather but is bad practice, as the raw gasoline will be drawn into the cylinders and will work its way to the crank case and thin the lubricating oil. It is necessary to prime in this manner when starting, as then the gasoline will be likely to be ignited.

The Kingston carburetor is shown in sectional view on page 105. This shows how the gasoline enters the carburetor, is vaporized in a current of air, and then passes through the inlet manifold to the engine in the form of an explosive mixture, which gives the power. This general layout also applies to the Holley carburetor.

The hot-air pipe from the air intake of the carburetor to the exhaust manifold (as shown in Fig. 7, page 105) is useful in summer as well as in winter with poor gasoline.

THE KINGSTON CARBURETOR

The Kingston model "Y" carburetor is shown in Fig. 114. It was used on the 1913 and 1914 Ford. It differs from the model "L-1" used in 1915 and 1916 and from the "L-2" used from 1916 to 1920 in that in the model "Y" the air supply was regulated in a different manner.

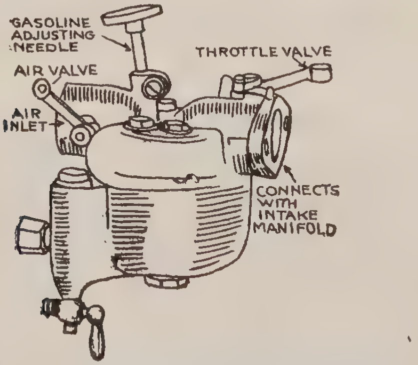

Fig. 114. Kingston model "Y" carburetor. See also Fig. 7, page 105 (this model is not now manufactured).

Description of Kingston Carburetor "L-2" and "L-1"

Fuel enters the carburetor from the tank at connection (**A**) (Fig. 116) and is maintained at a constant level (as shown), through the agency of the float acting on the needle valve (**K**).

The pool of gasoline formed in the base of the tube will always be present when the motor is not running, and is for the purpose of positive starting. When the motor starts, this pool is quickly lowered to the point of adjustment of the needle valve, and continues to feed from this point until the motor is stopped.

Let us follow the course of the air through the carburetor until it enters the cylinder, as a perfect mixture. To appreciate thoroughly what occurs in this carburetor, we must follow the course of the air and the atomized gasoline throughout its entire range.

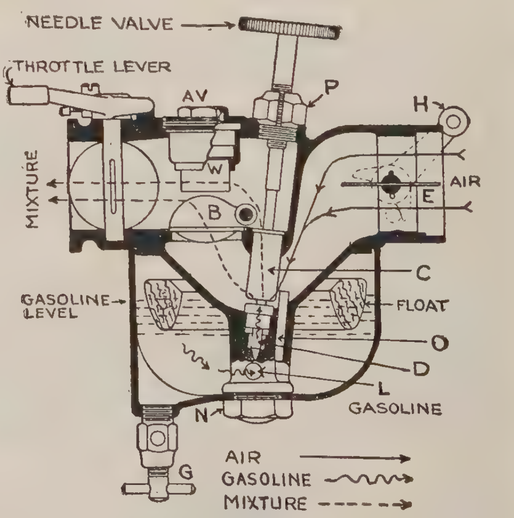

Fig. 115. Side sectional view of model "L-2" Kingston carburetor. The "L-1" is similar.

When the engine is running slowly, air valve (**B**) rests lightly on its seat, allowing no air to pass this point; consequently all air must pass through the low-speed tube (**C**). Since the lower end of this tube is close to the spray nozzle and all the low-speed air has to pass this point, the atomized gasoline drawn from nozzle (**D**) becomes thoroughly mixed with air in its upward course, and is carried in this state to the engine.

Let us now open the throttle slowly and see what occurs. The engine now requires a greater volume of mixture. Air valve (B) slowly leaves its seat, permitting a small volume of the mixture to pass by. At this point a change in operation occurs. The low-speed tube still continues to deliver a perfect mixture, but is being assisted by the air valve opening. The air being drawn by the air valve must pass across the spray nozzle between it and the low-speed tube.

As the engine speed is increased up to its maximum, the air valve continues to rise higher and higher, admitting more and more air, which, having to pass across the spray nozzle with an ever-increasing velocity, becomes thoroughly impregnated with the atomized gasoline producing a perfect mixture throughout the entire range.

(P)	Needle valve clamp nut.
(Q)	Air valve shaft.
(W)	Air valve weight.

This list refers to Figs. 115 and 116.

To start an engine at any time depends upon getting a combustible mixture in the cylinders: that is, proper proportions of air and atomized gasoline thoroughly mixed. Difficult starting in cold weather is the result of two inherent properties of gasoline. It does not vaporize as readily in cold weather as in warm, nor does it flow through the needle-valve adjustment as easily; consequently we cannot get as much by the adjustment in cold weather as we can in warm. This is why opening the needle valve slightly makes starting easier and keeps the engine running, which otherwise would have a tendency to stop when the load was thrown on.

In the Kingston model "L-2" this extra amount of gasoline for starting and warming-up period can be obtained by opening the needle-valve adjustment at the dash, or by the use of choke throttle (E), placed in the air passage.

When starting with a cold motor, choke throttle can be closed by pulling wire connected to (H). This cuts off nearly all the air supply and produces a very strong suction at the spray nozzle, which causes gasoline to jet up and be carried with the incoming rush of air to the cylinders.

A drain cock (G) is placed at the lowest point in the bowl, and should be opened from time to time to free the bowl of all water and foreign matter.

Note. A new design is the Kingston model "L-4," its most noteworthy feature being an automatic accelerating jet.

To Adjust Models "L-2" and "L-1" Kingston Carburetor

Retard the spark fully. Open the throttle about five or six notches on the quadrant on the steering post.

Loosen the needle valve clamp nut (P) on the carburetor until needle valve turns easily.

Turn the needle valve (with dash adjustment) until it seats lightly. Do not force it. Adjust away from its seat one complete turn. This will be slightly more than necessary, but will assist in easy starting.

Start the engine and open or close the throttle until the engine runs at fair speed (not too fast), and allow it to run long enough to warm up to service conditions.

Now make the final adjustment. This carburetor has but one adjustment—the needle valve. Close the throttle until engine runs at the desired idling speed. This can be controlled by adjusting the stop screw in the throttle lever.

Adjust the needle valve slowly toward its seat till the engine begins to lose speed, thus indicating a weak or lean mixture. Now adjust the needle valve away from its seat very slowly until the engine attains its best and most positive speed. This should complete the adjustment. Close the throttle until the engine runs slowly, then open rapidly.

The engine should respond strongly. Should acceleration seem slightly weak or sluggish, a slight adjustment of the needle valve may be advisable in order to correct this condition.

With the adjustment completed, tighten the binder nut until the needle valve turns under tension.

Float Level Adjustment of Kingston

In the **model "Y" Kingston,** used on 1913-14 Ford cars, the float should be set to show a clearance of 9/32″ from the top of the float to the top or face of the cup casting (the same is true of model "L," 1915 and early 1916).

Model "L-2": The action and the float setting of this carburetor are entirely different from those of the other two models. The float is hinged directly to the body, instead of in the cup, as in models "Y" and "L." To test the level of the float, turn the body upside down, and, when properly set, it should show a clearance of 7/16″ from the machined surface on the top casting to the top of the float, at a point directly opposite the point where the float is fastened to the body of the carburetor.

Miscellaneous Adjustments of Kingston Carburetor

The float chamber is removed and the float is repaired, as explained for the Holley carburetor.

The inlet needle-valve seat at (K) is removed and replaced, as in the Holley carburetor. Do not, however, replace it with the Holley valve or seat, as these parts are not interchangeable.

Before replacing the float chamber, see that the air-vent hole and gasoline feed holes (L) are clear. The chamber should be replaced with the drain cock (G) toward the inlet manifold. See that the float-chamber gasket is in place, and that the nut (N) is drawn up tight.

The spray-nozzle seat at (D) is integral with the mixing chamber, and should it become badly worn or scored, the entire mixing chamber must be renewed; however, it is seldom that this is necessary.

To remove the needle valve:

1. Unscrew the needle-valve clamp nut (P).
2. Screw out the needle valve.
3. When replacing, see that the point of the needle valve enters the taper of the spray-nozzle seat, as there is considerable play in the threads.

To remove the air valve:

1. Unscrew and remove the air valve cap (AV), thus exposing the weight (W) with its sleeve. On top of the weight is a small fiber disk which deadens the sound of the weight striking the cap. There is also a fiber ring between the shoulder of the weight and the sleeve which also is for the purpose of deadening sound.
2. Remove the weight and sleeve, thus exposing air valve (B).
3. Unscrew the air-valve shaft (Q) and remove.
4. Remove the air valve through the opening of the air-valve cap. There is a fiber gasket secured to the air valve, which acts as a sound deadener.
5. Inspect the valve for cracks between the ball and the shaft bearing.
6. When the air valve has been replaced and the shaft inserted, tilt the carburetor to see that the ball falls freely back and forth. If it requires a jerk to cause this, either a new shaft or valve must be used.
7. See that all gaskets are in place when assembling.

THE HOLLEY CARBURETOR

The model "G" Holley carburetor was used on Fords up to January, 1920. The later Holley carburetor model "NH" was installed in January, 1920, the main difference between the two models being that in the later model, the passage of air is in a straight line, thus decreasing air friction.

Holley Model "G" Carburetor

This carburetor is shown in Figs. 117 and 118. The distinguishing feature of Holley carburetors is the small number of moving parts.

From the float chamber, the gasoline passes through the ports (E) to the nozzle orifice in which is located the pointed end of the needle valve (F) (Fig. 117).

FLOAT CHAMBER
FLOAT

Fig. 117. Side sectional view of Holley (Ford) carburetor model "G."

A drain valve is provided for the purpose of drawing off whatever sediment or water may accumulate in the float chamber.

The float level is so set that the gasoline rises past the needle valve (F) and sufficiently fills the cup (G) to submerge the lower end of the small copper tube (H). Drilled passages in the casting effect communication between the upper end of this tube and an outlet at the edge of the throttle disk (see 2).

The tube and passage give the starting and idling mixtures.

The strangling tube (1) gives the entering air stream an annular converging form, in which the lowest pressure and highest velocity occur immediately above the cup (G); thus it is seen that the fuel issuing past the needle valve (F) is immediately picked up by the main air stream, at the point of the latter's highest velocity. This is termed the venturi principle. This gives thorough atomization of the fuel and results in a very economical and powerful performance. The lever (L) operates the throttle.

For facilitating starting in extremely cold weather a disk attached to lever (S) at the air intake opening, with a spring return, is connected to a priming rod. By closing this, an excess of gasoline is drawn into the cylinders.

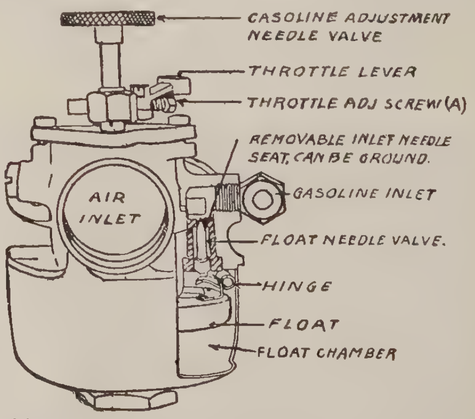

Fig. 118. End view of Holley model "G" carburetor.

Holley Model "NH" Carburetor

A sectional phantom view of the Holley "NH" carburetor is shown in Fig. 119.

Gasoline from the gasoline tank enters at the gasoline inlet passage (D), passes through the float-controlled valve (FS), and then into the float chamber (V). As a result of the suction of air caused by the engine piston, it rises in spray nozzle (**N**), where it is mixed with air from the primary air passage **T**).

When the engine is idling, this mixture is drawn through the low-speed fuel passage (**J**), and thus passes by the closed throttle plate (**H**) and thence into the engine. An air bleeding hole (**AB**) is provided in the low-speed fuel passage in order to cut down the suction, and consequently the amount of gasoline, when the throttle is completely closed.

As the throttle is advanced, a suction occurs at (**AB**), which increases the flow of gasoline through the low-speed fuel passage (**J**).

As the throttle is further advanced, the suction ceases through the low-speed fuel passage and passes to the choke in the center of the carburetor, thus causing the primary mixture to rise through the needle-valve passage (as shown in Fig. 119) and to become more thoroughly mixed with air before it enters the engine.

To Adjust the Holley Carburetor

This adjustment applies to both the models "G" and "NH." The usual method of regulating the carburetor is to start the engine, advancing the throttle lever to about the sixth notch. The flow of gasoline should now be cut off by screwing the needle valve (A) (Fig. 119) down to the right until the engine begins to misfire; then gradually increase the gasoline feed by opening the needle valve until the engine picks up and reaches its highest speed, and until no trace of black smoke comes from the exhaust. After determining the point where the engine runs at its maximum speed, the needle-valve clamp nut (C) should be tightened to prevent the adjustment from being disturbed. For average running, a lean mixture will give better results than a rich one.

The following indicate a lean mixture: To correct, turn the adjusting rod counter-clockwise.

1. The engine starts hard.
2. The engine backfires through the **carburetor** when the throttle is opened suddenly.
3. The engine will not idle.

The following indicate a rich mixture: To correct turn the adjusting rod clockwise.

1. Spark plugs foul quickly.
2. Exhaust gas causes the eyes to burn.
3. Black smoke from the muffler.
4. The engine operation is uneven, causing the rear axle to have an uneven hum which is distinctly heard at 13 m.p.h.

Holley Carburetor Needle-Valve Troubles and Remedies

Carburetors may leak from the following causes:

1. Sediment in the fuel lodging on the needle valve seat, preventing the needle from closing.
2. The inlet needle or seat damaged or worn.
3. The fuel level too high, flooding the nozzle.

These troubles may be overcome as follows:

1. Thoroughly clean the fuel tank, pipe, and carburetor, removing all sediment. After cleaning the fuel system, filter the fuel through a clean piece of chamois.
2. **Damaged float-inlet needle:** The inlet needle and seat should be replaced if a ridge is worn on the tapered point, or if the seat is scored; but in no case should a needle be replaced without a new seat, or vice versa.

   To remove the detachable seat, unscrew the float-chamber nut at the bottom of the carburetor, take off the float chamber containing the float and lever and inlet needle, then insert the socket wrench, as shown in Fig. 120.

   When installing new seat, do not turn it up too tight, as this may leave a burr inside which will interfere with the movement of the needle. After installing the seat and new needle, see that the latter works freely before attaching the float.

Adjusting of Fuel or Float Level on Model "G" Holley Carburetor

Attach the carburetor to the manifold and then take off the mixing-chamber cap by taking out the screws. This will enable you to see the nozzle and fuel level. Connect the fuel line to the carburetor; turn on the fuel; note where the level comes. The level should be as shown in Fig. 121.

Level too high, flooding the nozzle: Remove the float chamber and pry up the lever, as shown in Fig. 121 until the level is correct. The gasoline level should be from 1/16″ to ⅛″ lower than the top of the nozzle (Fig. 121).

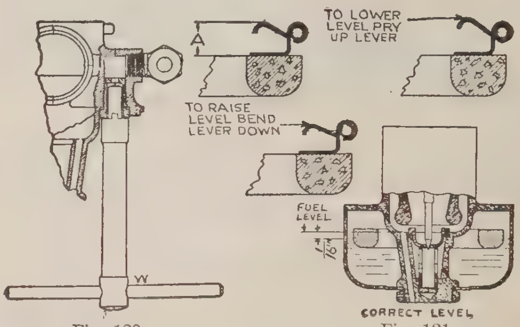

Fig. 120 Fig. 121

Fig. 120. Removing float needle-valve seat.

Fig. 121. Adjusting float level.

Fuel level too low: Should the level be lower than shown in Fig. 121, bend the tab on the float lever (that the needle rides on), down toward the float, as shown in Fig. 121 (upper sketch). It is best to detach the float and lever for this operation, by drawing out the float lever pin. The distance from the machined flange on the mixing chamber to the top of the float lever should be about ½″ when the float valve is closed.

Caution: It requires a bend of only 1/32″ on the float lever in order to change the gasoline level ⅛″. **When setting the float,** try to keep the part opposite the float lever at an angle, so that the pressure of the gasoline will assure a tight fit.

Adjusting of Fuel or Float Level on Model "NH" Holley Carburetor

Remove the float chamber bowl (V) (Fig. 119) by taking out the mixing-chamber body screw (R). When measuring at a point opposite to the float hinge, the distance from the flange, on which the gasket (U) fits, to the float should be ¼″ to 5/16″ when the float valve is closed. (For metal floats, the distance should be 3/16″ to ¼″.)

To Coat the Cork Float

(Applies to all Ford carburetors)

The float is impregnated with a composition to prevent it from becoming gasoline soaked. Sometimes this filler breaks down, destroying the buoyancy of the float, allowing too rich a mixture to enter the cylinders, or in extreme cases, causing the carburetor to flood. This condition may be noted by lack of luster on the surface of the cork, when the gasoline has dried from it. The float should be removed, by withdrawing the hinge pin, and it should be dried in a warm place, and then dipped into a thin shellac. A heavy coat of shellac will make the float so heavy that it will be impossible for it to control the gasoline supply. While the shellac is drying, the float should be suspended by a hook or string passed through the hinge. Nothing should be allowed to touch it until it is thoroughly dry.

Inspect the float to see that the cork is not cracked and that no pieces have been chipped out of it. See that the hinge is tight. If it is not, replace the float with a new one. While it is possible to tighten the hinge by peening the rivets, the chances of breaking the cork make this repair impractical.

Removing Spray Nozzle on Model "G" Holley Carburetor

First remove the small screws at the top of the carburetor and take off the plate into which the needle valve screws. Now remove the strangling tube, thus exposing the spray nozzle which may be removed with a socket wrench.

Removing Spray Nozzle on Model "NH" Holley Carburetor

Remove the float-chamber bowl, thus exposing the spray-nozzle seat, which may then be removed by a large screwdriver.

MORE MILES PER GALLON

There are three ways of obtaining more miles per gallon of gasoline: (1) by increasing the efficiency of the engine; (2) by reducing engine and running gear friction; (3) and last, but not least, by skilful driving.

The efficiency of the engine can be increased by careful carburetor adjustment, which must be changed frequently, if the best possible results are to be obtained. Worn carburetor parts waste gasoline and should be replaced. Either an attachment for leading hot air to the carburetor, or a special manifold, which heats the vapor mixture after it leaves the carburetor, should be used to insure complete vaporization of the fuel and give higher efficiency.

Carbon cuts down the efficiency of the engine and **should be removed occasionally.** Poor oil tends to form carbon, so good oil should be used, as it also causes less friction and wear.

Loss of compression, due to leaky piston rings or leaky valves, will cause a steady loss of power, which must be compensated for by opening the throttle wider, thus wasting gasoline. Scored or worn cylinders will have the same effect. And the valve tappets should be remedied, to provide the proper clearance, as given on page 1105.

Idling, or running the engine while the car is at rest, or racing the engine unnecessarily, tends to waste fuel.

Good ignition is another essential in making the most out of the fuel. Driving with a retarded spark tends to waste the power of the engine and causes overheating also.

Gasoline leaks from the tank, pipe line, or carburetor sometimes waste considerable gasoline and as the fuel evaporates as fast as it drips, this loss of fuel is not always quickly noticed.

The most economical driving speed is about 20 miles an hour.

Auxiliary Air Valves for Carburetors

The high cost of gasoline and the low cost of air has made many owners of cars wish that they could burn air instead of gasoline. While this is, of course, impossible, it is still quite true that a much greater mileage per gallon of gasoline can often be obtained by burning the gasoline vapor more completely in the presence of additional air.

Complete combustion occurs when there is sufficient air mixed with the fuel to furnish enough oxygen to combine with all the fuel particles. When complete combustion is obtained, no smoke or carbon will be formed. Thus the use of auxiliary air valves may reduce the amount of carbon deposited in the cylinders.

The mixture of gasoline and air as it comes from the carburetor is often full of little drops of almost pure gasoline. These drops are simply burned in the cylinder, instead of forming an explosive mixture, as they would if the mixture were more perfectly vaporized. The admission of air into the side of the stream of gasoline vapor often serves to form whirlpools which churn the gasoline particles into a more perfect mixture with the air.

If the carburetor mixture is perfect then the air valve is unnecessary. Unfortunately, most carburetors are far from perfect, and the air valve under the control of the driver compensates for carburetor deficiencies. The air valve, in most instances, increases the efficiency of any carburetor, if properly applied.

To determine if the auxiliary air valve is required, close the throttle and retard the spark until the engine runs as slowly as possible. Then adjust the carburetor until the engine runs smoothly and evenly on the least possible amount of gasoline.

Now take the car out on the road and, with the spark advanced and the car traveling at about twenty or twenty-five m.p.h., attempt to reduce the amount of gasoline by turning the carburetor dash-adjusting knob.

If the amount of gasoline can be reduced without greatly affecting the power and speed of the engine, the fitting of an auxiliary air valve will be advantageous.

Types of Air Valves for Carburetors

The type of air valve fitted should be one that supplies additional air at high speeds. But if, on the contrary, the engine requires a richer mixture at high speeds, when the carburetor is adjusted for good running at low speeds, then that type of air valve should be fitted that supplies air at low speeds, but is drawn closed by the suction at high speeds.

Correct adaptation of the air valve to the eccentricities of the particular engine and carburetor is necessary to get good results.

To obtain the best results from the auxiliary air valve, it should be easily controlled, preferably from the steering column. If it is operated from the dash, it will be little better than the carburetor adjusting knob, which is already provided. In fact, the idea of the air valve is to bring the carburetor more completely under the control of the driver.

Perhaps the **simplest form of auxiliary air valve** is that made by threading a **Ford oil cup** into a hole in the side of the intake manifold (see Fig. 122).

A strip of brass about ½" wide should be soldered to one side of the movable part of the oil cup, thus forming a lever by means of which the opening and closing of the air valve may be controlled. A hole may be drilled near the end of this lever, and a wire connected to the lever, this wire running through copper tubing, or a Bowden wire arrangement, to the steering column. The end of the wire may end in a loop or be connected to a small lever to suit the convenience of the driver.

Bowden wire is small, flexible, metallic tubing, with a strong but flexible wire running through it. It can be obtained from motorcycle agents, as it is used on the control system of many motorcycles.

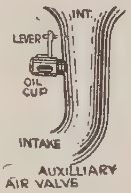

Fig. 122

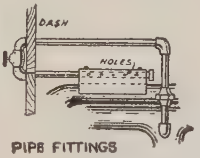

Fig. 123

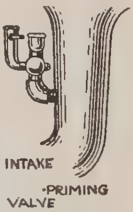

Fig. 124

Another simple form of air valve, which is more nearly airtight when closed, consists of a priming valve, screwed into an elbow attached to the intake manifold, as shown in Fig. 124. A hole can be drilled through the handle of this priming valve for the attachment of the wire to the steering-column control.

This air valve has the advantage that it can be used for priming in cold weather, or for introducing water or kerosene for loosening carbon deposits.

In winter, it is preferable to inject warm, rather than cold air into the manifold, and for this purpose it is often well to fit a soft copper pipe (which can be wrapped around the exhaust pipe) to the air valve.

An air valve made of standard quarter-inch pipe fittings and valve is shown in Fig. 123. The end of the intake pipe is covered with a sheet-iron sleeve, so that hot air will be drawn from the top of the exhaust manifold.

Another form of air valve, which eliminates the use of moving parts, is as follows: One end of a copper tube is fastened, by means of a brass coupling, to a hole in the side of the intake manifold. The tube is then given four turns around the exhaust manifold near the point where the exhaust pipe is connected. The copper tubing is then led along the dash and up the steering column, ending in an air valve directly under the steering wheel. Of course, this device can be used for priming the engine or injecting carbon-softening solutions.

When first installed, this device made a whistling sound when the air valve was opened, but this was overcome by rounding off the edges of the air valve, and since then has given entire satisfaction.

The auxiliary air valve is most useful in hilly country, for then conditions vary most widely. It is possible to use the air valve to make the engine act as a brake when coasting down hill. The admission of the air tends to cool the engine, so that the next hill will be climbed more easily. Opening the air valve also breaks the suction in the cylinders and keeps the oil from being drawn up and fouling the spark plugs when the engine is used as a brake on long hills.

A Primer

For extremely cold weather a method of priming is shown. Take off the inlet pipe and drill a hole for a 1/8" pipe tap, and fit a priming cock, as shown in Fig. 125.

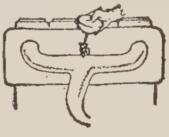

Fig. 125. Primer.

To operate: (1) turn off the switch; (2) pour about a tablespoonful of gasoline into the intake through this cock; keep an oil can filled for the purpose; (3) close up the cock; (4) crank three or four times with the switch off; (5) now turn on the switch, open the throttle, and the engine will start (see also page 1082).

Gasoline Tank Gauge

The method of constructing a gasoline tank gauge is explained on page 1082.

Control of Carburetor Mixture

A saving in gasoline: All Ford users are acquainted with the peculiarity of the Ford carburetor, in which variation of the strength of the mixture is obtained by altering the size of the jet, the alteration being effected by screwing a vertical needle up or down. This needle is tapered at its lower end, and the tapered portion enters the jet orifice; consequently, as the needle is lowered, the jet is closed; as the needle is lifted, the jet is opened and the size of the hole increased. This alteration is controlled by the driver through the medium of a rod which projects through the dash (Fig. 113). The top end of the rod is fitted with a suitable device, for convenience when handling; the lower end is forked, and the two prongs of the fork fit into suitable holes in a disk (on late models, a bar has been substituted) on the top of the needle already mentioned. (See holes in (A) Fig. 119.)

If you are a motor-wise driver, you set that disk differently for varying conditions, turning it counter-clockwise for starting, clockwise when you have started, and still further clockwise when you have been running for, say, 15 minutes. As the cool of the evening comes on, you will probably find it advantageous to turn the disk back again a little. In other words, you keep the disk set as nearly as possible for maximum efficiency of the mixture under all conditions.

The jet should be opened slightly so that sufficient gasoline is available for fast running, while at the same time the mixture would be too rich when running slow.

On the other hand, as the spark is advanced, the jet should be slightly closed and the mixture weakened.

The increase of fuel for an increased throttle opening is not much; it is just sufficient to allow of the correct proportions of gasoline and air being provided when the engine is demanding its full supply of gas. It is a known fact that a weak mixture can be readily fired by a spark when fully advanced. The result is an ecomony of fuel.

The conditions are always varying, and you cannot always be bending forward to twiddle that disk, and if you could, your adjustment would not be fine enough, and it means fine adjustment to keep the mixture just right. If it is not just right, you will be simply wasting gasoline instead of using it economically as an ingredient in an efficient explosive mixture.

This device provides an accessible control which will enable you to set the disk anew whenever conditions indicate the need, and to set it to a really fine point of adjustment, so that the mixture will not be in the nature of a compromise.

A method employed by an experimenter who is fond of tinkering is similar to devices used on some of the other makes of carburetors, and is nothing more than a hand control placed on the steering post as in Fig. 126 next column.

A steering column control is utilized, together with wire and casing. A small lever is riveted and soldered to the carburetor dash-control adjustment.

The fitting of the parts should be careful and accurate, so that there will not be the slightest play or lost motion.

If this device is used in conjunction with the throttle, as explained above, it is claimed that a saving of gasoline will be obtained, together with a cooler and smoother running engine. There are suitable graduations for different driving conditions, which the driver will soon learn, and the mixture can be made richer or weaker as required by the road driving conditions. Do not trouble, however, to experiment with this device unless you are a "fine point" driver, as it will be of little assistance unless you study out the principle and know when and how to regulate the adjustment.

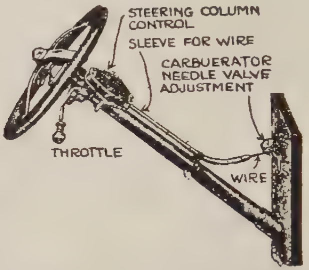

Fig. 126. Handy carburetor adjuster.

How to Save Gasoline

The illustrations below point out where care should be exercised in order to prevent loss of power, by decreasing friction and waste. To gain power means a saving of gasoline. The illustrations show where, if parts are kept in proper order, there will be a saving of power. Excess of power and loss of gasoline would come from poor driving, too much flooding of the carburetor, keeping the windshield constantly up, dragging brake bands, etc. See the three illustrations (Figs. 127, 127**A**, 127**B**). (*Ford-Owner and Dealer.*)

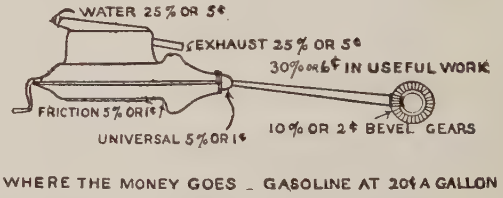

Fig. 127. **How the energy in a gallon of gasoline is distributed.** Note that if gasoline sells for 20c. a gallon, 30 per cent of it is consumed in useful work and 70 per cent in a loss, as follows: water 25 per cent, exhaust 25 per cent, bevel gears 10 per cent, universal joint 5 per cent, friction 5 per cent.

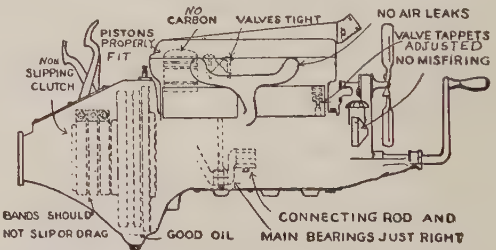

Fig. 127A. **In order to obtain the greatest percentage of power from the engine,** it is necessary to have properly fitted pistons and rings, tight cylinder-head-gaskets, no air leaks at inlet manifold, good carburetor mixture, no misfiring, properly seated valves, no air leaks at spark plugs or elsewhere, properly adjusted bearings, good oil, properly adjusted spark plug and coil, etc.

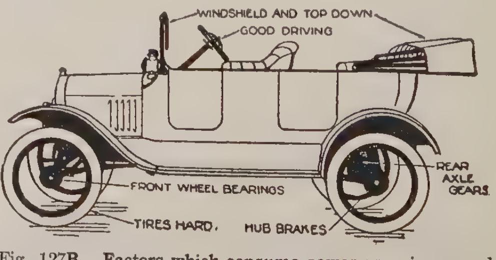

Fig. 127B. **Factors which consume power are:** improperly adjusted brakes that drag, improper lubrication, tires not fully inflated, wobbly wheels, improper use of spark and throttle control, windshield and top up, etc.

MISCELLANEOUS FORD TOOLS, TIME-SAVING DEVICES, AND ACCESSORIES

Device for Raising Rear End of Car

The illustration below (Fig. 128) shows the hook in position for raising the rear end of a car. By means of this device the rear end can be held up securely while removing or repairing the rear axle assembly or spring. In attaching the hook, place the clamps which are on the end of each bar on the frame; then bring the ends of the bars together, one bar resting in the safety clevis on the other bar. The links are then placed in the hook on the chain block, and the car is easily raised.

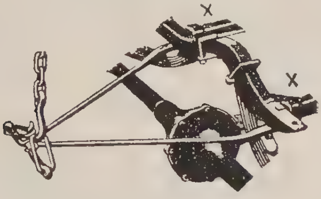

Fig. 128. Raising rear end of a Ford car.

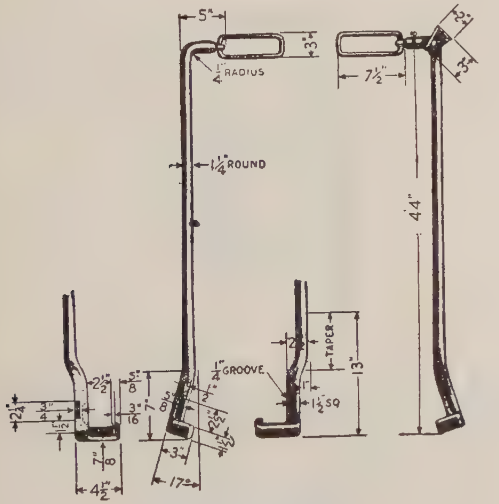

Fig. 129. Showing in detail with specifications the method of constructing the **rear-end hook.** This equipment can be made by local blacksmiths, and Ford agents will find it an efficient help in their repair work.

Device for Raising Front End of Car

The illustration (Fig. 130) shows a device in position for raising the front end of a Ford car while removing or repairing the front axle or spring. Each hook is placed on the fender iron below the nut on the end of the lamp bracket. The ring is placed in the hook on the chain-block, and the car is easily raised.

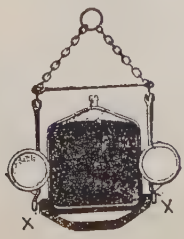

Fig. 130. Raising front end of a Ford car.

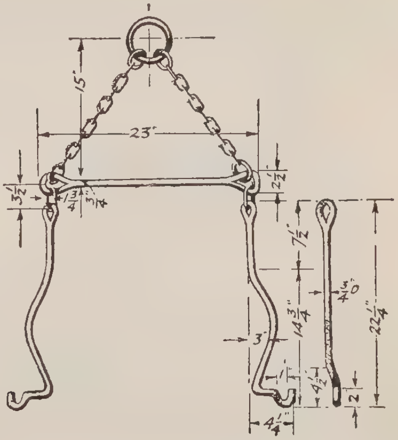

Fig. 131. Details of **front-end hoisting device.** Ford agents will be able to have this equipment made by local blacksmiths from the details and specifications shown. The front-end hook should be part of the equipment of every Ford repair shop. (*Ford Times.*)

Device for Raising Engine

An engine lifting hook, used in conjunction with a chain block, to remove the engine from the frame is shown in Fig. 132 below. It is in two parts, one U-shaped, and bent in the manner shown, having eyes to catch two manifold stud nuts; the other fastened to it, and bent to grab below the water jacket between the second and third cylinders. Ordinarily the manifolds, cylinder head, transmission-case cover, and crank-case base are removed, the illustration showing the application of the hook. When removed the engine will balance.

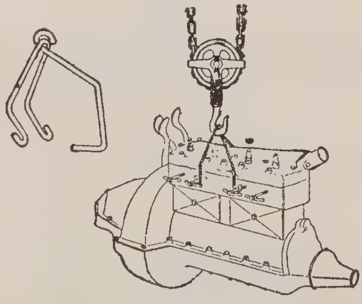

Fig. 132. Engine-lifting hook.

Towing in a Ford Car

When towing in a Ford car, when the differential happens to lock or the rear axle becomes defective, loosen the hub caps, remove the wheels, and withdraw the keys in the axle shafts. The wheels are then replaced, and the car can be towed in with the wheels turning free. Note: Grease well before starting.

Auxiliary wheels may be used for towing in a Ford that is disabled by having the rear axle broken near the hub. The device to be used is shown in Fig. 133.

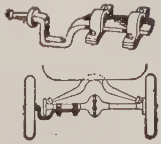

Fig. 133. **Auxiliary wheel for towing a disabled Ford.** A bar of steel about 3 ft. long and 1½ in. square is put in the lathe, and a standard Ford hub is turned on one end and fitted with the cones and locking nut. The other end of the bar is then forged out flat and bent to clear the rear brake band, after which the lower clamping straps are riveted on. The addition of the upper clamping straps and a standard Ford wheel makes the outfit complete. To use, the disabled car is jacked up and the auxiliary wheel clamped in place, permitting the car to be towed in. In the case of a front wheel the procedure is much the same, except that the cross-steering rod must be tied and the car towed very slowly. The device is not limited to use on the Ford, and has been used to bring in a 1-ton truck.

Valve Lifter

A tool for removing the valves may be made from a piece of steel ⅝" round and about 12" or 14" long, as shown in Fig. 134.

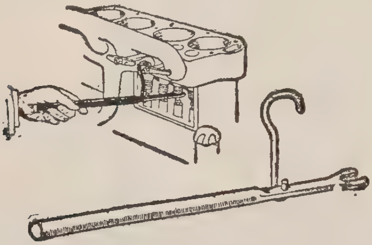

Fig. 134. **Ford valve lifter.** One end is flattened out for about 4", and is then drilled ¼", and the flattened end is then notched in the manner shown to permit insertion beneath the valve-locking washer. A piece of ¼" rod is then bent at both ends, one end passing through the ¼" hole in the lever, and the other being used to hook over one of the manifold studs. By the aid of this lifter the valve may be removed without removing either manifold.

Larger Valves

Valves, if made larger, will permit slightly more gas to enter and will increase compression and power, but heating will also be increased. In consequence, a circulating pump or a larger radiator may be necessary. A valve lift of 5/16" with a valve seat 3/32" measured across the slanting face would be about right.

Valves are now with a 1 5/16" outlet and 1½" diameter across the widest part, but for racing, valves of 1½" diameter outlet and 1 11/16" across the widest part would be better. The valve ports can be enlarged to this size by reaming and grinding. Tungsten valves of 1⅝" are sometimes used.

Circulating Pumps

Circulating pumps of unique and simple design are manufactured, by Giddings & Lewis, Fond du Lac, Wis.

Increasing Compression

This means that by reducing the space in the combustion chamber from the head of the piston to the inside top of the compression chamber of the cylinder—when the piston is in its uppermost position—the gas would be compressed tighter, and therefore a more explosive force would result when combustion takes place.

Opinions vary on this. For high-speed work it might possibly help—but the heating will increase, and a circulating pump or a larger radiator (special racing type—see Index) will probably be required. Refer to the discussion under "Compression."

The question was recently asked of a manufacturer of Ford parts:

Q.: Would you advise cutting the cylinder base down ⅛" to increase compression on the engine for racing?

Ans.: It is much easier to plane off the cylinder head. Another method would be to use special pistons to increase compression by ⅛ inch. We had an experimental machine fitted in this manner and found it satisfactory. This is no doubt the most practical way. Increased water capacity is necessary, and some form of circulating device, such as a pump, is advisable.

Right here the writer wishes to add that in a recent race tournament of Fords, not one of the engines had increased compression.

Miscellaneous Engine References

Piston clearance: See pages 809 and 811.

Remedying pumping of oil by the piston: See page 168.

Ford oversize pistons, etc.: This is treated under "Pistons." See page 812.

The piston pin is 47/64" in diameter by 3½" long.

Piston-pin bushings (pairs) are of phosphor bronze, 15/16" in diameter by 1 7/32" long.

Standard oversize pistons are supplied by the Ford Motor Co. Pistons of .0025" can be used in worn cylinders without reboring, but necessitate careful lapping. See page 811.

If a cylinder is out of round, reboring is necessary. Cylinder reboring tools can be secured of the Universal Tool Co., Inc., 435 Woodward Ave., Detroit, Mich., or of K. R. Wilson, Buffalo, N.Y. See also page 821 under "Enlarging cylinders."

Aluminum pistons: See page 807.

Ford Carburetor Wrench

A specially made wrench for tightening the carburetor to the inlet manifold is shown in Fig. 135.

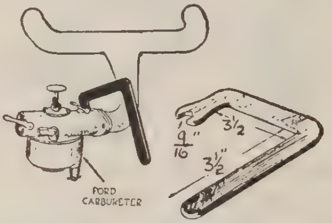

Fig. 135. **A special wrench for tightening the carburetor to the inlet manifold can be made of flat metal.** Dimensions are shown in the illustration.

Priming Cups

To fit priming cups to a Ford cylinder head, replace four of the cap screws with studs drilled as shown in Fig. 136.

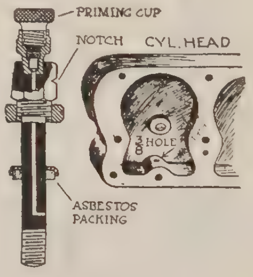

Fig. 136. Home priming bolt for the Ford car.

The cylinder-head bolts are removed, and the heads drilled as shown; that is, four ⅜" holes are drilled through the cylinder head. The special bolts are then inserted and permit the engine to be readily primed.

Priming Spark Plugs

Some spark-plug manufacturers make a spark plug with priming cup attached (Fig. 137). The old plug is removed and the priming plug is installed without making any changes on the engine. Priming is accomplished by pouring gasoline in the cup and then turning the pet cock on the cup, thus permitting the gasoline to flow into the cylinder.

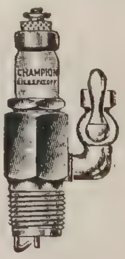

Fig. 137. Priming spark plug for a Ford car.

Pointers on Replacing Transmission and Cleaning a Clogged Engine Oil Pipe

The illustrations (Figs. 138 and 139) explain the method of replacing the transmission and of cleaning a clogged oil pipe.

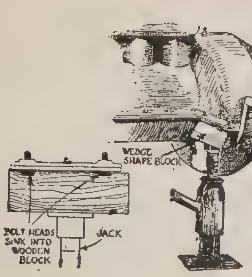

Fig. 138

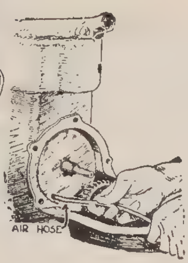

Fig. 139

Fig. 138. **The four bolts on the front of the Ford transmission can be replaced** by one man working alone, by inserting the bolts from under the car, laying a block of wood on top of a jack, and lifting the jack till the heads of the bolts are pressed into the wood. This keeps the bolts in place and prevents them from turning while the nuts are put on.

Fig. 139. **When the oil pipe of a Ford engine is clogged,** remove the radiator and take off the front gear plate. The cam gear is then removed with a puller. This will expose the end of the pipe. An air hose is connected to it and air is turned on, blowing the clog out. This saves tearing the engine down. If the pipe is clogged, the gears will be noisy. (*Motor World.*)

Oil-Level Gauge

A glass gauge oil-level indicator, when screwed into the engine crank case, will indicate the amount of oil at a glance (see Fig. 140). It is advisable to place a stock cock between the gauge and the crank case, and to keep it closed; open only when testing—to prevent loss of oil if the gauge breaks.

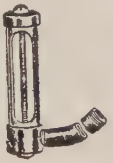

Fig. 140. Oil-level gauge for Ford engine.

Drill Press to "Run in" Ford Bearings, etc.

Ford main bearings, connecting-rod bearings, or oversize pistons can be run or worn in by bolting the cylinder block to the drill-press table, with the cylinder head removed and with four ½" pieces under the corners between the head and the table to give clearance to the pistons (See Fig. 141).

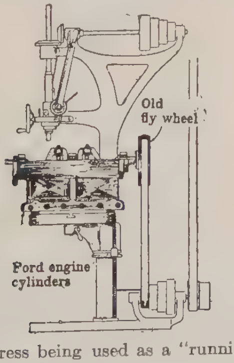

Fig. 141. Drill press being used as a "running-in" machine.

A flywheel of the bolted-on type is drilled to fit the flange of the Ford crank shaft, and is bolted on.

The table is turned so that the flywheel lines up with the drive pulley of the drill press, and is then belted up. An elevating screw is used to tighten the belt. See Index under "Running-in bearings."

Aligning Reamer

A reamer designed to ream all three main bearings simultaneously saves much time in scraping and refitting bearings. (See Fig. 142.)

The unequal distribution of weight and driving strain on the crank shaft of a Ford engine naturally causes unequal wear in the main bearing. It can be seen that tightening up only on the bearing caps will spring the shaft out of line and throw additional strain on the bearings, causing them to wear loose again very rapidly. This reamer will bring all bearings to proper size and perfect alignment An allowance of .0025" is made for wear of the crank shaft.

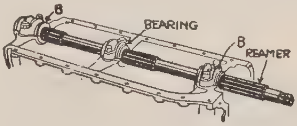

Fig. 142. Main bearing aligning reamer.

This reamer can also be used for reaming the connecting-rod lower bearings, as they are of the same diameter as the main bearings. (Stevens Co., N.Y.) See page 789, 714: "Align-reaming main bearings."

Running-in and burning-in Ford bearings is fully treated elsewhere in this book. See pages 787, 789.

Clutch Spring Tool

A device for compressing the Ford clutch spring is shown in Fig. 143.

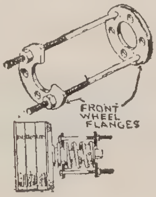

Fig. 143. **A device for compressing the Ford clutch spring.** The end plates are Ford front-wheel flanges, one being cut away, so that it may be inserted over the shaft, behind the spring. Two bolts connect the plates, and by tightening the nuts, the plates are drawn together, compressing the spring. With this device, only one pair of hands is needed to remove the pin.

Special Ford Wrenches

Some speed wrenches to save time on rear-axle work are shown in Figs. 144, 145, and 146.

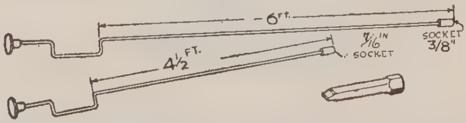

Fig. 144. The 6 ft. brace, with a ⅜" socket wrench is used for removing the **universal flange nuts** from the rear without having to get under the car. The 4½ ft. one, with a 7/16" socket, is used to remove the **torque tube retaining nuts** after the axle has been placed in the axle stand (Fig. 145).

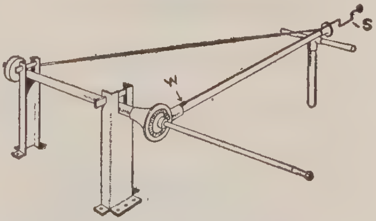

Fig. 145. Method of removing the torque-tube retaining nuts with a special speed wrench.

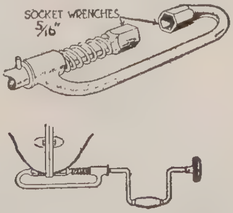

Fig. 146. Styled a "jew speeder wrench"; used in removing the 5/16" flange nuts and bolts holding the two halves of the axle housing together. (*Motor World.*)

A Home-Made Rear-Axle Stand

An axle stand designed for the Ford rear axle is shown in Fig. 147.

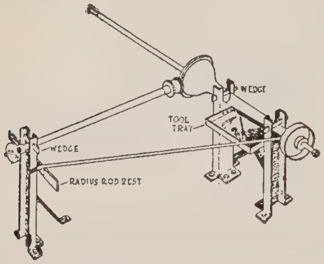

Fig. 147. **Rear axle stand** constructed of channel iron throughout. Each upright is laid out at a point of an L on the floor as shown. One half of the rear axle housing passes through, and is held by two of these uprights, the other upright holding the torque tube. A steel cross-piece is riveted to this latter upright, serving as a rest for the radius rods.

Special Reamers for Ford Car

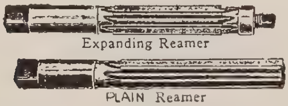

Fig. 148. Ford reamers.

An expanding reamer is shown in Fig. 148. A good set of reamers is very essential to the repairman. The particular reamer shown in Fig. 148 marketed by the Stevens Co., 375 Broadway, New York, is of an expanding type. They are ground .005″ undersize, and can be brought up to .005″ oversize. This is an added advantage.

Reamers are used for reaming out such parts as piston-pin bushings, steering-spindle bushings, transmission triple gear bushings, cam-shaft front and rear bushings, etc. In fact they are indispensable to the repairman.

A reamer for spindle-body and spindle-arm bushing is the 2-in-1 reamer for front-axle bushings. The 5″ section reams the spindle-body bushings in perfect alignment at one operation.

The 1″ section is for use in the spindle arm bushing.

A reamer for piston-pin bushing is used for reaming through both the piston-pin bushings to secure perfect alignment of the piston pins.

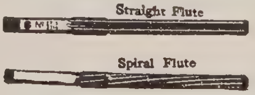

Fig. 149. **Reamers** are usually made with either straight or spiral flutes (see Index under "Reamers"). The Stevens Co., 375 Broadway, New York, furnishes reamers.

A spindle-bushing remover is shown in Fig. 150. The knurled end is inserted through either bushing and pulled through until the expander slips over the inside end of the bushing. Then by tapping on the knurled end of the tool with a hammer, the bushing is readily removed. By reversing the tool, the opposite bushing is readily removed. Made of carbon steel, spring hardened. (G. H. Dyer, Cambridge, Mass.)

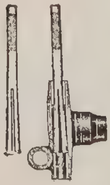

Fig. 150. Ford spindle-bushing remover.

Data on Overhauling a Ford Car

Fair charges for overhauling a Ford car are given elsewhere in this book. See page 758.

What constitutes an overhaul is described elsewhere in this book. See page 758.

Lights from Magneto

The "St. Louis Evenlite" is a device (Fig. 151) that controls the current from the magneto, and is for the purpose of producing lights that have the same degree of brilliancy at all engine speeds when the lighting current is taken from the magneto. It produces the full candlepower of the lights at 10 miles per hour, and will afford a full, clear light at 6 or 7 miles per hour with a very slight decrease from highest speed. It is made in two models, one to go on the dash under the hood; the other, to go on the steering post, includes a horn, a push button, and a switch with which the lights can be turned on, dimmed, or cut off. The device can be installed in thirty minutes. (Can be secured of A. L. Dyke, Granite Bldg., St. Louis, Mo.)

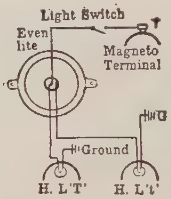

Fig. 151. Wiring diagram of the "St. Louis Evenlite."

The Atwater Kent Ignition for Ford Cars

This system is not the standard or regular equipment for a Ford car, but is a good ignition system to be installed on this car, especially when overhauling. With this system, only one coil is used, which is of the non-vibrating type. See Index under "Atwater Kent type CC ignition coil and distributor." (Atwater Kent Co., Philadelphia, Pa.)

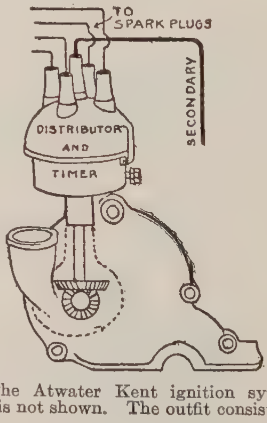

Fig. 152. The Atwater Kent ignition system for Ford engines. Coil is not shown. The outfit consists of the following parts:

1 No. 3079 Type CC 4 cylinder Unisparker with adjustable advance lever and mounting bracket attached.
1 No. 3071 coil adapter unit for primary circuit.
1 No. 3074 cap screw, 4 ⅛″ long.
2 No. 1049 cap screws, 1 ½″ long.
1 No. 3076 primary lead.
1 No. 1046 lock washer.
1 No. 1044 bevel gear.
1 No. 1910 complete set of secondary wiring.
1 No. 1048 advance rod.
4 No. 3075 spacing washers.
1 No. 1524 switch connection.
1 No. 187 wood screw, U. B. 71.

The Kemco Electric System for the Ford

Generator: Consists of a direct-current generator (13 lbs.), driven from the crank shaft by a Whittle V belt. It is mounted in the fan and charges a 6-volt battery which supplies current for lights, ignition, and the starting motor.

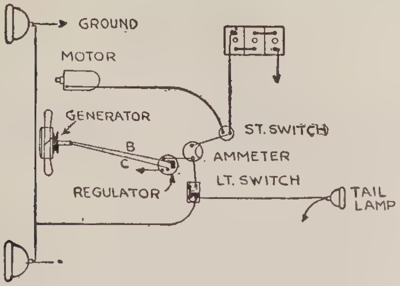

Fig. 153. The Kemco wiring diagram.

The starting motor is geared back 16 times. It is a series-wound motor, and starts the engine through a roller chain connecting with a sprocket on an over-riding clutch connected to the crank shaft. (Kemco Electric Co., Cleveland, Ohio.)

A Battery Charger

A battery charger illustrated in *Ford-Owner and Dealer* is shown in Fig. 154. With this device the alternating current is rectified to direct current. The magneto is intended to supply the current for charging. The rectifier and battery are placed in a battery box on the running board. The manufacturers are Warnerlite Products Co., Davenport, Iowa. Another rectifier of a different design is manufactured by Double EE Co., 2307 Bosworth Ave., Chicago, Ill.

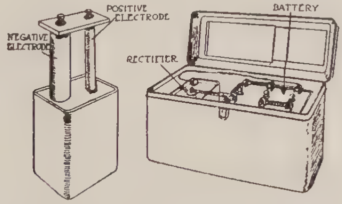

Fig. 154. **Warner battery charger for Fords,** for the purpose of charging storage batteries for the lighting system with current generated by the magneto.

Cotter Pins for Ford Cars

There is a total of 95 cotter pins used throughout the Ford car, and 6 different sizes, as enumerated in Fig. 155.

5—3/32 x ½″ No. 66
33—3/32 x ⅝″ No. 88
27—3/32 x ¾″ No. 753
4—3/32 x 1″ No. 421
11—1/16 x ½″ No. 544
15—1/8 x 1″ No. 82

Fig. 155. Ford cotter pins.

Tires

Two Ford cars may be so changed that each has the same size tires all around, without extra expense except for a set of 31″ x 3½″ tires. One will have 31″ x 3½″ tires, and the other will have 30″ x 3½″ tires.

Remove the wheels without hubs from the front of one car and the rear of the other. Place 30″ x 3″ rims all around on one car, and 30″ x 3½″ rims on the other. Put 31″ x 3½″ tires on the car with 3″ rims, and 30″ x 3½″ tires on the other car. This gives equal size tires all around, and extra size.

Spokes and rims can be had complete from the Ford Motor Co., ready to assemble to fit in the hubs.

Extra oversize tires: The 30″ x 3″ front rim on a Ford will take a 31″ x 3½″ or a 32″ x 4″ tire.

The 30″ x 3½″ rear rim will take a 31″ x 4″ or a 32″ x 4½″ tire. The 4″ and 4½″ tires, of course, will fit tight and are not recommended, but they can be put on by lapping the beads slightly.

Demountable Rims and Wheels

The advantages of demountable rims are explained on page 597. Rims for 30″ x 3½″ tires all round will make riding easier, will give longer life to the tires, and one has only one size of tire and tube to bother with. The Firestone Tire and Rubber Co., Akron, Ohio, makes this equipment for Ford and Chevrolet cars. The outfit consists of 5 rims for 30″ x 3½″ tires, 4 being applied to the wood wheels, and 1 spare; 24 hub bolts, and a socket wrench.

Visor Windshield Protector

To keep rain and snow off the windshield, a straight piece of fiber or thin sheet metal (6″ to 10″ wide) should have the corners bent at right angles, as shown by the dotted lines in the sketch (Fig. 156). These side flaps keep the snow from blowing in at the sides, and help to support the front edge of the visor. The rear of the visor should be fastened to the lower side of the front bow of the top, by means of a number of small, round-head wood screws and washers. (*Fordowner and Dealer.*)

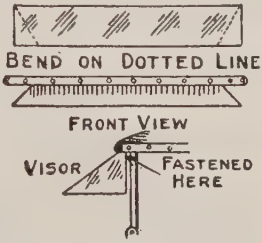

Fig. 156. Windshield protector.

Starting-Crank Rattle

This is prevented by the means shown in Fig. 157.

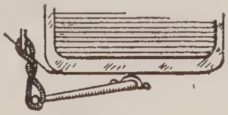

Fig. 157. A twisted spring will keep the starting crank from rattling. A screen door spring is often used.

Tool Box

A device showing how the door on a Ford car can be utilized as a tool box is shown in Fig. 158.

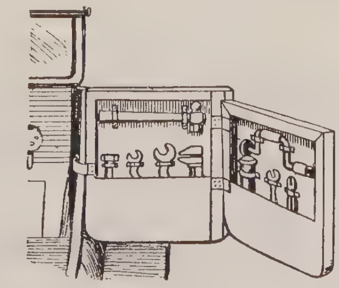

Fig. 158. **A tool box on the door.** The front door is arranged with a light door of strips of wood properly braced, the hinges screwed to a strip of wood placed up and down behind the metal door lock; the inner door-spring catch fits nicely in the notch left by removing the center cross-brace next the leather stop. Then a pocket made of canvas or leather is fastened in the lower portion of each door with a strap or two to keep the tools in place. Replace the door lining and put new strips of gimp, tacking with black-headed tacks as it was before. (*Motor World.*)

Power from Rear Wheels

This is unusual, but has been done, as shown in Fig. 159.

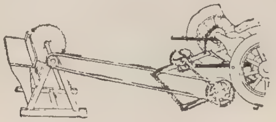

Fig. 159. Power from rear wheels. The device shown is self-explanatory.

Broken Speedometer Shaft

A simple method of repairing the speedometer shaft is shown in Fig. 160.

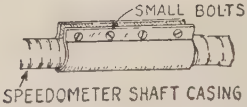

Fig. 160. To repair a broken speedometer-shaft casing, a sleeve is used as shown. A layer of tape is applied first.

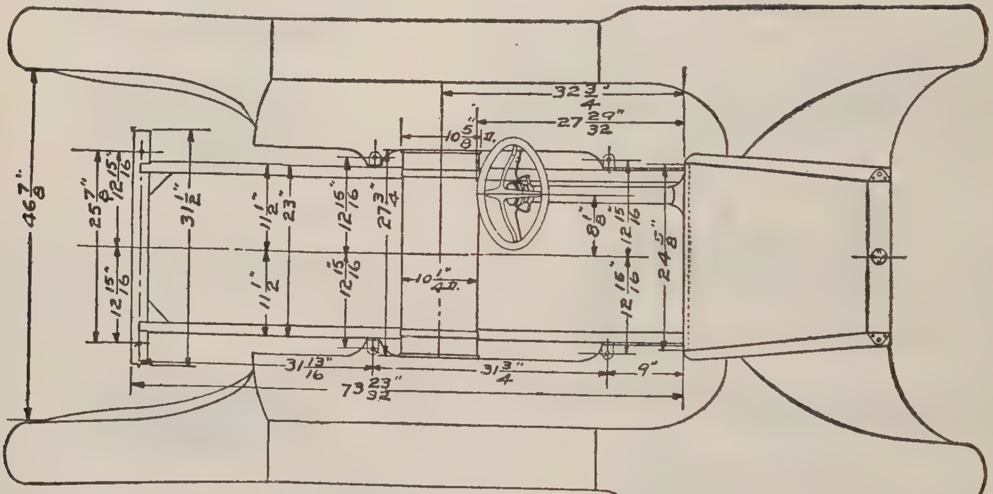
Muffler and Cut-Out

The construction of the Ford muffler and a method of attaching one type of cut-out is shown on page 49. The outside diameter of the exhaust pipe of a Ford is 1½"; therefore a cut-out would be required which would fit over it.

COMMERCIAL APPLICATION OF THE FORD MODEL "T" CHASSIS

The Ford is being rapidly adapted to a variety of commercial uses.

The illustrations (Figs. 1 and 2) show the principal dimensions of the side view (Fig. 2) and top view (Fig. 1) of the model "T" Ford chassis. These dimensions will be of value when figuring measurements for bodies for commercial use which can be applied to the model "T" Ford chassis.



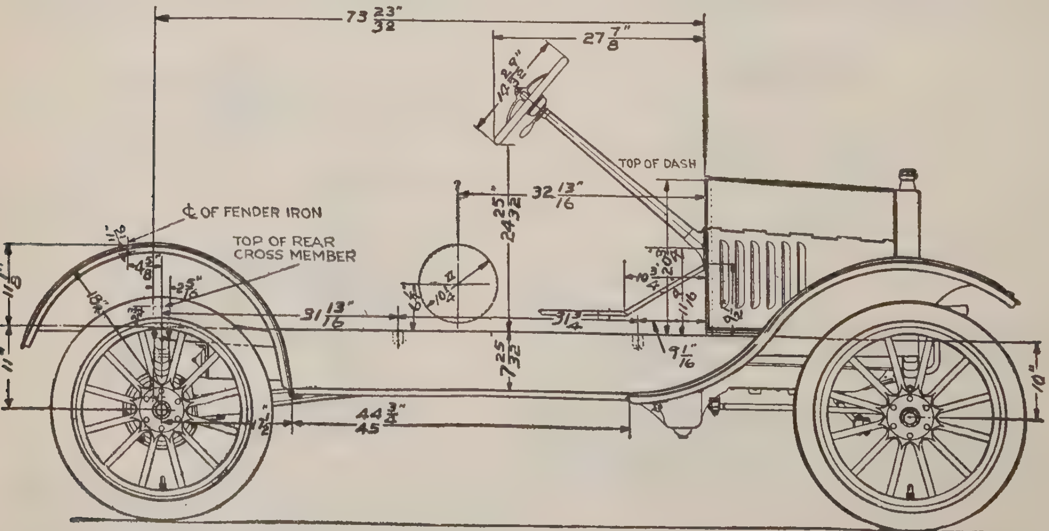


Fig. 1 (upper). Top view of Ford model "T" chassis.
Fig. 2 (lower). Side view of Ford model "T" chassis.

In the illustrations above, an assembly drawing of the model "T" chassis, with the principal dimensions for commercial body designing is shown. These dimensions apply regardless of the type of body to be installed.

The Ford Motor Co. does not recommend that the model "T" chassis with standard rear axle be used for truck use. The Ford truck with a special worm-driven rear axle (see Index) is furnished for this purpose. However, as there are many owners who desire to convert the Ford model "T" for commercial use, the following information may be of assistance.

See page 913: "Ford truck" for dimensions of the Ford truck chassis.

Combination Bodies for Model "T" Ford Chassis

The illustrations (Figs. 3 to 9) show how **several different types of bodies for commercial use can be made** from the lot of detachable parts illustrated in Fig. 10.

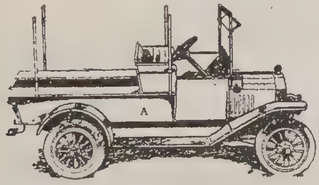

Fig. 3 shows the chassis with the base (A) fixed thereto, which forms the ground work of all the variations. The base (A), it will be noted, includes the seat for the driver and his companion.

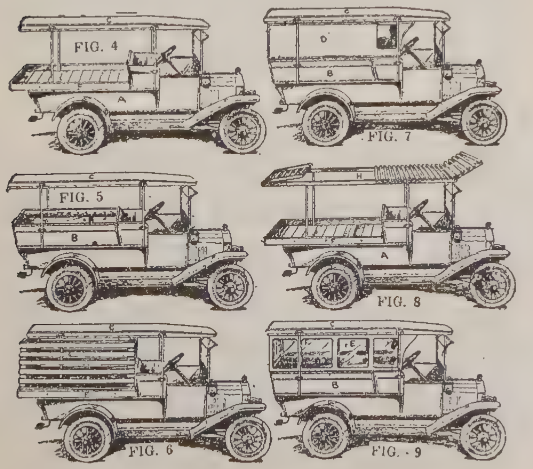
In certain cases individual pieces of parts shown in Fig. 10 have more than one use, for instance, the upright for the canopy top of the wagonette (Fig. 5) and the station omnibus (Fig. 9) is used to support the rack of the hay and straw wagon (Fig. 8), though when the last-named is used, an additional pair of supports can be fitted.

The station omnibus body has double doors, for the base carries permanently a half-door at the back. The upper half for the omnibus use is attached to the detachable panels; the half-doors are bolted together in use, so as to form a single unit.

The seat backs used for the wagonette (Fig. 5) and the station omnibus (Fig. 9) also form a part of the sides of the closed van (Fig. 7), and for the latter, the same canopy and upright are used. Instead of the upper half-door and rear panels of the station omnibus, the van has a back panel hinged at the top, two supports being provided to hold it open when required.



Figs. 4 to 9, showing different body constructions which can be assembled from the parts shown in Fig. 10.

The parts in Fig. 10 will make the following:

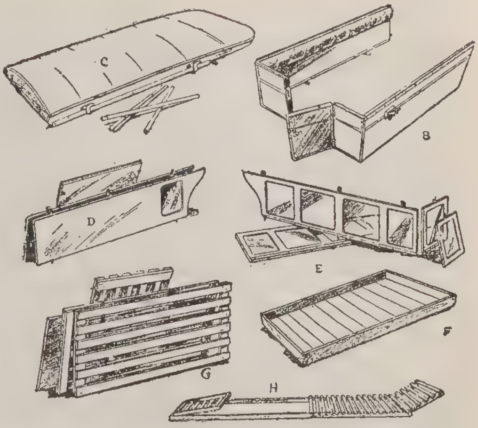


Fig. 10

Fig. 4. **The Flat Lorry** is made up of the base (A) (as on Fig. 3), the float (F), and the uprights and the canopy (C) (Fig. 10).

Fig. 5. **The Wagonette** is made up of base (A) (Fig. 3), and the parts (B) and (C) (Fig. 10).

Fig. 6. **The Live-Stock Dray** has a lattice (G) (Fig. 10), placed on base (A) (Fig. 3), and float (F) (Fig. 10).

Fig. 7. **The Closed Van** for perishable goods is made up of the base (A) (Fig. 3) with parts (B) (C) and (D).

Fig. 8. **The Hay and Straw Wagon** is made up of base (A) (Fig. 3) and parts (F) and (H) (Fig. 10), with canopy uprights.

Fig. 9. **The Station Omnibus** is made up from base (A) (Fig. 3), with sides (B), glass sides (E), and canopy (C).

Trailers[1]

Trailers are divided into two general classifications: the two-wheeled, or cart type; and the four-wheeled, or wagon type. The two-wheeled type is of course much simpler, and does not require any steering gear, being simply attached to the rear by a tongue and flexible connection. The attachment is usually made to the center of the rear cross-member of the chassis frame, where the spring is fastened—the spring clip bolts often being used to fasten the trailer connection.

On level country roads, Ford cars are sometimes used to pull from two to three of the light, two-wheeled trailers. When much used for pulling trailers, it is advisable to change the bevel gear and pinion in the rear axle, so that a gear ratio of 4 to 1, or as high as 6 or 7 to 1, can be obtained. This lessens the strains on the engine, transmission, and other parts of the power plant.

The capacity of the two-wheeled trailer is usually about half a ton, although some are made of a three-fourths ton capacity.

The capacity of the four-wheeled type of trailer is usually one ton or more. But a one-ton trailer is about as large as should be used in connection with a Ford car.

The speed, with trailer attached, is but little below that of usual touring-car speed. Twenty miles an hour is the usual speed.

Load distribution on two-wheeled trailers should be divided evenly in front of and behind the axle. Otherwise, severe strains will be placed on the connection between the car and the trailer, and the car may have to carry part of the load.

The coupling, or connection, between the car and the trailer should be quickly detachable, and should be provided with a cushion spring to asborb jerks and shocks when starting and stopping.

---

INSTRUCTION No. 86

THE LIBERTY ENGINE: History; Construction. GNOME ENGINE

BRIEF HISTORY

At the declaration of war, Mr. H. E. Coffin, and soon thereafter, Mr. E. A. Deeds, were called upon to organize the production of aviation equipment.

J. G. Vincent, Chief Engineer of the Packard Motor Car Co., and E. J. Hall of the Hall-Scott Co., of Berkeley, Cal., were called into conference at Washington, May, 1917. On May 29, these two men started the design of an 8-cylinder aviation engine to develop approximately 200 h.p., and a 12-cylinder engine to develop 300 h.p. The first engine, an 8-cylinder, was delivered to the Bureau of Standards, Washington, July 4, 1917, and ran successfully.

The Engine Production Department, a section of the Division of the Signal Corps, was created in August, 1917, with Lieut. H. H. Emmons in charge as Chief Engineer of the Engine Production Department.

The horsepower of the 12-cylinder engine was increased to 440 h.p., and in spite of many difficulties, more than 15,000 engines were produced by November 29, 1918, or within eighteen months after work began—certainly a marvelous accomplishment.

OILING SYSTEM

The oil supply for the Liberty engine is carried in a reservoir which is cooled. This reservoir is mounted somewhere in the vicinity of the engine, and from it oil is led to the connection on the right side of the oil-pump body, which is marked "oil in."

There are two oil pumps: a delivery pump and an oil-return pump. See Fig. 1.

Oil-return pump: Immediately above the oil-delivery pump is located the "oil-return pump" consisting of three gears, and driven by the same shaft as the delivery pump. The function of this oil-return pump is to draw the excess oil out of the crank case and return it to the oil reservoir. One half of this pump draws oil from the oil sump at the propeller end of the crank case, and the other half draws oil from the sump at the distributor end of the crank case. Both halves of the pump deliver oil to the connection on the left side of the oil-pump body marked "oil out," from which point it returns to the oil reservoir.

The oil-delivery pump takes the oil and delivers it under pressure to a distributor pipe (**C**) running the entire length of the crank case.

There is a pressure regulating valve between the pump and the distributing pipe which holds the pressure so that it does not exceed 50 lbs. per sq. in.

The oil-gauge pressure, after about 3 minutes of running at 600 to 800 r.p.m., should show about 5 lbs. pressure, and at 1,600 r.p.m. up to 30 lbs.

From the distributor pipe, there are pipes (**P**) leading to the main crank-shaft bushings. The crank shaft is hollow, and in the center of each main bearing there is a radial hole drilled through the shaft into the hollow center. A passage leads from each hollow main bearing to the adjacent crank pin, which is also hollow. A radial hole is drilled through each crank pin and carries the oil out on the surface of the pin.

There are oil grooves and passages in the connecting-rod bushings to insure proper lubrication for both the forked and plain connecting rods.

The oil spray thrown off by centrifugal force from the ends of the connecting rods lubricate the piston pins and cylinder walls.

A part of the oil conducted to the crank-shaft main bearing at the propeller end of the engine goes through a passage around this bearing and up through pipe leads (F) and (E), to the propeller end of the cam-shaft housings. From the end of the cam-shaft housing it is led around the end of the cam-shaft bearing through a passage drilled diametrically through the bearing midway of its length.

Once in every revolution of the cam shaft, a hole drilled through the cam shaft into its hollow center registers with the oil passage through the bearing.

Thus once in every revolution of the cam shaft a small quantity of oil is forced into the hollow cam shaft.

The oil is led through the cam shaft and out through holes drilled in it to each cam-shaft bearing.

The excess works out of the ends of these bearings and collects in small reservoirs to a depth of about ¼". The cams, in revolving, dip into this oil and splash it over the cam rollers.

The excess oil eventually finds its way to the gear end of the cam-shaft housings, over the gears, and down the drive-shaft housing into oil chamber (**O**), just above the oil pump.

The excess oil thrown off in the crank case by the connecting rods collects in this same chamber when the engine is inclined, so that the propeller end is high. If the propeller end of the engine is low, this oil collects in the oil pump or chamber at the propeller end of the crank case.

Starting Engine

Block wheels securely. With the ignition switches "off," turn the propeller forward five or six revolutions to distribute oil over the cylinder walls.

Set throttle slightly open, at a point which will run the engine at 600 to 800 r.p.m. Set spark at fully retarded position.

Prime engine (fill priming cock twice), and with ignition switch "off," turn engine forward two revolutions. Turn one (either one) ignition switch "on" and start the engine by pulling steadily down on the propeller blade. When the engine starts, turn on both switches and advance the spark halfway, leaving the throttle approximately in starting position, and allow the engine to run at idling speed (about 800 r.p.m.) for five or ten minutes until warmed up. At the same time test the crank-case temperature with your hand. The crank case should be warm by the time the temperature of the water has increased to 150° F. Accelerate and slow down the engine occasionally to throw oil up into the cylinders. When the engine is well warmed up, the throttle may be opened wide (wheels blocked), and the speed of the engine noted. The tachometer should show 1,550 to 1,600 r.p.m. on the ground.

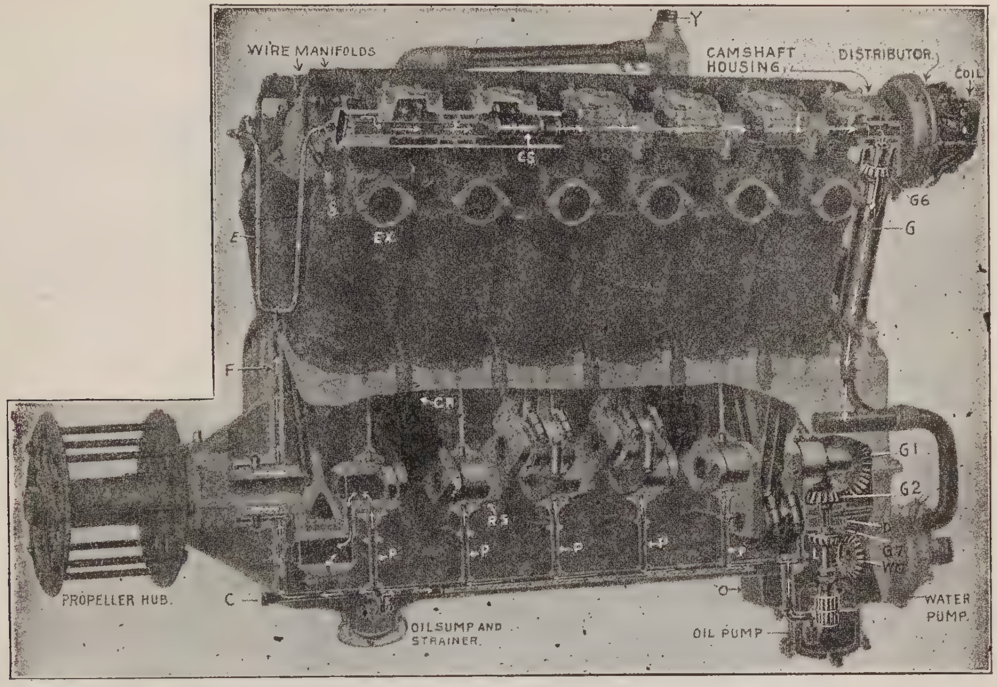

Fig. 1. (**Ex**) exhaust ports; (**CS**) cam shaft; (G6) cam-shaft drive gear; (G) drive-shaft housing; (G1), (G2), (G7), (L) (D) correspond with Fig. 5; (O) oil chamber above oil pump; (**WG**) water-pump gear; (C) oil-distributor pipe; (**CR**) connecting rods; (**RS**) crank shaft.

GENERAL CONSTRUCTION

The Liberty engine used in the De Haviland and other land planes and many seaplanes is a 12-cylinder "V"-type, with overhead valves and overhead cam shaft. It **weighs** approximately 890 lbs., and the **horsepower** ranges between 350 and 400 in the army type with the high-compression pistons, and between 320 to 340 in the navy type with low-compression pistons.[1]

The rated fuel consumption is 0.54 lb. a horsepower, or 36 gal. an hour with wide-open throttle at 1,700 r.p.m. Under service conditions about 30 gal. an hour is a fairly representative consumption.

The oil consumption is 0.03 lb. a horsepower-hour, or 1½ gal. an hour with wide-open throttle at1,700 r.p.m.

The horizontal flying speed of the engine is 1,700 r.p.m., and the ground speed is 1,600 to 1,625 r.p.m.

Cylinders

Cylinders: The design follows the practice used in the German Mercedes, English Rolls-Royce, French Lorraine-Dietrich, and Italian Fraschini before the war and during the war.

The cylinders are made of drawn-steel inner shells surrounded by pressed-steel water jackets welded to the cylinders and at their own seam. Each cylinder has one inlet and one exhaust valve and two spark plugs.

Angle between cylinders: In the Liberty the included angle between the cylinders is 45°; in all other existing 12-cylinder engines it is 60°. This feature is new with the Liberty engine, and was adopted for the purpose of bringing each row of cylinders nearer the vertical and closer together, so as to save width and head resistance. By the narrow angle greater strength is given to the crank case, and vibration is reduced.

A disadvantage of this angle, if used for automobile work, would be the resulting uneven firing impulses, which would be noticeable at low speeds. Under these conditions, in the course of the distributor brush rotation, the sparks first occur close together (22½)° and then far apart (37½°).

With the airplane engine, however, where the speed is usually high and constant, the uneven impulse is not noticeable.

The bore is 5″ and the stroke is 7″, the same as on the Hall-Scott "A-5" and "A-7" engines, and as used on the Hall-Scott 12-cylinder engine. The **piston displacement** is 1,649.34 cu. in.

An engine in all respects identical with the Liberty airplane engine, but having cast-iron cylinders, is used in "tanks."

Pistons

The pistons are of aluminum, and are of the Hall-Scott design.

There are two designs of pistons used, one for the army and one for the navy.[1]

The army type of piston has a crowned head which gives an 18 per cent compression space.

---

[1] Engines required for different classes of work were: (1) elementary training planes; (2) advanced training planes; (3) combat planes. For (1) Curtis "OX", 90 h.p. engine, and Hall-Scott "A-7A." 100 h.p. engine, were used. For (2) the Gnome 110 h.p. engine, made by the General Vehicle Co., Long Island, N.Y., and the Le Rhone (similar), of 80 h.p., made by the Union Switch and Signal Co., Swissvale, Pa., and the Hispano-Suiza, 150 h.p., by the Wright-Martin Co., New Brunswick, N.J., were used. For (3) the Liberty engine was used. It was estimated that 22,500 would be required for the army and navy.

[1] The navy type usually works at low altitudes and the army type at high altitudes, hence the reason for low and high-compression pistons.

The navy type of piston has a flat head which gives a 20.5 per cent compression space.

The pistons are 5″ long, and have three rings of the eccentric type, all at the top of the piston. These piston rings are assembled with a gap between the ends of the rings not less than .025″. The pistons of the engine weigh 3 lbs. 3 oz. and are fitted with a clearance of .018″ to .020″.

Piston Pin

This is a seamless steel tube, the tube being a drive fit into the bosses on the aluminum piston. The tube is 1¼″ in outside diameter and is surrounded by a bronze bushing upon which the upper end of the connecting rod bears.

Crank Shaft

The design follows the standard 12-cylinder practice, except as to oiling.

The crank shaft is a drop-forged 7-bearing crank shaft 2⅝″ in diameter, the longer being at the propeller end.

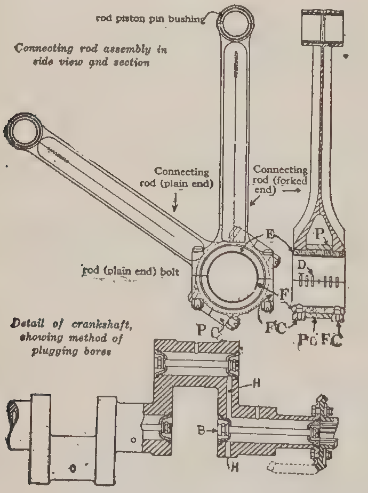
The shaft carries a propeller hub at its forward end, and at the rear end carries a bevel gear for driving the valve mechanism.

A double-row thrust bearing at the propeller-hub end of the crank shaft takes the end thrust on the shaft.

The shaft is drilled for oil passage, the openings being drilled through the crank cheeks through the crank pins.

Connecting Rods

The forked or straddle-type connecting rods of I-beam type are used. This type of connecting rod was first used on the French De Dion car, and on the Cadillac in this country. The length is 12″ between centers. Both crank shaft and connecting rods are made of chrome nickel steel.



rod piston pin bushing

Fig. 2. Note that the lower part of the plain end **connecting rod** is placed between the forks of the forked end rod. (P) shows a section of the lower end of the plain rod over the bearing bushing (E), which is the upper half of the bearing bushing, and (F) is the lower half. The plain rod has one cap (PC) and the forked rod, two caps (FC). The left rods are forked, and the right are plain.

The clearance between crank pin and lower connecting rod bushing varies from .003″ to .004″.

Clearance between the plain rod and the back of the bushing is .005″.

The bushing carried by the forked rod should have from .010″ to .020″ side play on the crank pin.

The plain end rod should have from .004″ to .008″ side play in the forked rod.

Crank Case

The crank case is in two pieces, both of which are aluminum castings.

The crank-shaft bearings are on a line with the split in the crank case, the lower halves of the crank-shaft bearings being held in the lower half of the crank case and the upper halves in the upper half of the crank case.

The two halves are tied together by long bolts or studs (S) (Fig. 3), which pass through the upper half of the crank case, through bosses, the nuts being at the top of the upper half of the case. This gives an accessible construction which is at the same time rigid.

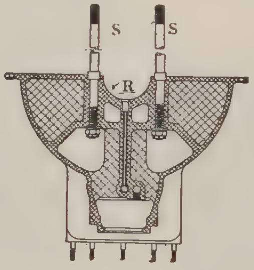

Fig. 3. Cross-section through lower half of crank case.

A careful joint is made between the two halves of the crank case in order to secure the desired alignment at the main bearings, the joint being lapped.

Cooling System

Cooling water is circulated through the Liberty engine by a centrifugal pump running at one and a half times the engine speed.

The capacity of this pump is 100 gal. a minute at 1,700 r.p.m. The cooling system from the pump inlet to and including the water outlet header will hold 5½ gal. of water, or 46 lbs.

Cold-Weather Instructions

Anti-freezing preparations are not used. The cooling system is filled with boiling water.

Hot lubricating oil is put into the crank case. Oil can be heated in an open-top container set in boiling water.

The engine is primed to start at slow speed. It is then run on the ground until the oil has been thoroughly distributed.

The plane is not taken from the ground until the water temperature is 160° F. The engine should not remain stationary more than 10 minutes at a time, as it will get cold again. The temperature of the water should not exceed 200° F., and should average about 180°.

After finishing a test flight, all oil and water should be drained before the engine cools.

The spark plugs should be removed from the engine and kept in a warm place, if the engine is to stand idle over night or for a long period.

Propeller

The propeller is 9 ft. in diameter; the blade is 9″ in width. The difference in pitch between the two blades is 1/16″ in 9 inches. The Hall-Scott propeller hub was adopted.

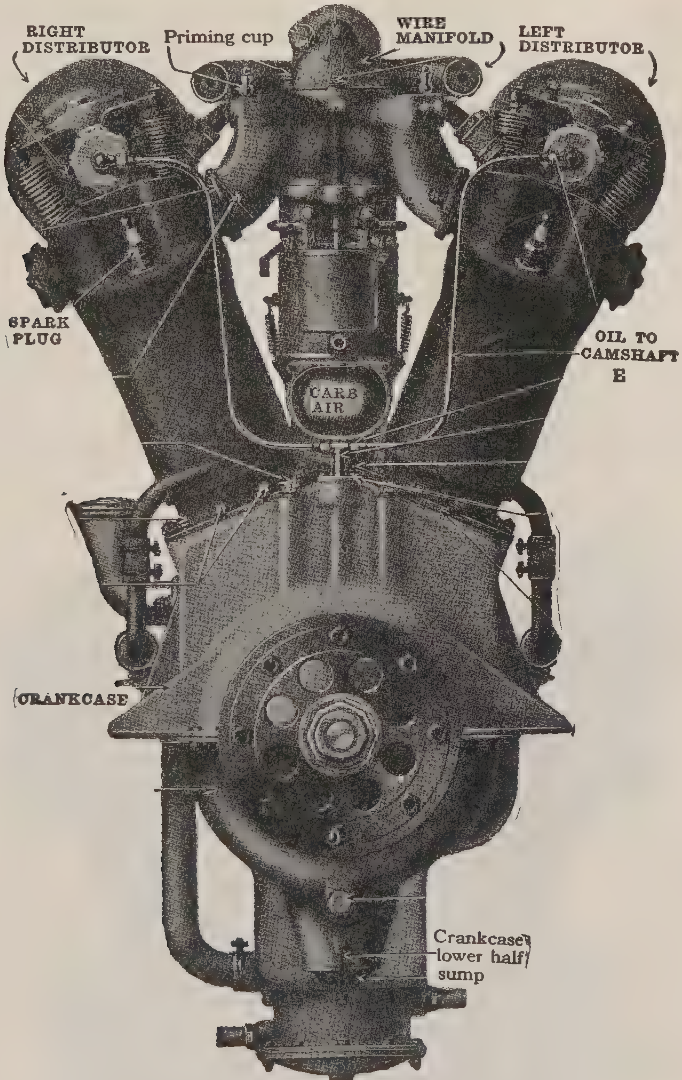

Fig. 4. Propeller end view of Liberty "12" engine.

Valves

The valves are mounted in the heads of the cylinders and are inclined at an angle of 15° to the center line of the cylinder, so that the angle made by the center lines of the two halves is 30°.

The valves are of the standard mushroom type with a 45° seat. The cylinder heads are bushed for the valves, and the valve springs are of the double concentric type.

The intake manifold passes between the two rows of cylinders, and the carburetors in most of the installations are mounted in the "V."

The entire valve drive is housed above the cylinders and can be readily removed without tearing down the engine.

The valves are operated from the cam shaft by roller cam followers, which actuate the rocker shaft and in turn the valve rocker arm or lever.

To adjust valve clearance: Turn the tappet screw (see Fig. 14, page 1151).

Cam-Shaft Drive

The cam-shaft drive was copied almost entirely from the Hall-Scott engine. In fact, several of the gears used in the first sample engines were supplied by the Hall-Scott Motor Car Co. This type of drive is used by the Mercedes, Hispano-Suiza, and others.

By referring to Fig. 5, on next page, the drive system can be seen.

Drive-Gear System

(G1) is the main drive gear on the end of the crank shaft; **(G2)** drive gear for lower oil and water-pump shaft; **(D)** bearing assembly; **(G7)** drive gear for water pump; **(N)** oil plug; **(L)** oil-pump shaft (runs at 1½ times the engine speed); **(G3)** driven gear for upper shaft; **(G4)** drive gear for the two inclined shafts (through **G5**), which drives the right and left overhead cam shaft.

The inclined shafts revolve at 1½ times the engine speed; **(G6)** is the gear (one on each inclined shaft) to drive the cam shaft; the **cam shaft** revolves at one-half the engine speed; the **distributor rotor** or brush, is driven from the cam shaft, at cam-shaft speed.

Tachometer drive and gun synchronizer: Provision is made for mounting a mechanically driven air pump on the distributor end of the engine crank case and for driving it by means of a splined shaft fitting into the crank-shaft gear. An extension of this shaft carries a double adjustable cam designed to operate a machine gun. The over-all length of the unit is 6″.

The tachometer is driven from the generator shaft.

Valve Pointers

One method for testing gas tightness of a valve: This can best be done by inverting the cylinder with the valves in place and pouring a small quantity of gasoline in the cylinder. Watch for seepage around the valve. If the valves show any leak, they should be carefully ground in. The cylinder, for this operation, should be **held in position** by means of the flange at the bottom.

Valves should not be ground any oftener than is absolutely necessary; and then only enough to "clean up" the seat. If a valve is pitted or warped to such an extent that it is necessary to grind it heavily, care should be taken that any ridge or shoulder formed on the edge of the valve seat be dressed down with a fine mill file. The abrasive should be carefully washed off the valve, the seat, and the inside of the cylinder. Test the seating of the valve with Prussian blue.

The exhaust valve spring exerts a pressure of 45 lbs. when compressed to a length of 2¼″. The intake-valve spring exerts a pressure of 23½ lbs. when compressed to a length of 2¼″.

Piston Pointers

Examine the piston for scores. It is very likely that the pistons will show scratches which were

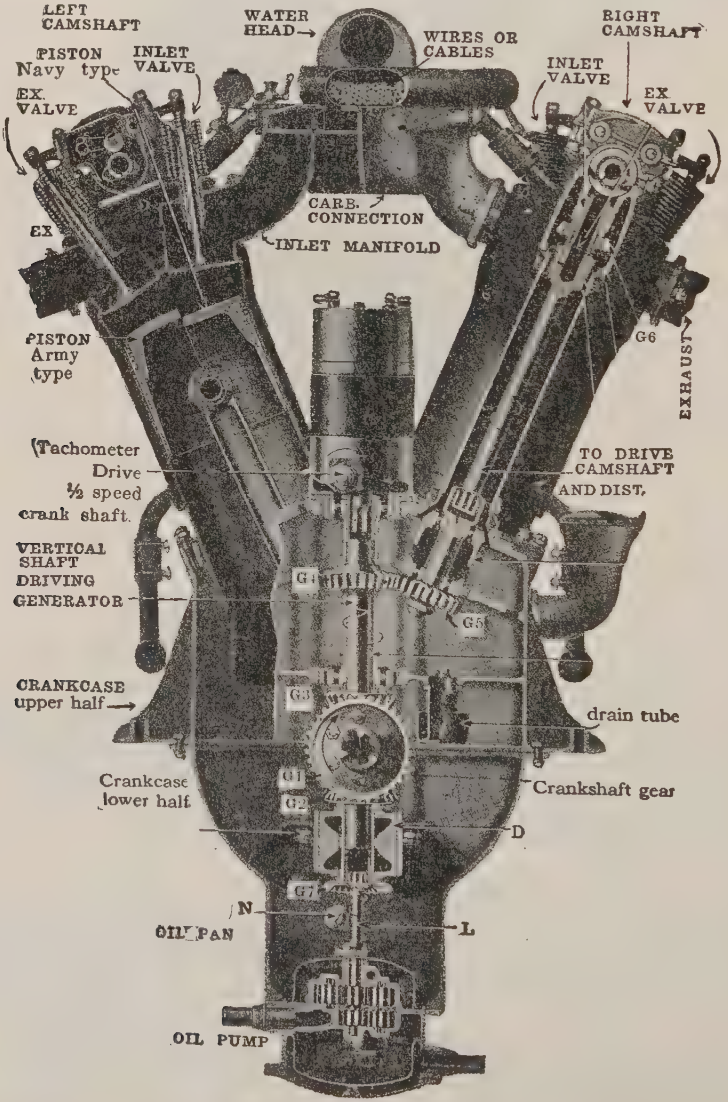

Fig. 5. Transverse section, **from distributor end,** showing how the **oil and water pump, generator and cam shaft are driven,** and also the valve action.

caused during the first run-in of the engine. It is difficult to draw a line of distinction between what is termed a scratch and a score. A piston should not be discarded unless the scores extend past the piston rings and seem to be of recent origin.

Examine the piston for even bearing on its outside surface. If any piston shows excessive wear on one side at the bottom and not at the top, it is an indication that the connecting rod is twisted or bent. This rod should be straightened up before assembling.

Piston Rings

Examine the piston rings for even bearing on the outside surfaces. The ring should be a free fit in the grooves, and should not be so loose that any shake is noticeable.

Inspect the condition of the ring grooves through the ring gap as to carbon deposit. If the carbon is soft and not of great amount, it may be wiped out with a soft rag over a splinter of wood inserted through the gap in the ring. If the amount of carbon is excessive and caked hard, the ring should be taken off.

Ring grooves should be wiped out with a soft cloth moistened with gasoline, and any carbon caked in these grooves may be scraped out with a piece of wood.

It is preferable to put back the old rings, if the wear has not been too excessive, than to fit new rings which have not been run in.

The gap between the ends of the ring should not be less than .025″ when the ring is fitted in the cylinder.

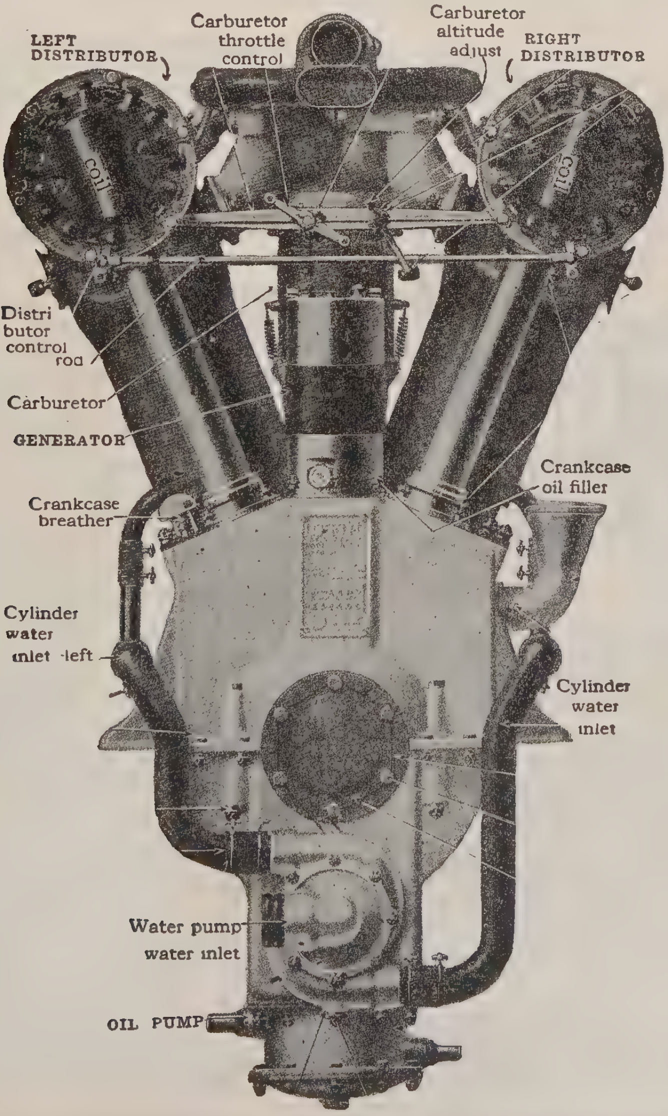

Fig. 6. **Distributor or rear-end view** of Liberty "12" engine. Note that the **high-tension ignition coils are an integral unit of each distributor,** being placed on their front. Note, too, that **all controls** are at this end of the engine.

Connecting-Rod Bearings

If the bearing has been damaged or shows wear to such an extent that it is advisable to replace it, the new bushings should first be fitted in the forked end rod. Be sure that bushing seats properly in rod and dowel does not hold it away at any point.

The caps of the forked end rod should be put in place and drawn up tightly.

Examine the joints between the cap and the rod and between the two halves of the bushings. Caps and bushings should bear equally hard at the joints.

The bushing should then be scraped to a free fit .003″ to .004″ larger than the crank pin.

The ends of the bushing should be dressed off with a fine mill file, and a sufficient amount should be removed to permit from .010″ to .020″ side play. Touch up the radius at each end of the bushing with a scraper until it clears the fillet of the crank pin. Test this point by coating the crank pin and each fillet lightly with red lead or Prussian blue.

After fifty hours of running, the engine should undergo a thorough inspection.

CARBURETION AND FUEL SYSTEM

Two Zenith duplex carburetors are used. This is equivalent to four single carburetors, each one supplying three cylinders of the engine.

Each duplex carburetor consists of a single float chamber (Fig. 7) and a single air inlet joined to two separate and distinct spray nozzles, venturi and idling devices. See also page 131.

Each of the two barrels of each carburetor is fitted with a throttle valve of the butterfly type. The two pairs of throttles are operated simultaneously by a shaft provided with an adjustment at each end by which the pairs may be synchronized.

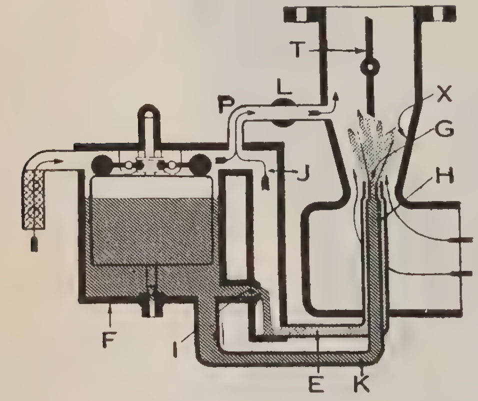

Fig. 7. Zenith carburetor.

An altitude adjustment is incorporated in this Zenith airplane type of carburetor, the purpose of which is to adjust the gasoline supply to the changed conditions met with at higher altitudes.

If a carburetor is adjusted to deliver a properly proportioned mixture at sea level, it will supply an increasingly "rich" one as the machine mounts to higher altitudes, owing to the fact that the air is lighter and less dense in the higher altitude.

The principle of the altitude adjustment, shown in Fig. 7, is as follows: The float chamber is open to the air through two screened air inlets.

The well (J) is in open communication at its top with the float chamber.

A passage (P) is provided from the float chamber to the carbureting chamber below the throttle valve; this passage is fitted with a stop cock (L), which is manually operated from the pilot's seat.

Under normal conditions, that is, on the ground, the stop cock (L) should be closed and the gasoline in the float chamber will be subjected to atmospheric pressure through the screened-air inlets.

When the engine is running, the partial vacuum produced in the throat or choke (**X**) will draw the gasoline out of the nozzle (**G**) and (**H**) in proper proportions.

At an altitude of about 6,000 feet, the aviator will begin to open the valve (**L**), thus drawing air from the float chamber and establishing therein a partial vacuum, which depends on the degree of opening of stop cock (**L**); this partial vacuum will impede the flow of gasoline through the jets, and the mixture will be made more lean.

The altitude valve should be opened as far as possible consistent with obtaining the greatest number of r.p.m. of the engine.

The float level is set so that the gasoline level is ⅛″ below the main cap jets.

Gasoline System

The air-pressure feed is used from the main gasoline tank. The initial pressure (3 lbs.) is obtained from the hand pump (Fig. 8). After the engine is running, the air pressure is obtained from the power air pump on the engine.

The auxiliary gravity feed tank, located overhead, is filled by pressure from the main tank. See Fig. 8, for further details.

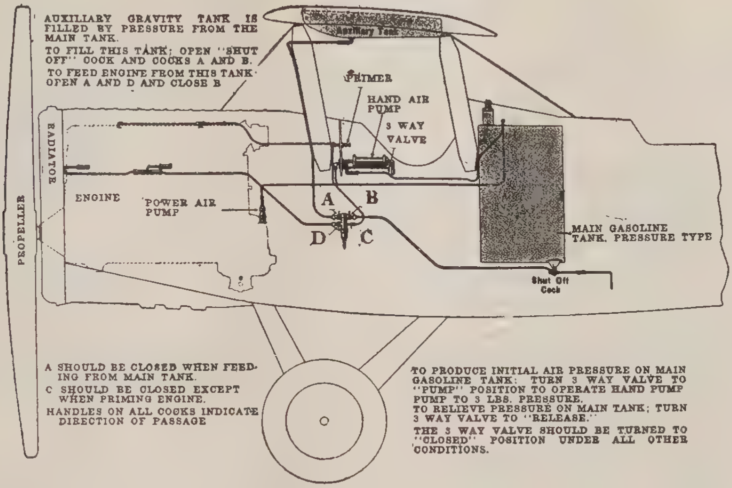
The engine-driven air pump with its regulator is designed to hold the pressure on the gasoline tank to approximately 3 lbs. In order to determine whether or not the pump is functioning properly, screw **down** the pressure-regulator adjusting screw. This should cause the pressure in the tank to rise, if the pump is operating as it should. Now screw the regulator adjustment **up** until the pressure is held steadily at 3 to 4 lbs.

Gasoline recommended: Specific gravity; 58 to 65 Baume; initial boiling point, 102° F., not higher than 120°; final boiling point 350° F.

Fuel consumption is .54 lbs. per horsepower-hour, or 36 gal. per hour with wide-open throttle at 1,700 r.p.m.

The gasoline pipe is annealed copper tubing ⅜″ inside diameter from the tank to the T between carburetors. From this T to each carburetor, the pipe is 9/32″ in diameter.

The air-pressure pipe is 3/16″ inside diameter, copper tubing.



AUXILIARY GRAVITY TANK IS FILLED BY PRESSURE FROM THE MAIN TANK.

TO FILL THIS TANK; OPEN "SHUT OFF" COCK AND COCKS A AND B.

TO FEED ENGINE FROM THIS TANK OPEN A AND D AND CLOSE B

A SHOULD BE CLOSED WHEN FEEDING FROM MAIN TANK.

C SHOULD BE CLOSED EXCEPT WHEN PRIMING ENGINE.

HANDLES ON ALL COCKS INDICATE DIRECTION OF PASSAGE

TO PRODUCE INITIAL AIR PRESSURE ON MAIN GASOLINE TANK: TURN 3 WAY VALVE TO "PUMP" POSITION TO OPERATE HAND PUMP PUMP TO 3 LBS. PRESSURE.

TO RELIEVE PRESSURE ON MAIN TANK; TURN 3 WAY VALVE TO "RELEASE."

THE 3 WAY VALVE SHOULD BE TURNED TO "CLOSED" POSITION UNDER ALL OTHER CONDITIONS.

Fig. 8. Fuel system.

LIBERTY ENGINE ELECTRICAL SYSTEM

Ignition

The ignition system (Delco) used on the Liberty "12" is of the battery type with two independent breaker and distributor mechanisms, mounted on the ends of the cam shafts, identical in every respect and each one firing all twelve cylinders.

These distributors are supplied with electrical energy from two sources: For starting and idling speeds up to 650 r.p.m., current is drawn from the specially constructed 4-cell storage battery which has sufficient capacity to ignite the engine at full speed for 3 hours and is so constructed that it will function properly upside down (8-volt, 11 ampere-hour capacity).

The generator builds up so that it takes up the load at 650 r.p.m.

Two main contact-breakers connected in parallel are located in each distributor box, and the two circuit-breakers are timed to operate simultaneously. The two contact-breakers are furnished in duplicate, as a precautionary measure. The breaker cams have 12 lobes.

Auxiliary contact-breaker is to prevent the production of a spark when the engine is turned backward or "rocked." This auxiliary breaker (Fig. 9) is connected in parallel with the other two through a resistance unit which reduces the amount of current flowing through it. The breaker is so timed that it opens slightly **before** the other two when the engine is turned in a forward direction. The opening of the main breakers then results in the production of a spark.

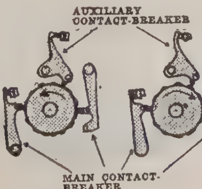


Fig. 9. Auxiliary ignition contact-breaker.

When the engine is turned in a **backward** direction, the two main breakers open first and no spark is produced owing to the fact that the current continues to flow through the coil through the auxiliary breaker, but in diminished quantity, because of the resistance unit. By the time the circuit is opened at the auxiliary breaker, the intensity of the magnetic field of the coil has weakened to such an extent that no spark is produced.

A coil is incorporated in the cover of each distributor head (see Fig. 6, page 1147).

Generator

In addition to the battery, a positively driven generator, mounted at the rear of the engine (Figs. 5 and 6), is provided, so geared that it runs at 1½ times crank-shaft speed. It is a 4-pole shunt-wound machine.

As stated above, electrical energy for starting and idling speeds is supplied by the battery. As the engine speed is increased, the generator "builds up" and its output grows greater until at about 650 r.p.m., the generator voltage equals that of the battery.

The maximum generator output exceeds the requirements for igntion, so that, at speeds above 650 r.p.m., the direction of flow of the current is reversed and the excess output of the generator goes to recharge the battery.

Regulation: The generator is controlled by a "voltage regulator," mounted on the cowl of the plane. It consists of an iron core on which are wound three coils, the connections of which are shown in Fig. 15. The regulator prevents the output exceeding a predetermined figure. In view of this fact, the generator will supply **current for ignition** indefinitely, without the battery, so long as the engine speed is not allowed to drop below 500 r.p.m. It is not possible to crank the engine fast enough to start it on the generator, however.

Switch

A duplex ignition switch, mounted on the cowl of the plane (Fig. 16, page 1151) is provided which will permit of either one or both distributors being turned "on." This switch is so constructed that either set of igntion alone can be used without connecting in the generator.

In starting, only one side should be used as, with both switches "on," the generator is connected to the battery. Under these conditions the discharge from the battery through the generator before the engine is started would be an excessive drain on the battery. It is essential that both switches be "on" at all flying speeds.

When operating at a speed under 650 r.p.m., only one switch should be used, as with both switches on, the generator is in the line and working as a motor. The result is, with both switches on, the pull on battery is about 12 amperes. With one switch on, the draw is 4 amperes, which is the ignition load.

Idling at 650 r.p.m. for an hour, with both switches on, will discharge the battery.

The ignition switch has an ammeter incorporated in it, and this ammeter should be watched occasionally as it indicates the amount of current flowing to or from the storage battery.

If the ammeter shows a discharge at any speed above 650 to 700 r.p.m. with both switches "on," it is an indication that something is wrong with the generator circuit and that all electrical energy is being supplied by the storage battery.

If the ammeter stands at zero under the same conditions, it indicates that the storage battery is not receiving a charge, but that the ignition is being carried by the generator.

There are two ignition resistance units mounted on the back of the ignition switch (see Fig. 15, page 1151).

Storage Battery

The storage battery is charged at .7 amperes for 70 hours if discharged. It is an 8-volt 4-cell battery.

Spark Plug

There are two spark plugs per cylinder to the Liberty "12."

One airplane type of spark plug (Splitdorf) is illustrated in Fig 10.

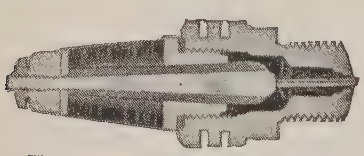

Fig. 10. Airplane type of spark plug.

The spark plugs are subjected to a pressure of 90–110 lbs. The gap distance is .015" to .018". The life of a plug of this type is 25 to 100 hours.

The parts of the Splitdorf plug (Fig. 10) **are as follows:** Brass terminal, mica washers, lateral wound mica, steel center rod, 98 per cent pure nickel electrode point, carbon steel from brass terminal to electrode, and carbon steel shell.

The AC Titan, one-piece porcelain spark plug is used on the Liberty 12-cylinder engine.

Firing Order and Valve Timing

Valve timing: Inlet opens 10° after top dead center; closes 45° after bottom dead center; exhaust opens 50° before bottom and closes 10° after top. Note that if the spark is fully advanced the spark will occur 30° before top dead center on the compression stroke. See Fig. 13 for valve-timing diagram.

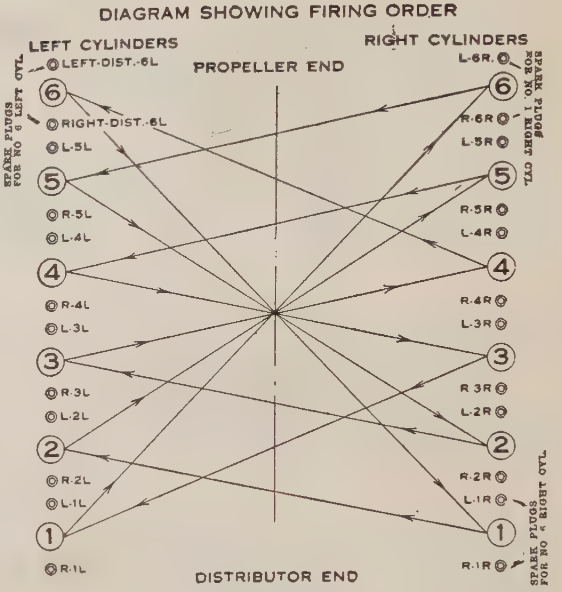

Fig. 11

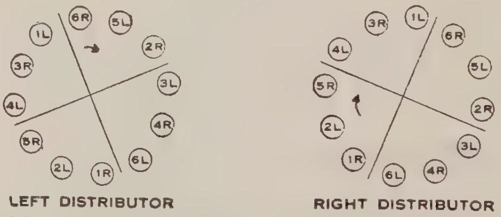

Fig. 12. **Order of firing**—Standing at the distributor end of the engine and looking toward the propeller, the groups of cylinders are designated as "Left" and "Right" respectively and are numbered 1, 2, 3, 4, 5 and 6 beginning at the distributor end. The order of firing is as follows:

1	2	3	4	5	6	7	8	9	10	11	12
1L	6R	5L	2R	3L	4R	6L	1R	2L	5R	4L	3R

INLET .014 TO .016 CLEARANCE
VALVE SPRING

Fig. 14. Valve-clearance adjustment on Liberty engine.

Electric Wiring and Ignition System

Electric wiring: For low-tension work, No. 14 stranded cable for a distance of 10 feet or less, or No. 10 for a distance up to 25 feet, well insulated with rubber and braid. Wires taped and shellaced where clipped to the fuselage. See Fig. 15, wiring diagram. A single-wire grounded-return (G) system is used.

The spark-control advance and retard at the distributor is 10° after dead center "retarded," and 30° before dead center "advanced" (see Fig. 13, page 1150).

The contact-breaker (timer) gap, when the breaker is wide open, should be .010″ to .013″.

The spark-plug gap: .015″ to .018″ of an inch. Defects in all spark plugs are most apparent when the plugs are hot.

Timing: When the engine is set on the firing point of No. 1L cylinder, in other words, with No. 1L crank set 10° past top of "compression" dead center, the carbon brush in the end of the distributor rotor should bear on the brass contact marked 1L on the distributor head.

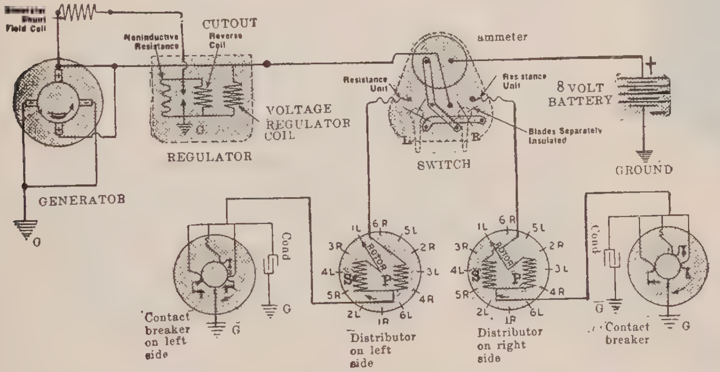

Fig. 15. Wiring diagram of Liberty engine.

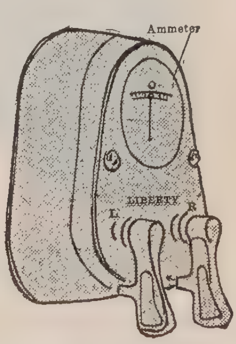

Fig. 16. Duplex ignition switch.

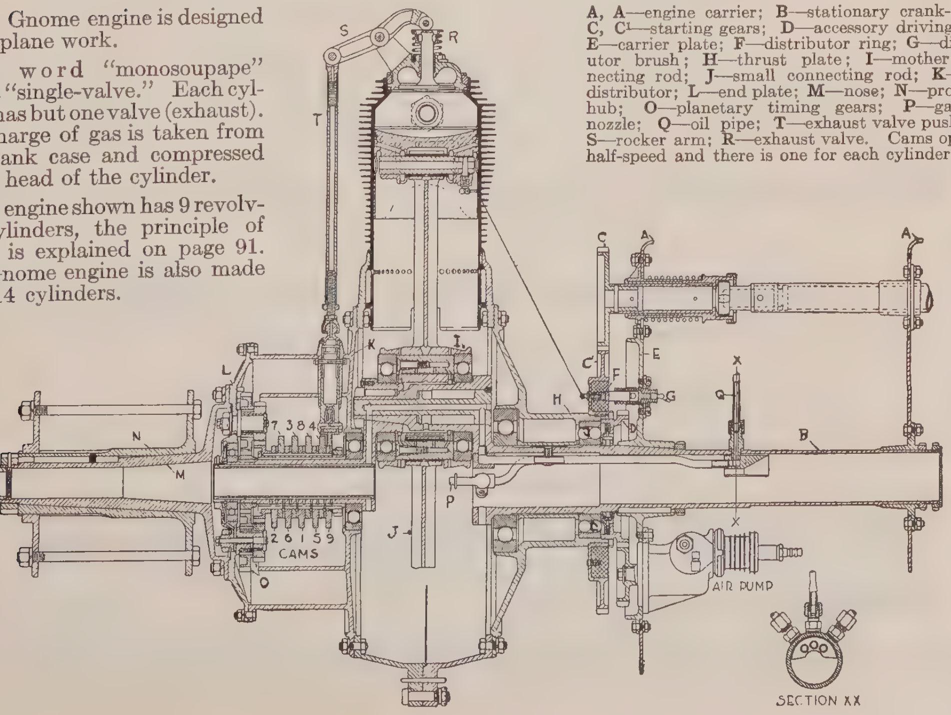
GNOME MONOSOUPAPE REVOLVING CYLINDER ENGINE

The Gnome engine is designed for airplane work.

The word "monosoupape" means "single-valve." Each cylinder has but one valve (exhaust). The charge of gas is taken from the crank case and compressed in the head of the cylinder.

The engine shown has 9 revolving cylinders, the principle of which is explained on page 91. The Gnome engine is also made with 14 cylinders.

A, A—engine carrier; B—stationary crank-shaft; C, C¹—starting gears; D—accessory driving gear; E—carrier plate; F—distributor ring; G—distributor brush; H—thrust plate; I—mother connecting rod; J—small connecting rod; K—cam distributor; L—end plate; M—nose; N—propeller hub; O—planetary timing gears; P—gasoline nozzle; Q—oil pipe; T—exhaust valve push rod; S—rocker arm; R—exhaust valve. Cams operate half-speed and there is one for each cylinder.



The Only Complete and Accurate

Automotive Electrical Data

Ever Published

Each page contains the Wiring Diagram as well as the Data for Tests and Adjustments of some car. ***All on the same page***—Information is given for all cars built since 1912.

Internal diagrams of every electrical unit are given for each car, making field and all other winding tests easy.

The direction or rotation of all armatures and moving parts are given; this is a new and ***exclusive*** feature.

Diagrams received from car and Electrical equipment Manufacturers are checked and re-checked for absolute accuracy and are re-drawn to conform to the **same** and **consistent** style used throughout the book. You don't have to interpret the many different styles of drawing used by the manufacturers.

Standard Auto-Electrician's Manual

"The Red Covered Standard"

Loose leaf and kept up-to-date

It is printed in large readable type, on specially prepared paper that can be washed with gasoline without injury to either the paper or print.
Size, 10½ x 12¾ inches

All the Automotive Electrical Data and Wiring Diagrams Complete in One Book

Indispensable to the Service Man

GENERAL INDEX

Instructions how to use the Index: This Index is prepared so that a student, a novice, an expert, or an instructor can readily find any subject in the book. It is advisable, therefore, to take a few minutes' time to study the Index and to follow the instructions given herein before starting to study the book.

The subjects are alphabetically arranged, but classified as **major, minor,** and **miscellaneous** subjects.

Major subjects are: *Assembly of the Automobile, Principles, Troubles, Adjusting, Testing, Repairing, and Timing.* These subjects are indexed in **black face type.** For example, if you desire to find the Fundamental Principle of any subject, first look under *"Principle of."*

Likewise, if you desire to find how to Diagnose or to Test for a Trouble, first look under *"Troubles"* and then under *"Testing."*

If you desire to find how to adjust any part of a car, first look under *"Adjusting."* If what you are looking for is not found, then look under the part to be adjusted, such as *"Clutch"* or *"Carburetor,"* etc.

If you desire to find how a certain car, truck, or tractor is constructed, look under *"Specifications,"* pages 1056, 966, 996.

If you desire to find how to adjust the axle, carburetor, clutch, or some other part of a certain make of car, truck, or tractor, and do not know the make or type used on that car, first look under *"Specifications of Passenger Cars, Trucks, or Tractors,"* then turn to that page and find the make or type of axle, carburetor, clutch, etc.; then turn to the Index for the part of that particular make; or if the make is not given, the type will be given; then turn to the page whereon it is described.

For example: Suppose you wished to find the method of adjusting the clutch on an Auburn car; first turn to the specifications where you would find that the clutch used was a Borg & Beck; now turn to the Index under *"Borg & Beck clutch adjusting,"* and if not found, turn to *"Clutch, adjusting (Borg & Beck)."*

Measurements: Before the student can clearly understand valve timing, ignition timing, and the many other subjects treated in this book, it is advisable for him to turn first to the Index and to find such subjects as *"Decimals," "Thousandth Part of an Inch," "Degrees,"* etc., and to learn fully their meanings.

Terms, Symbols, and Index Review: Likewise the student should study the meaning of words and terms in the Dictionary, and also refer to the Index for *"Glossary of storage battery terms," "Glossary of gear contacts,"* and also *"Electrical symbols"* and *"Symbols of degrees, feet, inches, and seconds,"* all of which can be found by referring to the Index.

Table of Contents: In the first part of this book a brief digest of subjects is given, together with the page number and instruction number. It is advisable to read it carefully first.

If you don't find what you want under one heading, stop and THINK—what other heading it could be under. For instance, if you are looking for the *"Adjustment of floats of carburetors,"* it may be under *"Carburetor float adjustment,"* or *"Adjustment: carburetor float,"* or *"Floats for carburetors."*

Subjects, as a rule, are cross-indexed in three ways:

(1) Part, Operation, Make.
(2) Part, Operation, Make.
(3) Make, Part, Operation.

For example: "Clutch adjusting (Borg & Beck)" can be found in three ways:

(1) Clutch (part); adjusting (operation); Borg & Beck (make).
(2) Adjusting (operation); clutch (part); Borg & Beck (make).
(3) Borg & Beck (make); clutch (part); adjusting (operation).

The Ford is indexed under *"Ford," "Ford truck," "Ford tractor."*

Note: Where there are hyphens between figures, as for example 865–867, all pages between these pages are included.

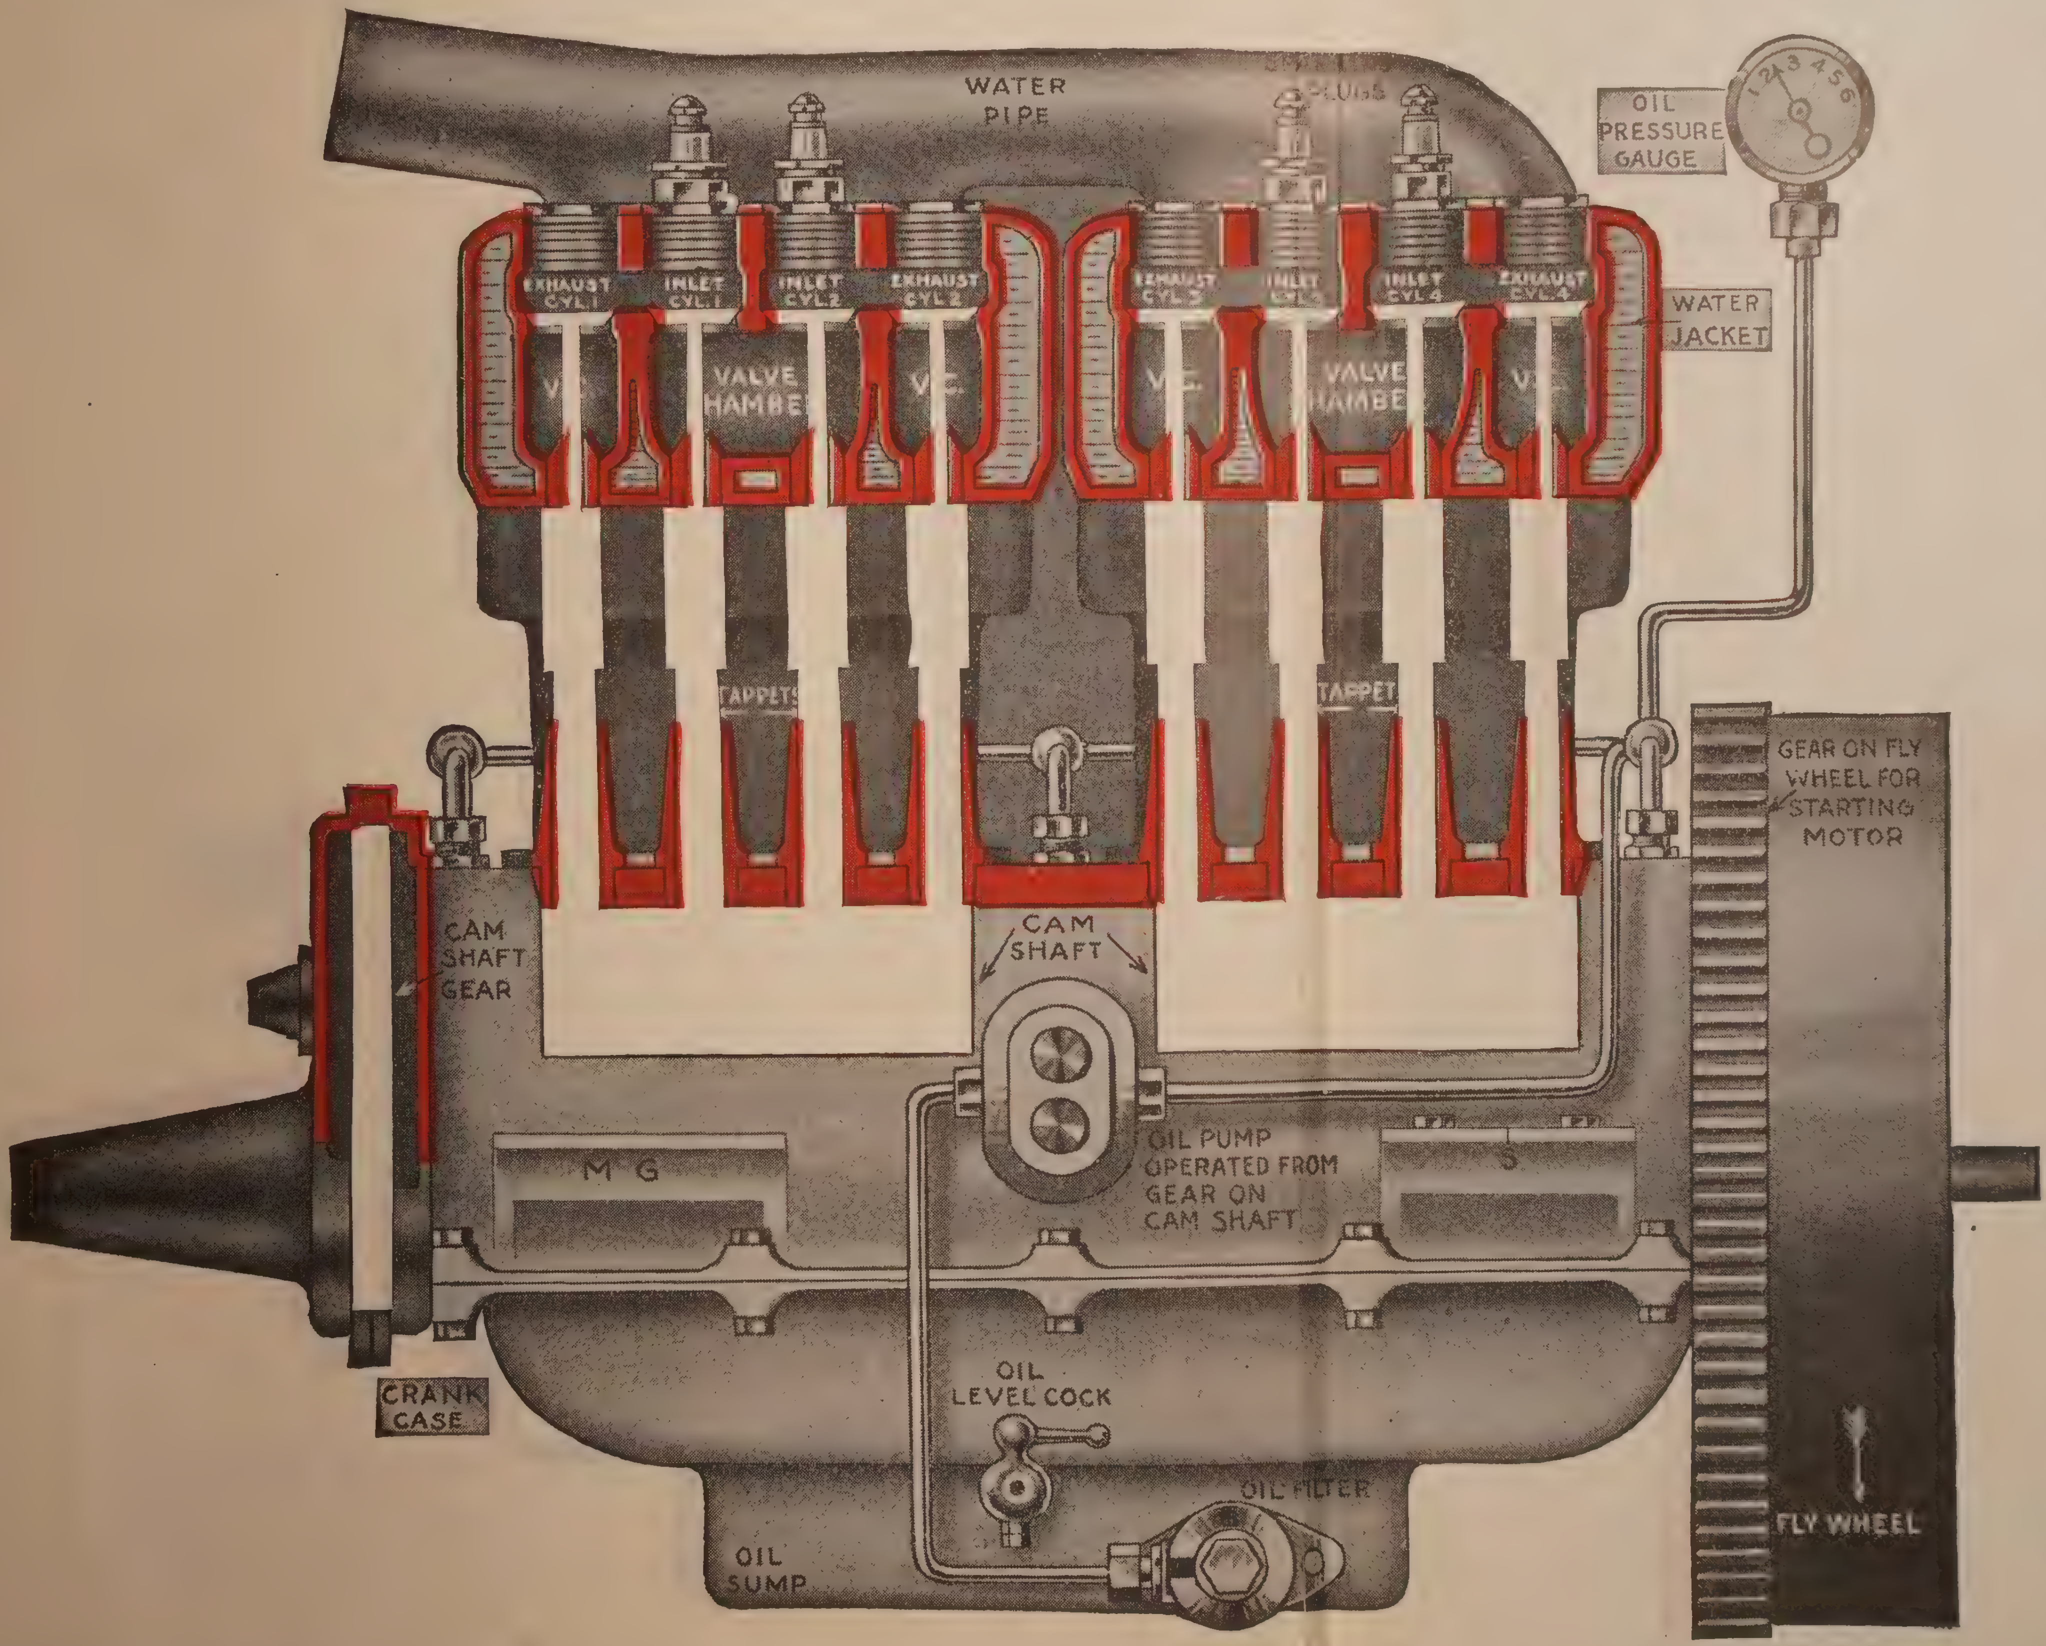
VALVE AND CAM SIDE OF FOUR-CYLINDER ENGINE. (Draw in the Parts.)

Draw in the other side first (shown on the reverse side of the sheet); then draw in the parts on this, the valve side of the engine.

Valves: Draw in the valve head in its seat or slightly raised where necessary, taking it for granted that No. 1 piston is just starting down on the power stroke. The firing order, we will say, is 1, 2, 4, 3.

Valve springs come next; then the valve-spring retainers.



Cam gears should now be drawn; then the **cam shaft** with its eight cams. Place the cams in position, as near as possible as if No. 1 piston was just starting down on the power stroke; No. 2 just starting up on compression; No. 3 just starting up on exhaust, and No. 4 just starting down on the suction stroke.

Valve guides are drawn next, then the **valve tappets**; on the upper part of the valve tappets place adjustment nuts.

The lubrication system of the forced-feed principle can now be outlined—the oil pump being operated from the cam shaft. Show arrows pointing in the direction of the flow of oil.

Ignition: A magneto of the high-tension type can be installed, or a battery and coil system, as desired.

If a battery and coil system is decided upon, place the ignition unit on the generator, and place the generator on the bracket (MG). Chains usually run the generator—but in this case we will use gears.

Connect up the wires from timer to battery (place a battery below somewhere); connect cables from the distributor to the spark plugs for a firing order of 1, 2, 4, 3.

Starting motor: Place a starting motor, using a Bendix drive on the bracket (S); connect this starter with the battery and switch.

INSERT NO. 1. Four-Cylinder Engine Drawing Diagram.

(Copyrighted, 1922, by A. L. Dyke, St. Louis, Mo.)

PISTON AND CRANK SIDE OF FOUR-CYLINDER ENGINE (Draw in the Parts.)

In order to understand more clearly just where the parts of an engine are located and their purpose, this illustration and the one on the back have been provided. If the reader cares to, he may take his pencil (a soft one) and **draw in the parts** as enumerated below. This will assist very materially in gaining a practical knowledge of the parts involved.

Crank shaft: Draw this first. Bear in mind that the stroke of the piston is approximately 1⅛"; therefore the "throw" of the crank shaft must be one-half of this, or 9/16". The crank shaft is an 180° crank.

The pistons are next. They are approximately ¾" diameter. The length should be approximately ⅞". There is a slight clearance.

Piston rings: Place three on the piston for No. 4 cylinder.

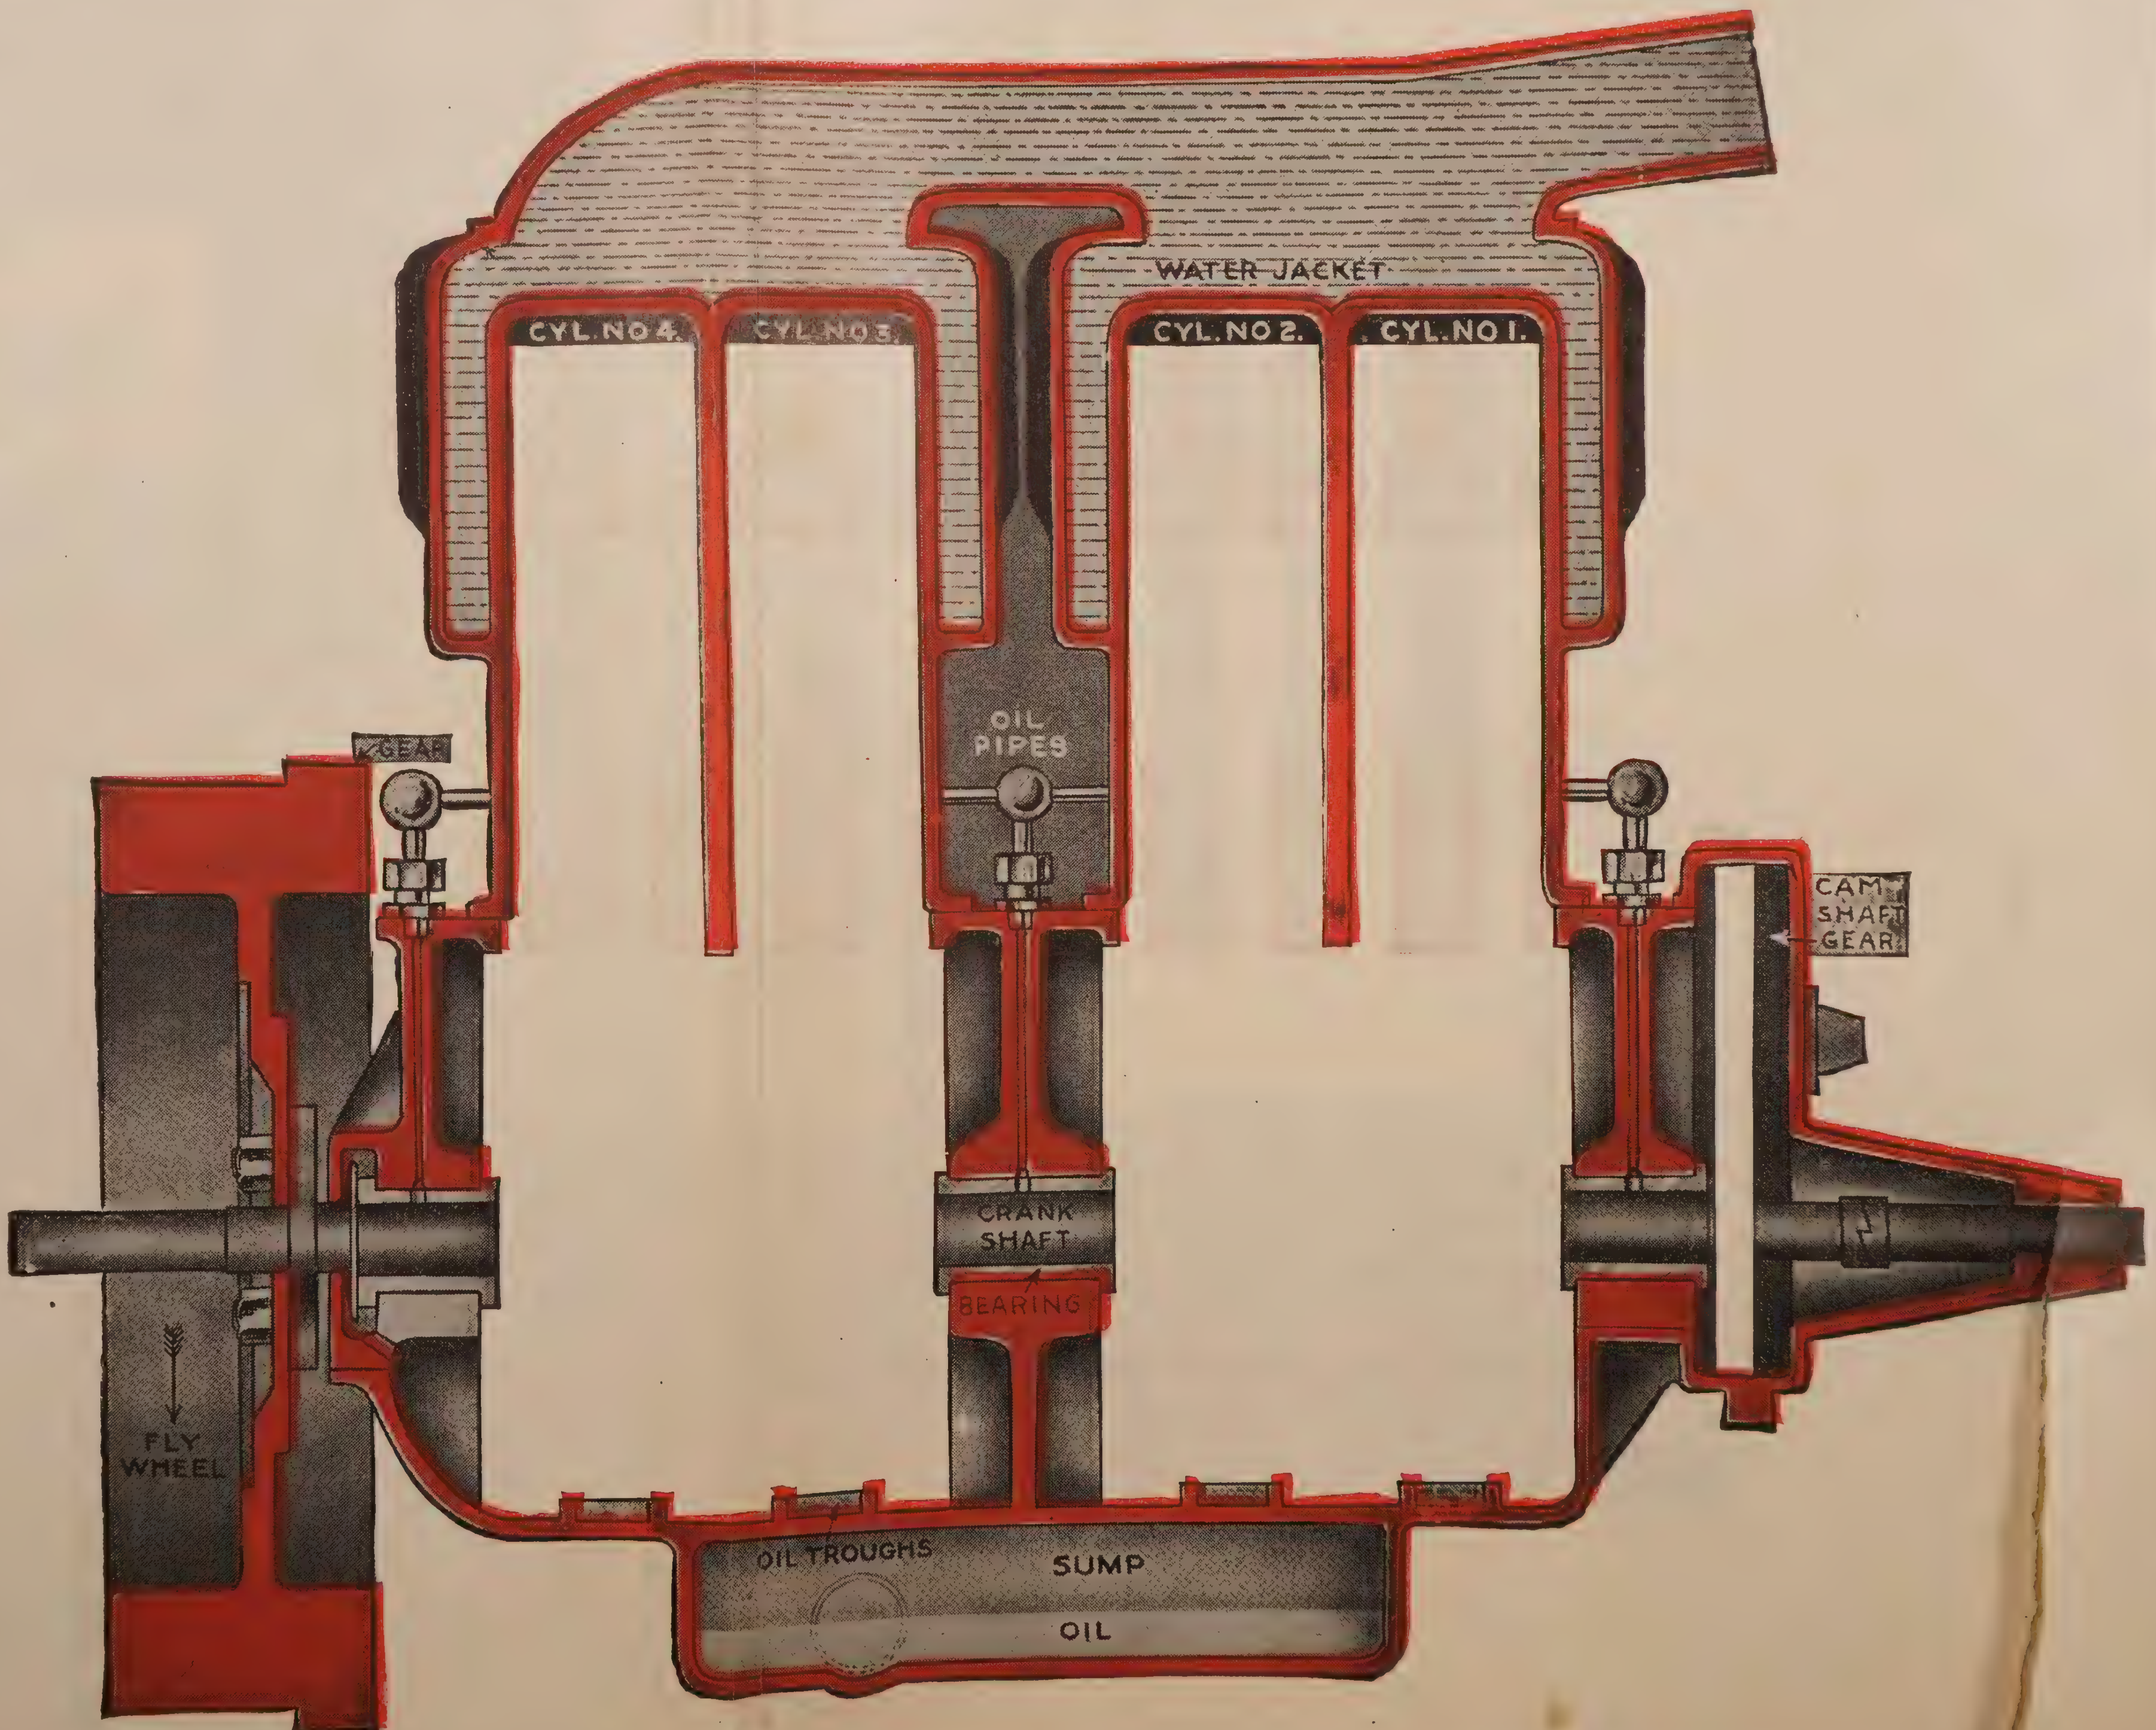
The wrist pin is next; the piston for No. 3 cylinder should be drawn in section so as to show it. Draw pistons for cylinders No. 2 and No. 1 in like manner.

Connecting rods (with the lower bearing split and bushings provided and shims between the upper and lower parts) should be drawn next. The **oil scoop** or dipper is to be provided on the lower end of the connecting-rod cap.

Timing gears: The crank-shaft timing gear is one-half the size of the cam-shaft timing gear.

The cam shaft is drawn in next. Bearings are not provided, but can be indicated.

Clutch: Draw a cone or plate clutch (in section) in the flywheel. It will be necessary to taper the inner face of the flywheel rim for a cone clutch, and to re-design it for a plate clutch.



DIXON'S No. 677 Gear Lubricant

An automotive lubricant for enclosed spur and bevel gear installations, to do effectively the work for which it is intended, must perform many vital functions, some of which are:

1. It must lower friction so that wear on bearings and gears is reduced to the minimum.
2. It must resist cold, permitting gears to shift as easily in freezing weather as in midsummer.
3. It must show minimum temperature rise for bearings and gears.
4. It must show minimum power losses in hot and cold weather operation.
5. It must smother the cutting action of road dust and the metal particles chipped off in shifting gears.
6. It must insure quietly running gears by providing a film of lubricant between teeth meshing with a minimum clearance.
7. It must have long life, i. e., maintain unimpaired the above properties for a long period.

**For
Worm
Drives
Use
DIXON'S
No. 675
Gear Oil**

All of these conditions are met fully by Dixon's No. 677 Gear Lubricant. Complete details of interest will be gladly sent.

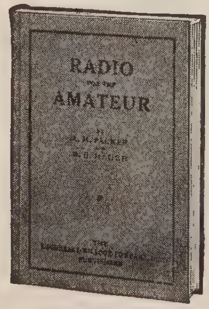
SIMPLE **THOROUGH** **PRACTICAL**

Radio *for the* Amateur

by A. H. PACKER *and* R. R. HAUGH



208 Pages, Cloth, Size 5x7½ Inches

This book is written by two experts in radio telephony and discusses in simple language what is needed for the beginner to understand how to build a set and be able to operate it. There are scores of books on the market that purport to tell all about radio, but nothing heretofore has appeared that tells the amateur the simple underlying principles, without which a real understanding is impossible.

Illustrated with 73 original drawings which are usually in pairs, one showing something with which you are familiar, while the other illustrates something about Radio by comparison, for example:

> The circuit of air passing through a furnace illustrates the circuit of electricity passing through a battery; in one case the coal is consumed to produce heat, while in the other metal is consumed to produce electricity.

Table of Contents:

Radio Waves.
Foundation of Radio.
Currents.
Kinds of Radio Waves.
Pure Sound Wave.
Magnetic effect of Straight Wire.
Carrying Electrical Current.
A Simple Receiving Circuit, using an aerial, a ground, a crystal detector, and a pair of phones.
Tuning the Circuit.
The Condenser and what it does in Radio receiving.
Oscillating Currents used in Radio Receiving.
How to make a loose coupler.
Assembling and using the loose coupler set.
The Carborundum Detector.
Aerials.
The Audion Bulb Receiving Set.

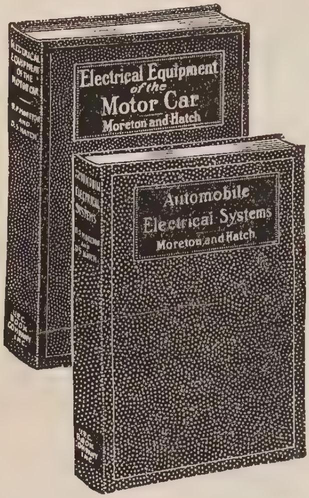
RECOMMENDED AUTOMOBILE BOOKS



Electrical Equipment of the Motor Car
Moreton and Hatch
Automobile Electrical Systems
Moreton and Hatch

Automobile Electrical Systems $3.50

By David Penn Moreton and Darwin S. Hatch

Here is an analysis of all the systems now used on motor cars with over 200 wiring diagrams. Special electrical specification tables are given for all makes of cars and for different years which eliminates all guesswork.

Electrical Equipment of Motor Car . . . $3.50

By David Penn Moreton and Darwin S. Hatch

This book is a working guide on the installation, care and repair of the starting, lighting and ignition systems of all cars, with 256 blueprint wiring diagrams. With this book, it is an easy task to trace out and locate all cases of electrical trouble in a very definite and systematic way.

Automobile Repairman's Helper – Vol. I $3.00

By S. T. Williams and J. Howard Pile

This invaluable reference for the mechanic, owner, chauffeur and student, gives in concise form every operation required to adjust or repair the troubles likely to be found in all standard cars.

Automobile Repairman's Helper – Vol. II $3.00

This new book is right up to the minute and contains such new chapters as General Shop Practice, Storage Battery Equipment and Repair, Passenger Cars, Parts and Equipment.

Battery Service Manual $2.50

By Donald D. Blanchard

The battery repairman will find this book an accurate guide in testing, locating troubles, making repairs and charging batteries. A trouble chart in which all known defects are listed with the cause of the trouble and the proper remedy opposite each will prove of immeasurable value every day.

Modern Methods on Ford Repairing . . $2.50

By J. Howard Pile

This complete manual on Ford repair explains the use of all the up-to-date tools and shop equipment, and minutely describes the methods of performing the work on all the mechanical parts of the car.

Each of these books is an acknowledged authority

RECOMMENDED AUTOMOBILE BOOKS

Motor Vehicles and Their Engines........................**$2.00**

By E. S. Fraser and R. B. Jones

A complete book on the automobile written in the simplest language.

The fundamentals of gas motor operation, as well as the care and operation of the principal accessories of the motor vehicles concerned, are discussed in detail and at greater length than usual.

It is the one book for constant every day use, and it has been built with the idea that it must stand hard wear. Well printed from good, clear type on strong, thin paper and bound in flexible waterproof fabric. Just the book to take along on trips and to have handy in the garage.
374 pages 6x9 inches. 317 pictures, many in colors. Flexible fabrikoid.

Electricity and Its Application to Automotive Vehicles..................................**$4.00**

By Paul M. Stone

STONE is written for the practical man who desires a thorough grounding in the fundamentals of electricity and magnetism and a detailed study of all types of electrical equipment of automobiles.

The book was developed during years of teaching of the subject at the Michigan State Auto School and other schools. Every chapter was submitted to the test of actual classroom use and nothing is included which is not considered vitally essential to a perfect knowledge of this subject.
820 pages, 7x9 inches, 900 illustrations, flexible.

Motor Truck Transportation..................**$2.00**

By F. Van Z. Lane

A brief, logical presentation of the principles that govern successful motor truck operation.

Valuable to anyone having a special problem in hauling, delivery, distribution or transportation. **160 pages, 50 illustrations, 6x9 inches.**

Service Station Management................**$2.00**

By C. L. Jones

This book offers: A complete analysis, based on years of close touch with the industry, of the successful operation of a garage, covering every detail of service station management, from advertising for business and its efficient handling in the shop and satisfactory delivery to customers;

Suggestions as to methods and practices that have proved valuable when employed by some of the most progressive and successful automobile dealers and service stations; giving detailed instruction for their practical application;

A workable basis for efficiency and profit through the employment of the successful experiences of others.

Motor Truck Design..........................**$2.50**

By C. T. Schaefer

Mirrors accurately the standard practice in the motor truck industry, written primarily for the engineer but the information it gives is of the utmost value to the student, draftsman, motor truck owner, chauffeur, garageman and every one connected with the industry by C. T. Schaefer, Consulting Engineer, Member Society of Automotive Engineers, 324 pages, 292 illustrations, 6x9, cloth, postpaid, $2.50. **169 pages, 6x9 inches, illustrated, cloth, postpaid.**

Each of these books is an acknowledged authority

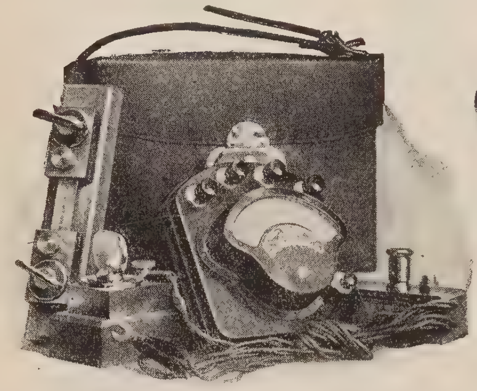
ELECTRICAL TESTING INSTRUMENTS

For Automotive Electrical Repairmen

The most profitable work of automobile repairing is that of electric work. After studying the subjects of the different electrical systems in this book, and the principle and construction of the Weston meter as shown on page 464, then how to test on pages 475 to 520 and 545 to 555, then how to diagnose troubles on pages 454 to 462 and 556, anyone ought to be able to test, diagnose and remedy almost any electrical trouble—**if equipped with the proper Testing Instruments, Wiring Manual and Data for making the tests.** The Instruments shown below are recommended and the Wiring Manual and Data book is described in the advertising section elsewhere of this book.



Weston Model "280" Combination Volt-Ammeter

This instrument can be used to make all average tests the electrical repairman will be called upon to do (see page 464) **and it will also make cadmium tests,** as the scale (fig. 7, page 548) is now provided without extra cost. Weston cadmium test points and test cables (fig. 8, page 548) are $5.00 extra. Ambu cadmium test points and test cables $2.25 extra. Either can be used.

Price Weston Model "280" Volt-Ammeter with three shunts; 3, 30 and 300 ampere and test cables and book of instructions—$41.25 (case $7.00 extra).

Ambu High Rate Battery Discharge Tester

This tester provides an accurate, reliable means of testing the performance of a storage battery under discharge, without removing the battery from the car. Simply place the two sharp prods; one on the positive, and other on the negative post of each cell, and the voltmeter flashes the condition of battery instantly.

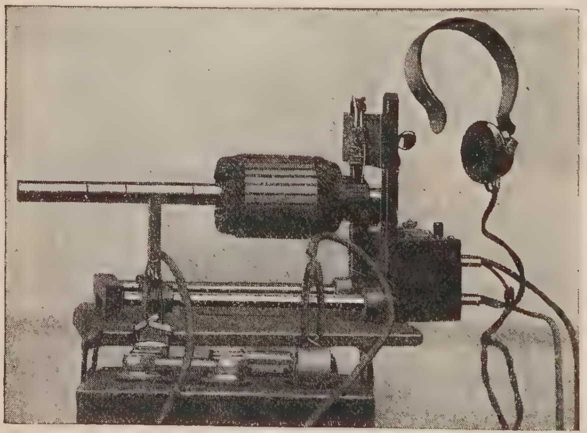
The **voltmeter** has a range of 2 volts on each side of the center zero. The readings are easily made during tests.

The **prods** are made of heavy ⅜" square nickle-plated steel driven into a large wooden handle. The **shunt** is made of heavy Nichomre metal. Size 4" x 11½" high.

This tester in your shop will be invaluable as an aid in securing repair work and selling new batteries when the old battery is found to be "shot." **Price** complete with voltmeter **$6.75.**

Coil Tester and Remagnetizer

See page 223 for an **ignition coil tester** and pages 312 and 1118 for a **magnet remagnetizer.**



Testing Method: First the operator raises the sliding panel and places the armature to be tested in position, as shown. Lowering the panel then brings four contact arms to bear on the commutator bars. The operator puts on the special telephone receiver, turns on power, and tests by rotating the armature and listening in the receiver. As the armature is rotated, current from the center test points passes through each consecutive pair of bars, while the outer test bars draw a shunted current off two bars equally distant from the bar at which the current enters. This current passes through the primary of a transformer, the secondary of which is connected to the telephone receiver. The transformer develops the slightest variation in current strength into a marked change in the receiver's buzzing note. These changes indicate every fault in the armature.

Ambu Armature Tester

This new patented armature tester is priced low enough to be within the reach of the smallest shops and does the work of a "growler" or transformer test, "drop of potential" test and the telephone receiver test combined, and in less time than any of them.

It is designed for use with a 6 volt storage battery. Connecting a bank of lamps in series with it, equips the Tester to work on any ordinary direct or alternating current. Maximum current is ½ to 1 ampere.

The testing method is explained under illustration. So long as the armature coils are in good condition, the receiver gives a uniform loudness. An **open circuit** is indicated by a sudden, marked **increase** in loudness, and a **short circuit** is indicated by an equally pronounced **decrease** in loudness. **Reversed connections** between the coils and commutator are indicated by a loud tone every **second** pair of bars.

When one rotation has been completed, a small switch is thrown, and a second rotation tests for grounds. In every kind of trouble—open circuit, short circuits, grounds, and reversed connections—the Tester picks out the bars to which the faulty windings are connected. Each coil is tested against several others, and the **entire test requires only five minutes.**

Price Tester complete (wt. 15 lbs. packed) **$30.00**
